Cyclic steam injection is a single-well operation where steam is injected into a producing well for a limited time. The well is then shut in for a short period of time before it is put on production. The well is produced anywhere from a few months to a year before the cycle is repeated. Each cycle produces a decreasing amount of oil. Sometimes only a few cycles are employed, and other times as many as 15 cycles are employed before the production rate becomes so low that it is not economic. Steam cycling works best for thick sands, viscous oils, and small well spacings. Cyclic steam recoveries are generally 10%–25% of the oil in place compared with 50%–60% by steam flooding.

5.3.3.2 In Situ Combustion The *in situ* generation of heat involves injection of air or an oxygen–nitrogen mixture into a reservoir and burning part of the crude oil in the form of coke deposited on the sand grains just ahead of the moving combustion front. The combustion zone moves in the same direction as the flow of fluids. A clean sand is left behind the combustion front. The temperature in the combustion zone ranges from 315 to 650 °C. The combustion-zone thickness is perhaps 10–20 cm. The *in situ* combustion process is ideal in that an undesirable fraction of the oil (heavy ends) is consumed as fuel in the form of coke, a clean sand is left behind, and the heat generated is used as efficiently as possible. Oil recoveries for successful projects can range from 60%–90% of the oil in place at the time the project was initiated.

Basically, three physical processes are taking place simultaneously, but not independently of one another. These processes are chemical reaction, heat transfer, and fluid flow. *In situ* combustion is initiated by simultaneously injecting air- or oxygen-enriched gas into a well and heating the well bore opposite the formation to the ignition temperature. Occasionally, in the case of a highly reactive crude oil, spontaneous ignition will take place. Well-bore heaters are usually electrical or gas burners.

When applicable, the *in situ* combustion process is conducted in sandstone reservoirs. *In situ* combustion is generally not applicable to limestone or dolomite reservoirs, although there have been a few exceptions.

A variation of *in situ* combustion is wet combustion, also known as COFCAW (Combination of Forward Combustion and Waterflooding). Water is injected either with the air or intermittently. The process takes advantage of the latent heat of vaporization of water to recover heat energy stored behind the combustion front. However, one needs to be careful, as injecting too much water can extinguish the combustion front.

The Tulare formation of the South Belridge Field has undergone both *in situ* combustion and steam drive, and as a consequence an excellent comparison can be made between these two processes in this reservoir (Gates *et al.*, 1978; Gates *et al.*, 1975). *In situ* combustion was much more energy efficient than that of steam, using only about one-quarter of the surface energy compared with steam. From an environmental standpoint, steam emits about 2.5 times as much flue gas as *in situ* combustion. Well failures were as bad for steam as for *in situ* combustion. The question then arises as to why *in situ* combustion was not used more in this formation. The answer lies in the fact that steam was probably applied first and was an established improved oil recovery process in this field.

5.3.4 Micellar-Polymer Flooding Micellar-polymer flooding is a fluid-injection process wherein a phase-stable, optically clear (transparent or translucent) solution of oil, water, and one or more surfactants, along with electrolytes or salts, is injected into a formation and is displaced by a solution of polymer. The polymer solution is in turn displaced by water. Oil and water are displaced ahead of the micellar solution, and a stabilized oil and water bank develops. The micellar solution (microemulsion) is the key to the process. The micellar solution displaces the oil and water either miscibly or at very low interfacial tensions and thus has a high unit displacement efficiency. In addition, the mobility of the micellar solution can be controlled, resulting in high volumetric displacement efficiencies. The process is applicable over a wide range of reservoir conditions. Micellar-polymer flooding is usually applicable if water flooding is applicable because of the mobility relationships. The polymers used are usually partially hydrolyzed polyacrylamide. The surfactants used are petroleum sulfonates and alcohols. The alcohol is referred to as a co-surfactant.

Because of the cost of the micellar solution, only a limited amount is injected. Oil recovery by micellar-polymer flooding can be over 60% of the oil in place at the time the project was initiated.

The current price ($18–$20 per barrel) of crude oil makes micellar-polymer flooding uneconomic. Micellar-polymer flooding is front-loaded financially; that is to say, it takes a large initial investment to initiate a project and the maximum financial exposure is quite high. Unless the price of crude oil goes up to the $35–$45 per barrel range in 1994 dollars, micellar-polymer flooding will not be a factor in improved oil recovery.

5.3.5 Alkaline-Surfactant-Polymer Flooding A relatively new flooding process has been developed in recent years and shows considerable promise as a result of a number of field pilot operations. Many oils are reactive with alkali and produce surfactants that lower the interfacial tension between the oil and brine. However, the optimum alkali concentration to produce this reduction in interfacial tension is quite low. By adding a low concentration of a surfactant to the system, a synergism results wherein the interfacial tension is considerably lower than alkali or surfactant acting by themselves. Polymer is also added to the system to insure the best possible mobility control. Alkalis used range among caustic soda, soda ash, sodium orthosilicates, and trisodium phosphate. The polymer generally used is partially hydrolyzed polyacrylamide. Surfactants used are usually high–molecular-weight organic sulfonates. It has been shown in a limited number of field tests that alkali surfactant polymer (ASP) flooding can recover just as much oil as micellar polymer flooding but at considerably less cost per barrel of oil recovered. In 1994 dollars, the costs range from $2 to $3 per barrel of incremental oil recovered (Surkalo *et al.*, 1993). The design of ASP flooding systems is quite involved, requiring detailed knowledge of reservoir geology, and fluid and rock chemistry.

6. PRODUCTION OPERATIONS

Artificial lift is installed to increase production from naturally flowing wells and to produce from wells when the natural energy in the reservoir is no longer adequate to lift the oil and gas from the well. The following sections discuss natural flow and the four major methods of artificial lift used in the oil and gas industry: gas lift, sucker-rod pumps, electrical submersible pumps, and hydraulic pumps.

6.1 Natural Flow

The ability of a well to flow naturally is a function of the formation pressures and deliverability, well-head pressures, tubing size, and depth. Except in the case of a very strong aquifer that is providing pressure support as fluids are produced from the reservoir, the pressure of the reservoir will decline with production. As the pressure declines, the energy is no longer sufficient to lift the fluids from the well bore. At this time, an external means of lifting the fluids from the reservoir is considered. The goal is to match the ability of the formation to deliver fluids at a specified well-bore pressure with a method of artificial lift that will add sufficient energy to lift the fluids to the surface. Wells may be placed on artificial lift before natural flow ceases. Economics will govern when it is viable to place the wells on artificial lift.

6.2 Artificial Lift

The selection of an artificial lift method depends on several factors. Capital costs, operating costs, reliability, and salvage value are major considerations when comparing the various alternatives for artificial lift. Flexibility to handle changing production conditions over the life of the well should also be considered. A "cradle to grave" economic analysis should be performed when selecting artificial lift methods.

Approximately 10% of the wells on artificial lift in the United States are *gas lifted* (Clegg *et al.*, 1993). Gas lift is a common method of artificial lift offshore. In gas lift, an external source of gas is injected as deep as possible into the production tubing to augment the formation gas: see Fig. 12. In this sense, gas lift is an extension of natural flow. The injection gas lightens the fluid column in the production tubing and lowers the flowing bottom-hole pressure at the formation. The effect is to increase the formation flow and extend "natural flow." In cases where flow rates cannot be established by the continuous injection of an external source of gas, the well may be produced by the intermittent injection of high volumes of gas. In these cases, the well is alternately produced and shut in. During the shut-in periods, formation fluids accumulate in the well bore. High-pressure gas is then injected into the tubing below the slug of formation fluid to displace the formation fluids to the surface.

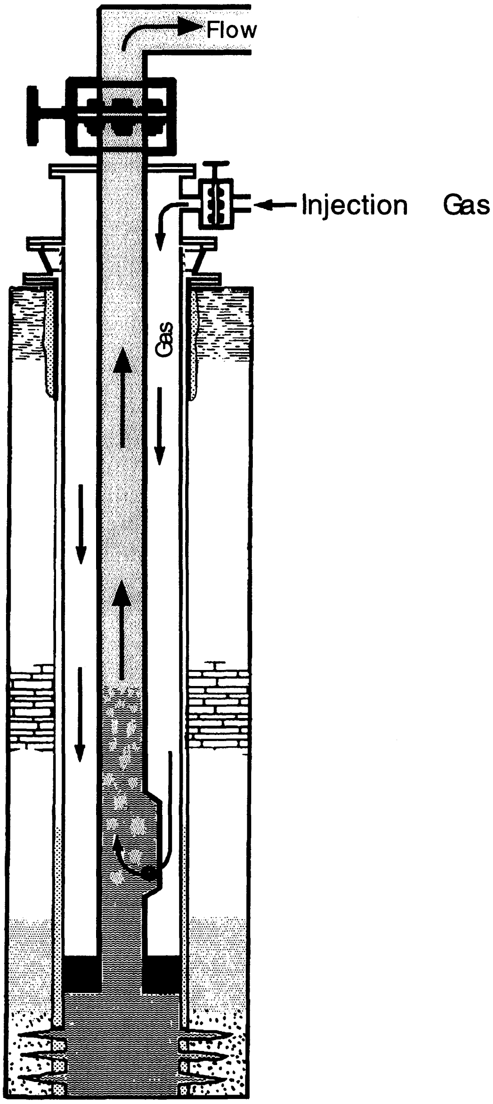

FIG. 12. Continuous gas lift.

The *sucker-rod pump* is the most common method of artificial lift: see Fig. 13. Approximately 85% of the wells on artificial lift in the United States are lifted with sucker-rod pumps. Sucker-rod pumps operate on the principle of positive displacement. The reciprocating motion of the down-hole pump is generated by a beam pumping unit at the surface and transmitted to the down-hole pump through steel rods called sucker rods. Part of the rod string may be made of fiberglass rods.

Sucker-rod pumps are easy to operate, and this is one reason for their popularity. Where space and weight are limiting factors, sucker-rod pumps are not a good choice. Sucker-rod pumps are rarely a good choice for offshore.

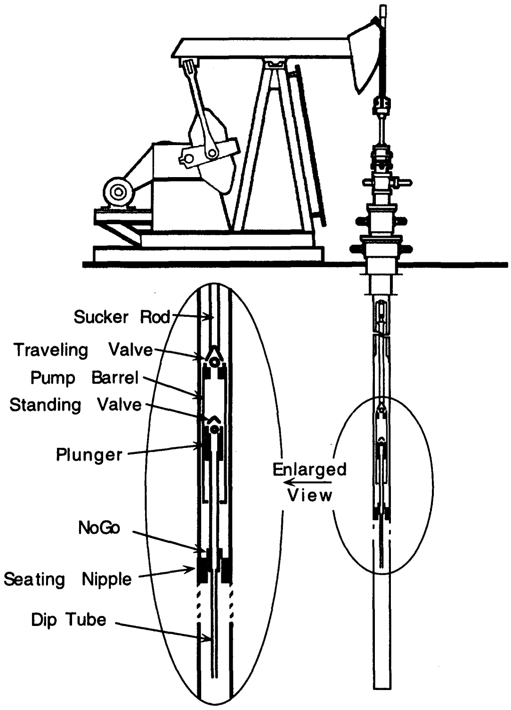

FIG. 13. Sucker-rod pump.

Depth of lift, especially for high-volume wells, is also a limiting factor for sucker-rod pumps.

Electrical submersible pumps (ESPs) are centrifugal pumps installed in the well on the end of the tubing and submerged in the well fluid. The down-hole components consist of an electric motor, motor protector, gas separator, pump, and power cable. The power cable, which is strapped to the tubing, transmits power from the surface to the down-hole motor.

ESPs are best suited for high-volume applications and are a common method of artificial lift where the reservoir is waterflooded. ESPs make up approximately 4% of wells on artificial lift in the United States (Clegg *et al.*, 1993).

There are two basic types of *hydraulic pumps* used in the petroleum industry, the positive displacement pump and the jet pump. In both cases, the pump is installed down hole to add energy to the produced fluid. Hydraulic pumps make up less than 2% of the wells on artificial lift in the United States (Clegg *et al.*, 1993).

6.3 Field Processing

When a reservoir fluid reaches the surface and flows through the wellhead, the reservoir fluid is further processed before entering a pipeline. In the case of a dry gas, the surface processing facilities can be quite simple, and in the case of a gas condensate or black oil they can be quite extensive. The objective of surface processing before the fluid enters the pipeline is to provide the purchaser with a water-free, hydrocarbon-liquid–free natural gas, or a clean condensate or crude oil.

6.3.1 Natural Gas Processing at the Wellhead Natural gas wells can produce both reservoir water and water that is in the form of vapor in the gas. Upon reaching the surface, water vapor condenses when the temperature is lowered. The presence of free water can cause corrosion and form solid hydrates of natural gas that can plug lines and valves. If the water problem is not too severe, the gas may be heated in an indirect heater to prevent water condensation and keep the temperature of the gas above the hydrate-forming conditions. Water produced from the formation is trapped in a surface separator. Gas sold to a pipeline must meet certain specifications in regard to its water content. To meet this specification, the gas is dehydrated, that is, the water is removed in equipment called a dehydrator. There are different types of dehydration equipment. One common unit uses glycol to remove the water from the gas.

6.3.2 Wet Gas, Gas Condensates, and Volatile Oil Processing at the Wellhead In the case of a wet gas, gas condensate, or volatile oil, the reservoir fluid must be separated at the surface into a liquid condensate and a gas stream. The reservoir fluid enters a separator that allows the gas and condensate to separate from one another. If free water is produced, three phases will exist in the separator. Quite often two separators are used and the pressure controlled on the separators to maximize the amount of liquid that enters the stock tank, which is at atmospheric pressure. The gas phase is then treated in a manner similar to that of a dry natural gas well.

6.3.3 Black Oils Processing at the Wellhead When black oils are produced from a reservoir, they may include solids such as sand and scale along with water. This is generally referred to as basic sediments and water. The produced water may occur in two forms, free water or an oil-in-water emulsion. The amount and degree of emulsification depend on the nature and amount of surfactants that are present in the crude oil. Some oil-field emulsions are difficult to break, and heat and chemicals must be used to separate the water from the oil. The well-stream effluent first flows into a separator where the gas, oil and/or emulsion, and free water are separated. The gas exits from the top of the separator, the oil and/or emulsion from the middle, and the free water from the bottom. The separators come in different designs, both horizontal and vertical.

The emulsion layer goes to a heater-treater where both heat and chemicals are applied to the emulsion. The emulsion breaks and water settles to the bottom of the vessel and clean oil floats to the top from where it is then piped to a stock tank. The stock-tank oil is then ready for the pipeline.

7. PETROLEUM RESERVES AND ECONOMICS

Industry and government agencies are interested in estimates of the future availability of petroleum. Unfortunately, consistent

Total World Oil Reserves =15.8 x 10^{10} m^3

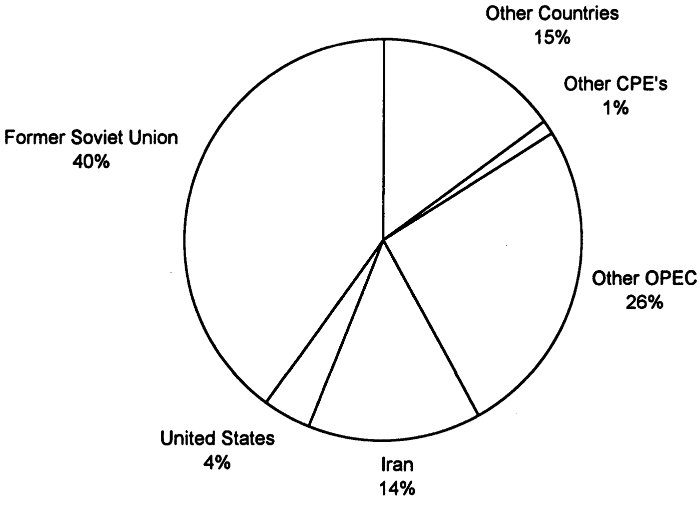
FIG. 16. Total world oil reserves.

terminology is not in use worldwide to describe future estimates of petroleum resources.

7.1 Definitions

The distinction between *resource base, resource,* and *reserves* is helpful in understanding resource assessment studies. The petroleum resource base is all the oil and gas in the earth regardless of the economic or technical feasibility of extraction. The term petroleum resource is used to denote the quantity of petroleum that is recoverable under *specified* economic and technological conditions (Lovejoy, 1965).

Petroleum reserves are the oil and gas that *remain* to be recovered under *current* economic conditions using *current* technology. This definition implies certain conditions:



Total World Natural Gas Reserves = 124.0x 10^{12} m^3

Note: Other CPE's includes former, evolving and current Centrally Planned Economies

FIG. 17. Total world gas reserves.

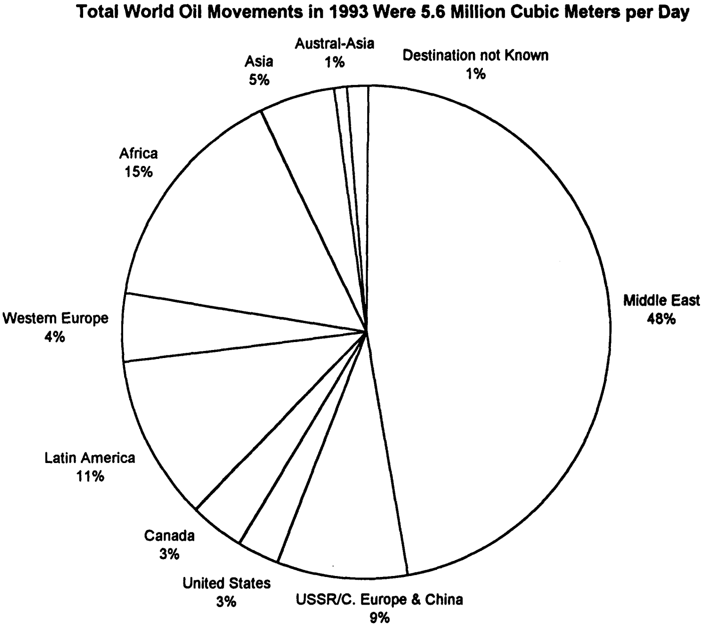


FIG. 18. World oil movements—exports.

First, in order to be called reserves, oil and gas must be physically producible. Second, it must be economic to produce the oil and gas. Third, since the resource has not been produced and is inaccessible, reserves cannot be measured but must be estimated. Finally, since reserves are remaining, there must be a time line associated with the estimate.

Hydrocarbons that have been produced up to a given date are referred to as cumulative recovery or production. The remaining reserves on this date are referred to as esti-

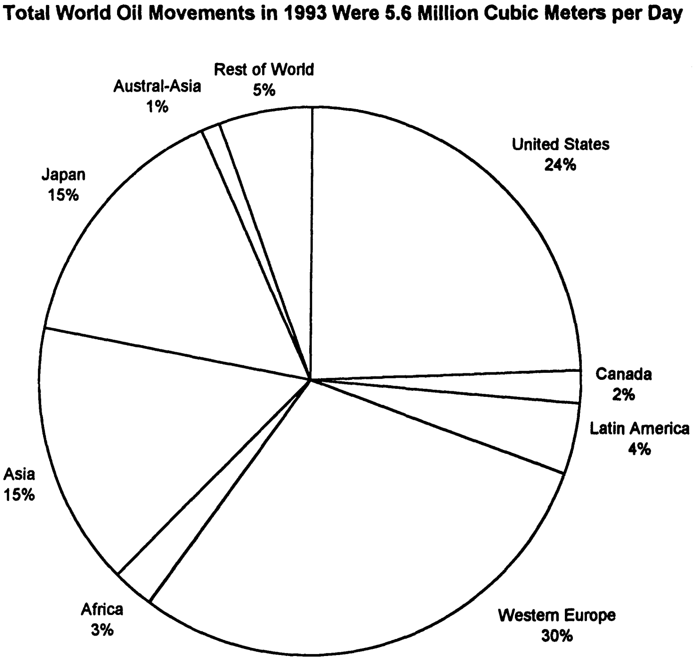

FIG. 19. World oil movements—imports.

mated remaining reserves (ERR). On a given date, the estimated ultimate recovery (EUR) would be equal to the cumulative recovery plus the estimated remaining reserves (Thompson, 1985).

7.2 Classification of Reserves

Classification systems commonly group reserves by the degree of uncertainty associated with the estimate. Three categories are proved, probable, and possible reserves. Proved reserves are those quantities that the estimator is *reasonably certain* are recoverable from known reservoirs under current economic and operating conditions. If the evidence does not support the proved reserves category, the reserves may be classified as probable. In cases where the evidence does not support either the proved or probable categories, the reserves may be classified as possible reserves.

7.3 Petroleum Resource Assessment

Since reserves are estimated, not measured, quantities, at the time of discovery there may be considerable uncertainty in the estimated ultimate recovery for a field. Historically, on an aggregate basis, estimates for the ultimate recovery for fields increase (or appreciate) from the initial estimate. The Energy Information Administration (EIA) has developed a database that contains the year of discovery, the initial estimate for ultimate recovery, and subsequent revisions in reserves on a field basis for the United States (Energy Information Administration, 1990). This information has been used to develop appreciation factors (also referred to as growth factors) that can be multiplied times the initial estimate for ultimate recovery to obtain a better estimate of the final ultimate recovery. The appreciation factors for oil and gas are shown in Figs. 14 and 15. The appreciation factors calculated from this database represent reserves additions from field extensions, new reservoirs, infill drilling, improved technology, enhanced recovery techniques, and longer productive life from an increase in oil and gas prices.

An interesting approach for estimating reserves growth for gas reservoirs has been developed by the Bureau of Economic Geology (Fisher, 1988). This method relates the depositional environment and the reservoir compartmentalization to the amount of reserves growth that may be expected from infill drilling gas reservoirs.

7.4 Petroleum Economics

On a macroeconomic scale, the changes taking place in Eastern Europe and the former Soviet Union and the worldwide distribution and movement of petroleum are examples of the global nature of the petroleum industry. The distribution of world oil and natural gas reserves is shown in Figs. 16 and 17 (Anon., 1991). The movement of oil, imports and exports, around the world is shown in Figs. 18 and 19 respectively (American Petroleum Institute, 1994).

On a microeconomic scale, actual or perceived supply disruptions are reminders of the capital-intensive and risky nature of the petroleum business and the long lead time from project inception to first production. Major projects, for example, often require 5 to 10 years and billions of United States dollars to complete.

The risk is often put into three categories: economic risk, political risk, and technological risk (Garb, 1988). The technical uncertainty includes the estimates of hydrocarbon volumes and the recovery rates. The economic risk includes prices and capital costs for drilling and development. Political risk includes local and national taxes, environmental regulations, and international instability. The petroleum industry is placing more emphasis on decision methods that help quantify the risks, including sensitivity analysis, portfolio analysis, and Monte Carlo simulation.

GLOSSARY

Christmas Tree: The control valves, pressure gauges, and chokes assembled at the top of the well to control the flow of oil and gas after the well has been drilled and completed.

Drilling Mud: The liquid that circulates through the well bore during rotary drilling. It brings cuttings to the surface, cools the bit and drill stem, controls subsurface pressure, and deposits a mud cake on the wall of the borehole to prevent fluid loss to the formation.

Enhanced Oil Recovery (EOR): The injection of special gases at miscibility pressures or of liquid chemicals or the use of thermal energy into a reservoir to interact with the rock–oil system to create conditions favorable to oil recovery. Factors such as lowering interfacial tension, lowering viscosity, changing rock wettability, and creating favorable phase behavior are EOR techniques.

Gas-Oil Ratio (GOR): The ratio of the volume of gas produced with a unit volume of oil measured at standard temperature and pressure.

Permeability: A measure of the ease with which a fluid can flow through the interconnected pore network of a porous rock.

Porosity: The fraction of the total bulk volume of the rock not occupied by rock solids.

Primary Recovery: Oil production from a reservoir in which the natural energy present initially in the reservoir fluids is the main source of energy causing the displacement of petroleum to a producing well.

Reservoir: A subsurface, porous, and permeable rock formation in which oil and/or natural gas have accumulated.

Retrograde Condensation: The condensation of a light hydrocarbon liquid that occurs when the pressure on a gas containing intermediate to heavy hydrocarbons is reduced at constant reservoir temperature.

Saturation Pressure: When a liquid is at its bubble-point pressure or a gas is at its dew-point pressure, the fluids are said to be at their saturation pressure.

Secondary Recovery: After the primary energy in a reservoir has been dissipated, the injection of water or gas into the reservoir to provide energy to displace the oil immiscibly to the producing well is referred to as secondary recovery.

Specific Gravity: For a liquid, the ratio of the weight of a unit volume of the liquid to that of a unit volume of water both measured at 15.56 °C and at atmospheric pressure. For a gas, the ratio of the weight of a unit volume of the gas to that of a unit volume of air under ideal gas conditions. This is equivalent to the ratio of the molal average molecular weight of the gas to the molal average molecular weight of air (28.96).

Well Completion: The activity and procedure necessary to prepare a well for production of oil and gas. The procedure depends on the characteristics of the producing formation. Examples of completion types include open hole, sand exclusion (gravel pack), and perforated casing.

Well Log: A systematic recording of data as a function of well depth such as a driller's log, mud log, electrical well log, or radioactivity log in order to obtain properties of the formations.

Well Stimulation: The treatment of a producing formation to obtain increased production of oil or gas, e.g., hydraulic fracturing, sand control, and acidizing.

INTRODUCTION

In general, a chemical system will consist of several phases, solid, liquid, and gaseous, of different compositions. The study of phase equilibria and phase transformations is central to materials science, chemical engineering, geology, and many other disciplines.

A phase diagram is a graphical representation of the conditions of temperature, pressure, composition, etc. for which equilibrium among the phases of a system is established. A system at equilibrium is one that has achieved a state of minimum free energy and is unchanging even over an infinite amount of time. Although departures from equilibrium will occur in any real system, a knowledge of the equilibrium state under a given set of conditions is the starting point for the understanding of most processes.

We restrict ourselves to phase diagrams with pressure, temperature, composition, and, in a few examples, partial pressures as the axes. However, other variables, such as electrical, magnetic, and gravitational fields, can also affect phase equilibria, and phase diagrams with these as axes could also be drawn.

In Secs. 1 and 2, we describe phase diagrams of one-component and two-component systems without rigorously justifying the rules governing their construction. This justification follows, however, in Sec. 3 on the Gibbs phase rule. The thermodynamic origin of phase diagrams is discussed in more detail in Sec. 6. Some simple examples of the relation between the phase diagram of a system and the structure and bonding of the phases at the atomic level are also presented in Sec. 6.

1. PHASE DIAGRAMS OF SINGLE-COMPONENT SYSTEMS

A single-component system consists of only one chemical substance which does not dissociate. The phases present may be solid, liquid, or gaseous. The most common type of phase diagram of a one-component system is a *P-T* diagram in which the axes are temperature and pressure as shown for the system H_2O in Fig. 1. Volume is not an independent variable since, for any phase in a single-component system, the volume is uniquely given, as a function of *P* and *T*, by the equation of state. Figure 1 can be considered to be an orthogonal projection, upon the *P-T* plane, of the nodal lines of the *P-V-T* surface.

In Fig. 1(a), regions in which the entire system is solid, liquid, or gaseous are labeled. The coexistence of two phases occurs along the lines of the diagram. For example, ice transforms to liquid water at a constant temperature of 0 °C at a pressure of 101.3 kPa (1.0 atm), and the liquid and gas coexist in equilibrium at this pressure at 100 °C.

If a previously evacuated container is partially filled with water, sealed, and heated, the pressure in the container will follow the two-phase boundary between the liquid and vapor regions of Fig. 1 as long as the liquid and vapor phases are both present. This line thus gives the *vapor pressure* of H_2O as a function of *T*. Solid, liquid, and vapor can only coexist at one point, the *triple point*, which, for H_2O, occurs at 0.0098 °C and 0.611 kPa. At pressures and temperatures below this point, ice sublimes directly to vapor.

At low pressures, ice has a hexagonal crystal structure. This form of ice is known as ice-I. At very high pressures, other *polymorphs* (i.e., other crystal structures) of ice, known as ice-II, ice-III, etc., are observed. The phase diagram at high pressures is shown in Fig. 1(b). Again, the diagram consists of single-phase areas, two-phase lines, and three-phase triple points.

The (liquid + vapor) two-phase line in Fig. 1(a) terminates at a *critical point*. For H_2O, the *critical temperature*, T_c, and *critical pressure*, P_c, are 374 °C and 22.3 MPa. At this point, all the properties of the two phases become identical. Above the critical point there is no longer a distinction between liquid and vapor. As discussed above, if liquid and vapor are heated in a sealed container, the pressure follows the two-phase line. As the critical point is approached, the densities of the two phases approach each other, becoming identical at the critical point. At the molecular level, the behavior of a system very near its critical point is complex. For a discussion, see CRITICAL PHENOMENA.

The slopes of the two-phase lines in Fig. 1 are given by the *Clapeyron equation*,

$$dP/dT = \Delta H/T\Delta V, \tag{1}$$

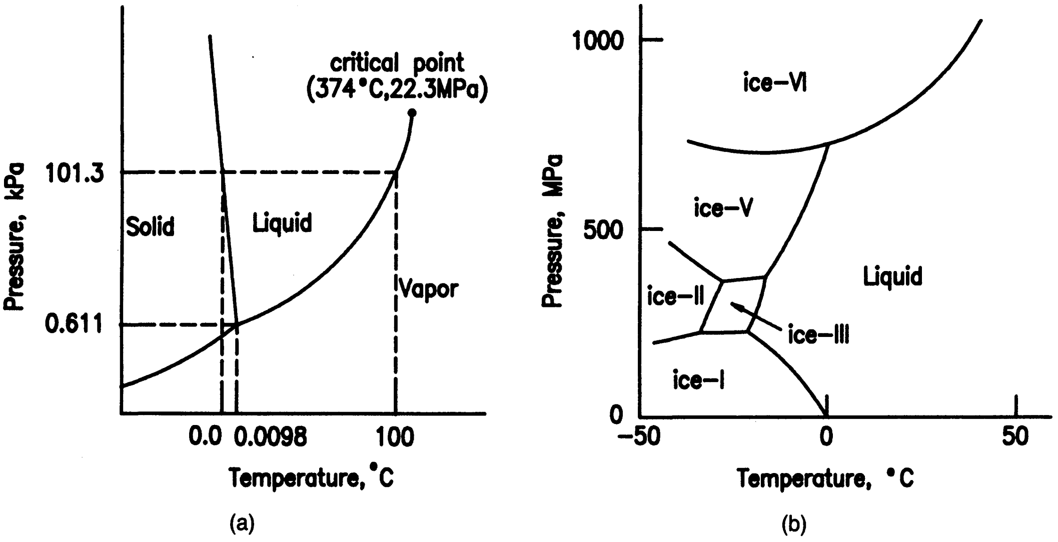

FIG. 1. *P-T* phase diagram of water at (a) low and (b) high pressures.

where ΔH is the heat (enthalpy) change for the transformation of one mole of substance from one phase to the other, ΔV is the corresponding molar volume change, and T is the temperature in kelvins. For the (liquid + vapor) line, ΔH is the heat of vaporization ($\Delta H > 0$) and ΔV is the volume change accompanying the vaporization of one mole of liquid. Hence, ΔH is very large and so, from Eq. (1), the slope of the line is small. For the (solid + liquid) boundary, however, ΔV of transformation from solid to liquid is small. Consequently, this line is very steep. It is interesting to note that H_2O is unusual in that $dP/dT < 0$ for the (solid + liquid) boundary. This is due to a negative ΔV of melting. (Ice floats on water.) For most substances, ΔV of melting is positive, and the (solid + liquid) boundary has a positive slope.

2. BINARY PHASE DIAGRAMS—DESCRIPTIVE

A binary system is one with two components. The precise definition of "component" is given in Sec. 3. However, the components of a system are usually evident. In this section we discuss binary temperature-composition (*T-X*) and pressure-composition (*P-X*) phase diagrams.

2.1 Systems with Complete Miscibility in All Phases

A *T-X* phase diagram at constant pressure $P = 101.3$ kPa for the methanol-water system is shown in Fig. 2. The abscissa is the composition, expressed as mole fraction of water, X_{H_2O}. Note that $X_{CH_3OH} = 1 - X_{H_2O}$. Phase diagrams are also often drawn with the composition axis as weight percent.

At a temperature and overall composition given by a point in the region labeled "vapor" in Fig. 2, the system, at equilibrium, will be entirely in the vapor phase. In the region labeled "liquid," the system, at equilibrium, will consist entirely of one miscible liquid phase. For example, it can be seen from Fig. 2 that pure water transforms from a liquid to a gas at 100.0 °C at $P = 101.3$ kPa (1.0 atmospheres), while the "normal boiling point" of methanol is 64.6 °C.

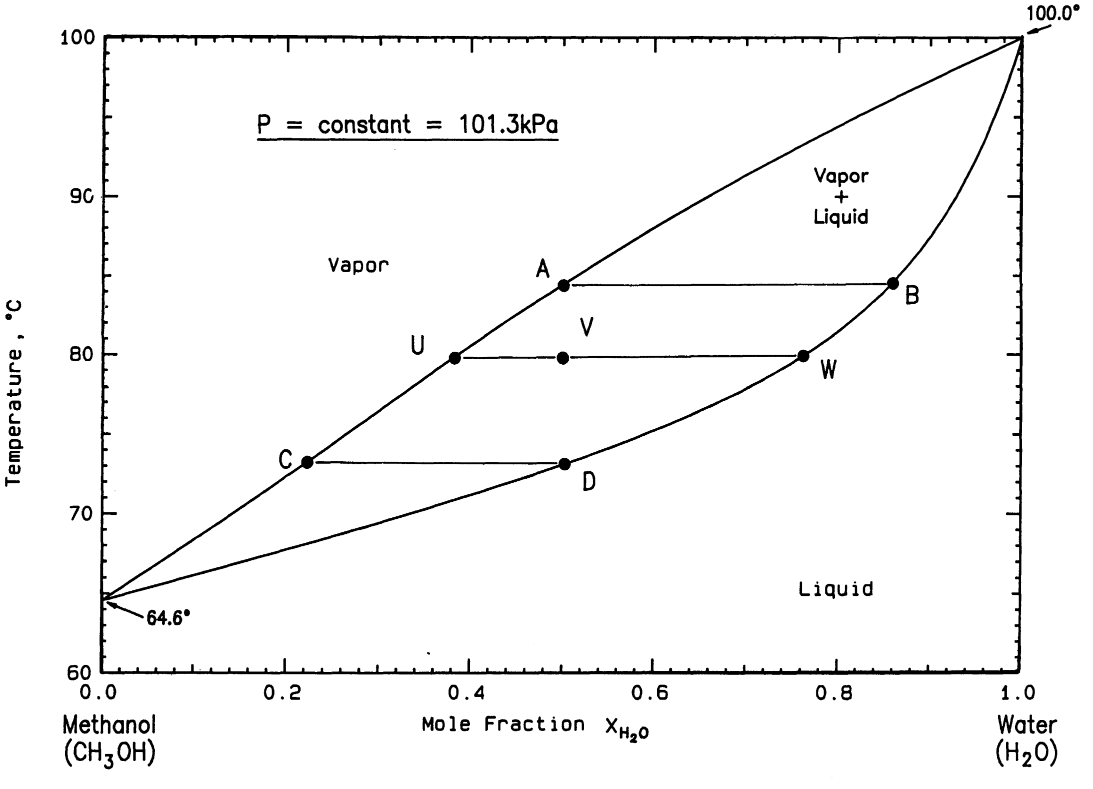

FIG. 2. *T-X* phase diagram at constant $P = 101.3$ kPa of the methanol-water system.

Suppose that a system at an overall composition of $X_{H_2O} = 0.5$ is held at 80 °C in a container at $P = 101.3$ kPa (i.e., at point V in Fig. 2). At equilibrium, two phases will be observed, a vapor phase of composition U ($X_{H_2O} = 0.385$) and a liquid solution of composition $W(X_{H_2O} = 0.76)$. The line UW is called a *tie-line* or *conode*.

If we were to add some water to the system to bring the overall composition to, say, $X_{H_2O} = 0.65$, keeping T constant at 80 °C, we would observe that the compositions of the vapor and liquid phases remain unchanged at points U and W, although the relative amount of the liquid phase would increase. From a simple mass balance, one can derive the *lever rule* for binary systems: (moles of vapor)/(moles of liquid) = VW/UV, where VW and UV are the lengths of the line segments.

Hence, at 80 °C and 101.3 kPa for a system with an overall composition $X_{H_2O} = 0.50$, the amounts of vapor and liquid at equilibrium are in the molar ratio $(0.76 - 0.5)/(0.5 - 0.385) = 2.26$. When the composition axis of a phase diagram is in weight percent, then the lever rule gives the weight ratio of the two phases.

Suppose that a gas with composition $X_{H_2O} = 0.5$ is slowly cooled at a constant pressure of 101.3 kPa. When the temperature has decreased to 84.5 °C the system is at point A on the upper phase boundary in Fig. 2. At this temperature (the "dew point") the first liquid condensate appears with a composition at point $B(X_{H_2O} = 0.86)$ on the lower phase boundary. As the temperature is decreased further, liquid continues to condense with the compositions of the equilibrium vapor and liquid phases at any temperature always lying on the phase boundaries. Condensation is complete at 73 °C, the last vapor to condense having composition $X_{H_2O} = 0.22$ at point C.

At pressures above (or below) 101.3 kPa, the T-X diagram in Fig. 2 will be shifted to higher (or lower) temperatures. It is often useful to plot a P-X phase diagram at constant T as illustrated in Fig. 3 for the methanol-water system. The interpretation of this diagram is analogous to that of Fig. 2. The tie-line UVW at 101.3 kPa at 80 °C in Fig. 3

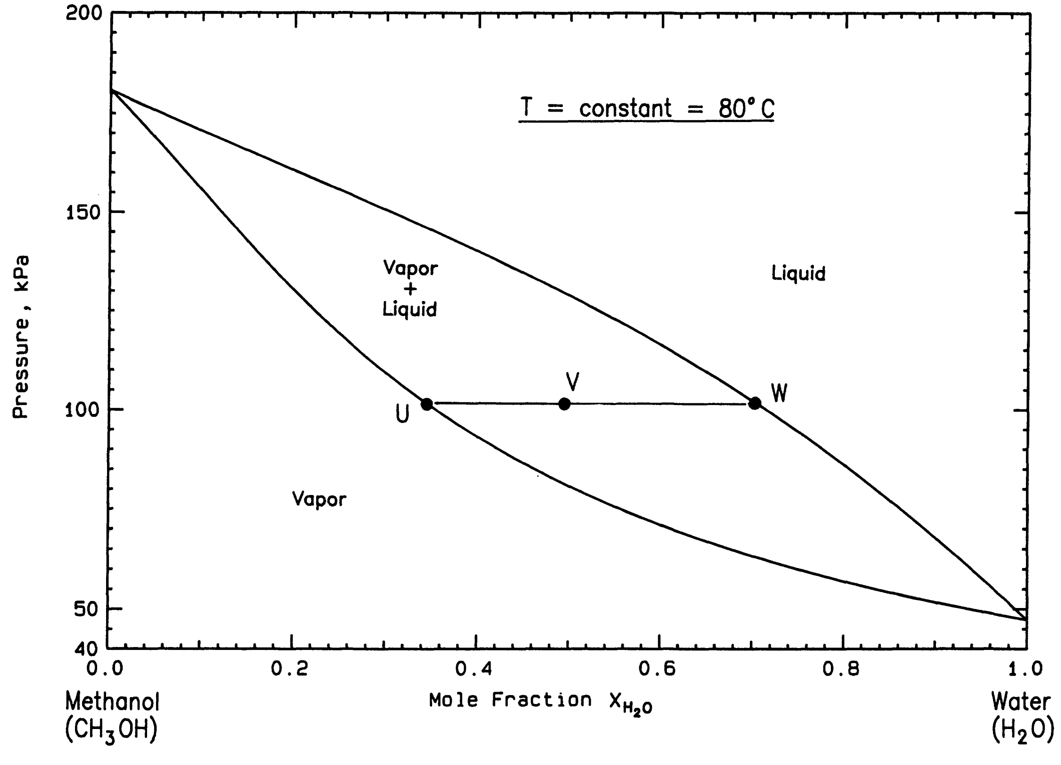

FIG. 3. P-X phase diagram at constant P = 80 °C of the methanol-water system.

is the same as the tie-line *UVW* at the same temperature and pressure in Fig. 2. The lever rule applies to *P-X* diagrams just as to *T-X* diagrams. At temperatures above (or below) T = 80 °C, the *P-X* diagram in Fig. 3 will be shifted to higher (or lower) pressures.

A *T-X* diagram at constant pressure of 101.3 kPa for the CaO-MnO system is shown in Fig. 4. The interpretation of this diagram is similar to that of Fig. 2. Pure CaO and MnO melt at 2572 °C and 1842 °C, respectively. CaO and MnO are completely miscible in the solid as well as the liquid state. The upper phase boundary, which gives the composition of the liquid phase in equilibrium with the solid phase, is called the *liquidus* line, while the lower phase boundary, the *solidus* line, gives the composition of the solid in equilibrium with the liquid.

Suppose that a liquid CaO-MnO solution with composition $X_{\mathrm{MnO}} = 0.60$ is cooled very slowly from an initial temperature of about 2500 °C. When the temperature has decreased to the liquidus temperature 2270 °C (point *B*) the first solid appears, with a composition at point *A* ($X_{\mathrm{MnO}} = 0.28$). As the temperature is decreased further, solid continues to precipitate, with the compositions of the two phases at any temperature being given by the liquidus and solidus compositions at that temperature and with their relative proportions being given by the lever rule. Solidification is complete at 2030 °C, the last liquid to solidify having composition $X_{\mathrm{MnO}} = 0.60$ (point *C*).

The process just described is known as equilibrium cooling. At any temperature during equilibrium cooling the solid phase has uniform (homogeneous) composition. In the preceding example, the composition of the solid phase during cooling varies along the line *APC*. Hence, in order for the solid to have a uniform composition at any temperature, diffusion of CaO from the center to the surface of the growing grains must occur. Since solid-state diffusion is a relatively slow process, equilibrium cooling conditions are only approached if the temperature is decreased very slowly. If a sample of composition X_{MnO} = 0.60 is cooled very rapidly from the liquid, concentration gradients will be observed in the solid grains, with the concentration of MnO increasing toward the surface from a minimum of $X_{\mathrm{MnO}} = 0.28$ (point *A*) at the center. Furthermore, in this case solidification will not be complete at 2030 °C, since at 2030 °C the average concentration of MnO in the solid particles will now be less than X_{MnO} = 0.60.

Since only condensed (i.e., nongaseous) phases are involved in Fig. 4, the phase diagram is very insensitive to pressure. Typically, phase boundaries involving only condensed phases are shifted by the order of one degree per 10 MPa (100 atm) change in pressure.

2.1.1 Minima and Maxima in Two-Phase Regions

A two-phase region may exhibit a minimum or a maximum. For example, in the chloroform-methanol system shown in Fig. 5, a minimum occurs at 35 mol % methanol at 53.4 °C. A liquid of this composition, when heated at constant pressure of 101.3 kPa, will

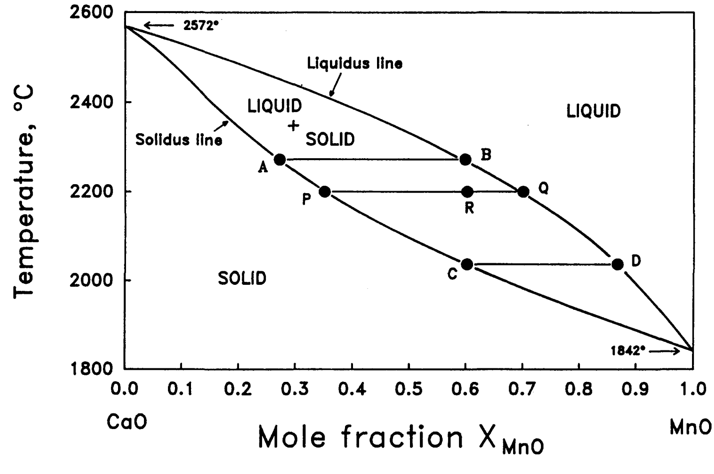

FIG. 4. Phase diagram of the CaO-MnO system at P = 101.3 kPa (after Schenck *et al.*, 1964, and Wu *et al.*, 1993).

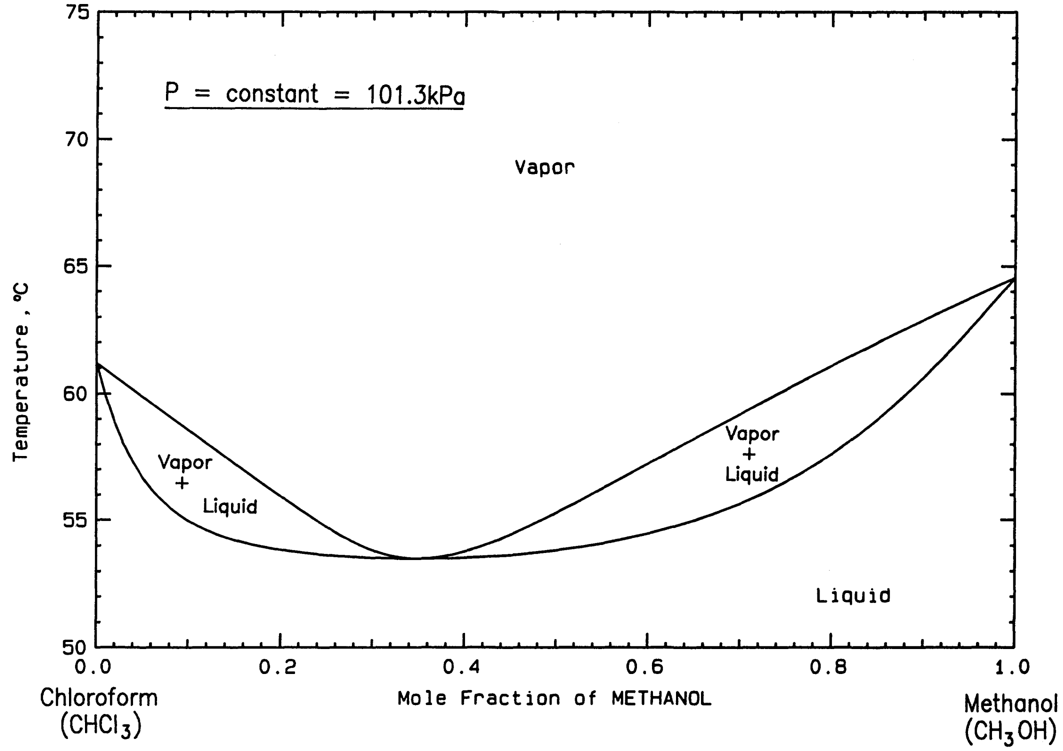

FIG. 5. *T-X* phase diagram at P = 101.3 kPa of the chloroform-methanol system (reprinted from Pelton, 1991).

transform completely to a vapor of the same composition at a constant temperature of 53.4 °C.

An extremum in a (liquid + vapor) two-phase region is called an *azeotrope*. Azeotropes are important in the design of distillation processes. In distillation, the aim is to separate the components of a mixture by virtue of the difference in composition between the liquid and vapor phases. At an azeotrope, however, both phases have the same composition.

Such extrema are not limited to (liquid + vapor) regions. Examples of extrema in (solid + liquid) regions are shown in Figs. 7, 9, and 19. Maxima in (solid + liquid) regions are usually associated with the existence of an intermediate compound as discussed in Sec. 2.5.3. At all such extrema, both phase boundaries must pass through their minimum or maximum at the same point.

2.2 Eutectics

The phase diagram of the Ag-Cu system is shown in Fig. 6. In this system, solid Ag and Cu have limited mutual solubility. At all compositions in the region labeled "solid S_1" a single-phase homogeneous solid solution of Cu in Ag will be observed. The *solvus line* shown in Fig. 6 indicates the solubility limit of Cu in Ag. Similarly, the solvus line on the Cu-rich side indicates the solubility limit of Ag in Cu. At overall compositions lying in the region labeled "2 solids," the system at equi-

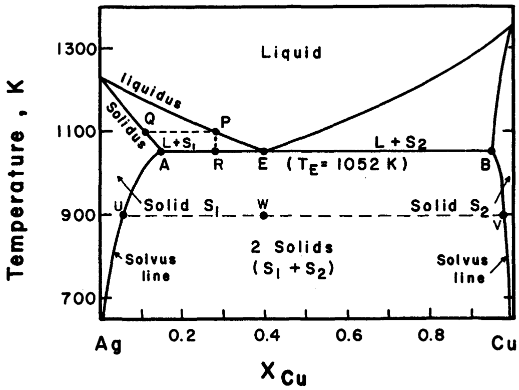

FIG. 6. Phase diagram at P = 101.3 kPa of the Ag-Cu system (after Hultgren *et al.*, 1973).

librium will consist of two phases: Ag saturated with Cu and Cu saturated with Ag. For example, at 900 °C, at an overall composition of 40 mol % Cu (point *W* in Fig. 6), the equilibrium microstructure will consist of two phases with compositions 5 mol % Cu (point *U*) and 97 mol % Cu (point *V*). The relative amounts of the two phases are given by the lever rule: (moles of S_1)/(moles of S_2) = $WV/UW = (0.97 - 0.4)/(0.4 - 0.05) = 1.63$.

The temperature T_E is called the *eutectic temperature*. At T_E, a liquid of composition *E*, the *eutectic composition*, is simultaneously in equilibrium with solid S_1 and solid S_2 of compositions *A* and *B*, respectively. Suppose a liquid Ag-Cu solution of composition $X_{Cu} = 0.29$ is cooled from the liquid state very slowly under equilibrium conditions. At 1100 °C, when the liquid is at point *P*, the first solid appears with composition *Q*. As *T* decreases further, solidification continues with the liquid composition following the liquidus curve from *P* to *E* and the solid composition following the solidus curve from *Q* to *A*. The relative amounts of the two phases at any *T* are given by the lever rule. At T_E, the overall system composition and temperature are given by point *R*. At a temperature just above T_E, two phases are observed, a solid and a liquid of compositions *A* and *E*, respectively, while at a temperature just below T_E, according to the diagram, two solids with compositions *A* and *B* will be observed. Therefore, at T_E, during cooling, the following *binary eutectic reaction* occurs:

$$\text{liquid} \rightarrow \text{solid}_1 + \text{solid}_2. \qquad (2)$$

Under equilibrium conditions, the temperature will remain constant at $T = T_E$ until all the liquid has solidified, and during the reaction the compositions of the three phases will remain fixed at points *A*, *B*, and *E*. For this reason, the eutectic reaction is called an *invariant* reaction.

After the eutectic solidification is completed, if the microstructure is examined at a temperature slightly below T_E, one will observe two types of grains. There will be grains of pure S_1 solid solution of composition *A* that solidified at temperatures above T_E. This is called the *primary* solid or *pro-eutectic* constituent. There will also be grains that formed during the eutectic reaction. These *eutectic* grains will have an overall composition at point *E*, and will consist of an intimate mixture of the phases S_1 and S_2 of compositions *A* and *B*. At high magnification it will be seen that this intimate mixture may consist of alternating lamellae of S_1 and S_2 or of globules or needles of one phase in the other, or of another morphology depending upon the system and upon kinetic factors. Although the pro-eutectic and eutectic *constituents* are not phases (the eutectic grains are two-phase mixtures), the lever rule may nevertheless be applied at a temperature just below T_E as follows: (moles of pro-eutectic constituent)/(moles of eutectic constituent) = RE/AR. If the composition axis is in weight fraction, then this ratio gives the weight ratio of the constituents.

Upon heating an alloy with overall composition between points *A* and *B* ($0.15 < X_{Cu} < 0.96$), the eutectic reaction (2) will occur in the reverse direction at T_E. Hence, 1052 K is the temperature of first appearance of a liquid phase for such alloys. For alloys with compositions outside this range the temperature of first appearance of a liquid phase, under equilibrium conditions, will be the solidus temperature. However, equilibrium conditions may not prevail. For example, an alloy containing 10 mol % Cu, which consists of two solid phases at lower temperatures, will consist of only one solid solution phase when at equilibrium above the solvus temperature of ~1020 °C. Hence, if the alloy is first held somewhat above 1020 °C until equilibrium is attained, before further heating, then the first liquid will appear at the solidus temperature of ~1110 °C. However, if the alloy is heated very quickly from room temperature to T_E, there will not be enough time for the S_2 phase to dissolve by diffusion in the S_1 phase. In this case, the alloy will arrive at T_E as a two-phase mixture, and a liquid phase will appear at T_E.

For further discussion of equilibrium and nonequilibrium heat treatment of alloys and other materials and the resultant microstructures, see MATERIALS TREATMENT and THERMAL ANNEALING.

2.3 Miscibility Gaps

The CaO-SiO$_2$ system is of great importance in the fields of ceramics, refractories, and metallurgy as well as in geology. The phase diagram of this system in Fig. 7 ex-

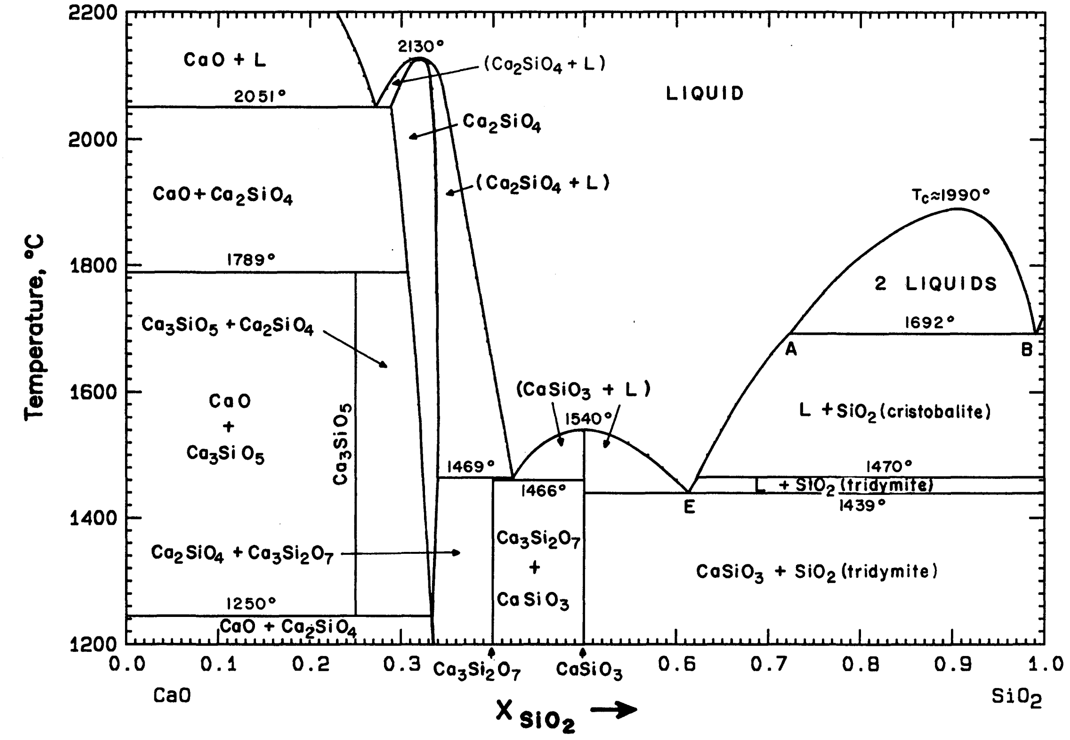

FIG. 7. CaO-SiO$_2$ phase diagram at P = 101.3 kPa (after Eriksson *et al.*, 1994).

hibits many features that are discussed in this section as well as in Secs. 2.4 and 2.5.

A *liquid-liquid miscibility gap* with a *consolute* or *critical point* at T_c = 1990 °C and $X_{c(\mathrm{SiO_2})} \approx 0.91$ is seen in Fig. 7.

Suppose that a liquid of composition $X_{\mathrm{SiO_2}} = 0.80$ is cooled slowly from high temperatures. At ~1820 °C the miscibility gap boundary is crossed and a second liquid layer appears with an initial composition of $X_{\mathrm{SiO_2}} \approx 0.966$. As the temperature is lowered further, the composition of each liquid phase follows its respective phase boundary until, at 1692 °C, the SiO$_2$-rich liquid has a composition of $X_{\mathrm{SiO_2}} = 0.99$ (point B) and in the CaO-rich liquid $X_{\mathrm{SiO_2}} = 0.725$ (point A).

At 1692 °C the following *invariant monotectic reaction* then occurs upon cooling:

$$\text{liquid } B \rightarrow \text{liquid } A + \mathrm{SiO_2(solid)}. \qquad (3)$$

The temperature remains constant at 1692 °C and the compositions of the phases remain constant until all of liquid B is consumed. Cooling then continues with precipitation of solid SiO$_2$, with the equilibrium liquid composition following the liquidus from point A to the eutectic E at 1439 °C.

The critical point in Fig. 7 is similar to the critical point in Fig. 1 in that the properties of the two phases become identical at the critical point and above the critical point there is only one miscible liquid phase. For further discussion, see CRITICAL PHENOMENA.

2.4 Polymorphism

Solid compounds can often exist in two or more crystal structures depending upon the temperature and pressure. The example of water ice has already been given in Sec. 1. As another example, pure SiO$_2$ transforms from the tetragonal tridymite crystal structure to the cubic cristobalite structure at 1470 °C. The transformation involves an invariant reaction, which appears on the phase diagram in Fig. 7. As yet another example, the polymorphism of Fe is seen on the phase diagram in Fig. 9, as is discussed in Sec. 2.6.

In Fig. 7, SiO$_2$ is shown as a *stoichiometric* solid. That is, the solubility of CaO in solid SiO$_2$ is negligible, such that the liquid on the liquidus AE is in equilibrium with pure solid

SiO_2. In reality, no solid is ever exactly stoichiometric (that is, no solubility is ever identically zero), so that there is actually a solidus line and solvus line in Fig. 7 just as in Fig. 6. However, these lines are indistinguishable from the vertical axis at $X_{SiO_2} = 1$.

2.5 Intermediate Compounds

2.5.1 Congruently Melting Compounds In the CaO-SiO_2 system in Fig. 7, there is a compound $CaSiO_3$ that melts at a constant temperature of 1540 °C to form a liquid of the same composition. $CaSiO_3$ is thus called a *congruently melting* compound. There is a eutectic on either side of this compound in Fig. 7. In the eutectic reaction at 1439 °C, for example, liquid of composition E solidifies at constant T to give $CaSiO_3$ and SiO_2. In the eutectic reaction at 1466 °C, liquid at the eutectic composition at $X_{SiO_2} = 0.425$ solidifies to give $CaSiO_3$ and $Ca_3Si_2O_7$.

2.5.2 Incongruently Melting Compounds The compound $Ca_3Si_2O_7$ in Fig. 7 is said to be an *incongruently melting compound*. When heated, $Ca_3Si_2O_7$ decomposes at a constant temperature of 1469 °C to form solid Ca_2SiO_4 plus a liquid of composition $X_{SiO_2} = 0.42$. This is the temperature of first appearance of a liquid. The material will not be completely liquid, however, until it is heated to the liquidus temperature of ~1630 °C. When a liquid containing 40 mol % SiO_2 is cooled at equilibrium, these events occur in reverse. The first solid, Ca_2SiO_4, appears at the liquidus temperature of ~1630 °C. At the *peritectic temperature* of 1469 °C, the following *peritectic reaction* occurs:

$$\text{liquid} + \text{solid}_1 \rightarrow \text{solid}_2, \tag{4}$$

where solid_1 and solid_2 are Ca_2SiO_4 and $Ca_3Si_2O_7$, respectively.

Like the eutectic reaction, this is an invariant reaction, which, under equilibrium conditions, occurs at constant temperature and a fixed compositions of all three phases. However, upon cooling, peritectic reactions generally occur with formation of the product solid ($Ca_3Si_2O_7$) on the surface of the reactant solid (Ca_2SiO_4). This coating can prevent contact between the reactant solid and liquid. Further reaction may thus be greatly retarded so that equilibrium conditions can only be achieved by extremely slow cooling. In the present example, if a liquid containing 40 mol % SiO_2 were cooled rapidly, some unreacted Ca_2SiO_4 would remain at room temperature.

An incongruently melting compound is always associated with a peritectic invariant in a phase diagram.

2.5.3 Nonstoichiometric Compounds In the phase diagram of the CaO-SiO_2 system, Fig. 7, the phase labeled Ca_2SiO_4 is a *nonstoichiometric compound* with nominal composition Ca_2SiO_4 ($X_{SiO_2} = 0.333$). At 2000 °C, for example, the width of the single-phase region extends from $X_{SiO_2} = 0.28$ to $X_{SiO_2} = 0.335$. This is the *range of stoichiometry* over which the compound can exist as a single homogeneous phase. Generally, as in Fig. 7, the range of stoichiometry becomes narrower at lower temperatures.

The nonstoichiometry of Ca_2SiO_4 can also be regarded as a solid solubility of CaO in Ca_2SiO_4 on one side and of SiO_2 in Ca_2SiO_4 on the other (the solubility of SiO_2 being less than that of CaO).

All compounds exhibit some finite range of stoichiometry. Although the compounds $CaSiO_3$ and $Ca_3Si_2O_7$ in Fig. 7 are shown as stoichiometric "line compounds," in reality they have finite, but very narrow, ranges of stoichiometry. That is, a "stoichiometric" compound like $CaSiO_3$ is simply a limiting case of nonstoichiometric compound.

Ca_2SiO_4 is a congruently melting compound with a congruent melting point of 2130 °C. It can be seen that this congruent melting point can also be regarded as the point at which the solidus and liquidus defining the two-phase ($Ca_2SiO_4 + L$) region pass simultaneously through a maximum (see Sec. 2.1.1). In this regard, it can be appreciated that the congruent melting point of the 'stoichiometric' compound $CaSiO_3$ is simply a limiting case of this construction as the range of stoichiometry becomes negligibly small.

As an example of the practical consequences of nonstoichiometry, consider a ceramic with $X_{SiO_2} = 0.31$ in the single-phase region at 2000 °C. If this ceramic is cooled to, say, 1200 °C in the two-phase region and then held at this temperature, fine precipitates of CaO will form. If, on the other hand, it is rapidly quenched to room temperature, there will be insufficient time for precipitation to occur by solid-state diffusion, and the single-phase metastable Ca_2SiO_4 structure will be frozen in.

Generally, nonstoichiometry in a compound results from the presence of lattice *point defects*. Let A_mB_n be the ideal stoichiometry of a compound as given by its crystal structure. An excess of B, $A_{m-x}B_{n+x}$ with $x > 0$, can result from defects such as interstitial B atoms, B atoms occupying lattice sites normally occupied by A atoms, vacant A sites, etc. An excess of A can result from similar defects. The energy of forming such defects will determine the number of defects at equilibrium. If this energy is very high, few defects will be present and the range of stoichiometry will be narrow. A relatively low energy of formation, on the other hand, will result in a large number of defects and a wide range of stoichiometry. In Fig. 7, it can be seen that the energy of forming defects that permit an excess of SiO_2 in Ca_2SiO_4 is larger than the energy of forming defects permitting an excess of CaO.

2.6 Topology of Binary Phase Diagrams

From the preceding examples it can be seen that all binary *T-X* and *P-X* diagrams obey the same topological rules of construction. Scanning horizontally across the diagrams, at constant *T* and *P*, one encounters single-phase regions alternating with two-phase regions. Two-phase regions can pass through maxima or minima as discussed in Sec. 2.1.1, or they can terminate in a critical point as discussed in Sec. 2.3.

There are only two general types of three-phase *invariants* in binary phase diagrams. These are the *eutectic-type* and *peritectic-type invariants* as illustrated in Fig. 8. Let the three phases concerned be called α, β, and γ with β as the central phase as in Fig. 8. The α, β and γ can be solid, liquid, or gaseous phases. At a eutectic-type invariant, the following invariant reaction occurs isothermally as the system is cooled:

$$\beta \rightarrow \alpha + \gamma, \tag{5}$$

while, at a peritectic-type invariant, the invariant reaction upon cooling is

$$\alpha + \gamma \rightarrow \beta. \tag{6}$$

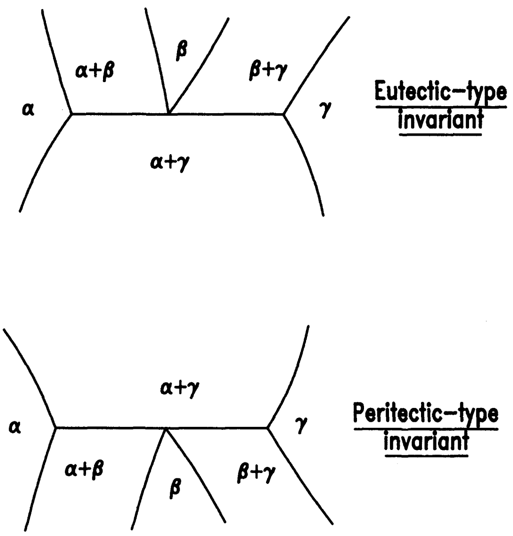

FIG. 8. The two types of invariants in binary *T-X* and *P-X* phase diagrams.

For example, at a *eutectic*, α = solid$_1$, β = liquid, γ = solid$_2$. The eutectic reaction is $l \rightarrow s_1, + s_2$. A *monotectic*, as seen in Fig. 7 at 1692 °C is also a eutectic-type invariant with α = liquid$_1$, β = liquid$_2$, γ = solid. The monotectic reaction is $l_2 \rightarrow l_1 + s$.

Other examples can be seen in the phase diagram of the Fe-Mo system in Fig. 9. *Peritectics*, in which α = liquid β = solid$_1$, γ = solid$_2$, are seen at 1540 °C, 1488 °C, and 1450 °C. The peritectic reaction is $l + s_2 \rightarrow s_l$. At 1235 °C and 1200 °C in Fig. 9 are examples of *eutectoids* (which are eutectic-type invariants) involving three solid phases. With α = solid$_1$, β = solid$_2$, and γ = solid$_3$, the eutectoid reaction is $s_2 \rightarrow s_1 + s_3$. Examples of *peritectoids* are seen at 1370 °C and 950 °C. These are peritectic-type invariants. The peritectoid reaction is $s_1 + s_3 \rightarrow s_2$. In Fig. 7 the invariants at 1250 °C and 1789 °C are, respectively, limiting cases of a eutectoid and a peritectoid where the range of homogeneity of the phase Ca_3SiO_5 is negligibly small.

Many other eutectic-type and peritectic-type invariants are observed such as *syntectics* ($l_1 + l_2 \rightarrow s_1$) and *catatectics* ($s_1 \rightarrow l + s_2$).

In Secs. 2.2 and 2.5.2, the microstructures resulting from heat treatments of systems with eutectics and peritectics were briefly described. Similar considerations apply in the case of eutectoids and peritectoids. For ex-

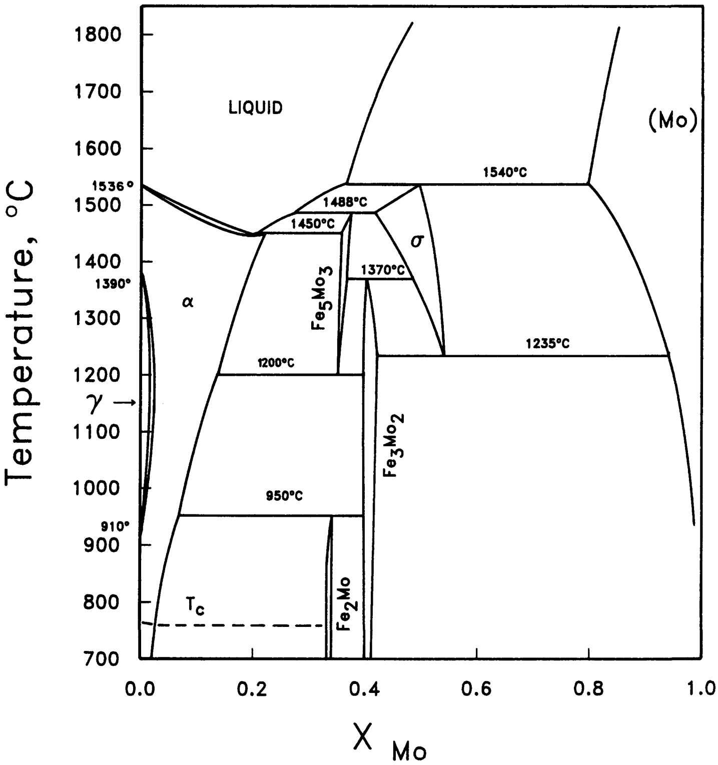

FIG. 9. Fe-Mo phase diagram at P = 101 kPa (Kubaschewski, 1982; reprinted from Pelton, 1991). The α and γ phases have the body-centered-cubic and face-centered-cubic structures, respectively. The σ phase is an intermediate solid phase.

ample, the best-known example of a eutectoid microstructure is that of pearlitic steel. For more information, see MATERIALS TREATMENT; METALLURGY, PHYSICAL; and STEEL AND IRON.

A final point of interest in Fig. 9 is the two-phase ($\alpha + \gamma$) γ *loop* between 910 °C and 1390 °C. Pure Fe adopts the face centered-cubic (fcc) γ crystal structure between these two temperatures, but exists as the body-centered-cubic (bcc) α phase at higher and lower temperatures. Mo, however, is much more soluble in the bcc than in the fcc structure. Hence, small additions of Mo stabilize the bcc structure, thereby producing the γ loop.

2.7 Phase Diagrams of Systems with Liquid-Crystalline Phases

In Sec. 2.4, solid polymorphism was discussed. In certain systems, liquid polymorphism is also observed. For example, the phase diagram of the system EEBC-TBBA is shown in Fig. 10.

All the phases shown with the exception of solid$_1$ and solid$_2$ are liquid phases. The high-temperature "isotropic" phase is a "normal" disordered liquid. In all the other phases there exists, on the average, an orientational order of the molecules. This orientational order may be distinguished from the positional order found in solid crystals. Generally, the molecules of liquids that form liquid crystals are elongated and rigid. If, on the average, the molecular axes are aligned, a *nematic* liquid-crystalline phase results. In other liquid-crystalline phases, the molecules tend to be both aligned and arranged in layers. Such phases are termed *smectic*. Various smectic phases can exist, differing, for example, in the angle between the molecular axes and the planes of the layers. In all respects, the phase diagram in Fig. 10 obeys the topological rules of binary T-X diagrams discussed in Sec. 2.6. For example, pure EEBC and TBBA transform from the smectic A to the nematic liquid crystal structure at 158.3 °C and 199.0 °C, respectively. At intermediate compositions there is a two-phase (smectic A + nematic) region, with a minimum at 156.2 °C. Several eutectic-like and peritectic-like invariants are

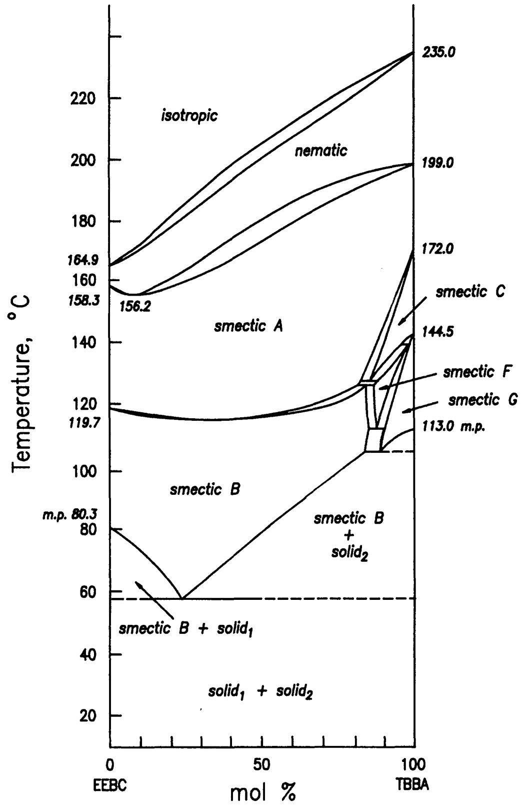

FIG. 10. Equilibrium *T-X* diagram at $P = 101.3$ kPa of the EEBC-TBBA system, which exhibits liquid-crystalline phases (after Richter *et al.*, 1981). (EEBC = ethyl 4-[4-ethoxy benzylidene-amino]-cinnamate: TBBA = terephthalylidene-*bis*-[4-*n*-butyl-aniline].)

seen in Fig. 10. For further discussion see LIQUID CRYSTALS, STRUCTURE OF.

3. THE GIBBS PHASE RULE

In Secs. 1 and 2 the topology of phase diagrams was described with no justification given as to why these topological rules should be obeyed. The present section addresses this question, although space restrictions do not permit a completely rigorous development to be made. For a more complete treatment see THERMODYNAMICS, EQUILIBRIUM.

First, the term *component* should be defined more precisely. At most, the number of components in a system is equal to the number of chemical elements. However, there may be chemical constraints such that certain elements always appear in fixed ratios. If these constraints apply *in every phase* that could possibly appear over the ranges of interest of *T* and *P*, then there will be a consequent reduction of the number of components. For example, in the methanol-water system, Figs. 1 and 2, the elements are always combined as CH_3OH and H_2O in every phase. Hence, this is a two-component system. A system of water and sodium chloride near ambient conditions is a two-component system since the number of Na^+ ions must equal the number of Cl^- ions in every phase. A system prepared by mixing the salts NaCl, KCl, NaF, and KF is a three-component system because the number of cations must always equal the number of anions. (A solution of any desired composition could always be formed by mixing only three of the four salts.)

Next we must determine the number of variables required to define the equilibrium state of a system. We choose these as temperature *T*, total pressure *P*, and the compositions of the phases at equilibrium. In the general case, other variables such as electrical, magnetic, and gravitational fields can also influence phase equilibria. However, we do not consider these here. It must be stressed that the overall (global) composition of the system is NOT a variable in the present context. We are interested in knowing which phases are present and their compositions, but not their relative amounts. For example, in a two-phase region in a binary system, as long as the overall composition lies on the tie-line between the compositions of the two phases, they will both be present and their compositions will not change.

Now, in order to specify the composition of a phase in a system with *C* components, $C - 1$ composition variables are required, since the sum of the mole fractions is unity. Hence, if *P* phases are present at equilibrium. $P(C - 1)$ composition variables are needed. Along with temperature and pressure, the number of variables is thus $P(C - 1) + 2$.

When we say that two phases are at equilibrium we mean that there is no net transfer with time of any component between the phases. Now, there must be some solution property that determines the direction of spontaneous transfer of a component between two phases in contact. This property is called the *chemical potential of component i*, and is given the symbol μ_i (where the components are numbered 1, 2, 3, . . ., *C*). Just as electrical charge is transferred spontaneously from high to low electrical potential, so component i will migrate spontaneously from a phase of higher chemical potential to a phase of lower chemical potential.

Therefore, if two phases, α and β are in equilibrium, then $\mu_i^\alpha = \mu_i^\beta$ for all components $1 \leq i \leq C$. If P phases are present at equilibrium, then there are $C(P - 1)$ such equations. However, μ_i, being a property of a phase, is a function of T, pressure, and the composition of the phase. That is, each of the $C(P - 1)$ equations is an equation relating those variables which specify the equilibrium state of the system.

The difference between the number of variables, $P(C - 1) + 2$, and the number of equations relating the variables, $C(P - 1)$, is called the *variance*, or the *number of degrees of freedom*, F, of the system. This then is the Gibbs phase rule:

$$F = C - P + 2. \tag{7}$$

That is, F is the number of variables which can and must be specified in order to specify completely the state of the system.

In a one-component system as in Fig. 1, $C = 1$. Hence, the phase rule reduces to $F = 3 - P$. The only variables being considered are temperature and pressure. In a single-phase area, $F = 3 - 1 = 2$. That is, T and pressure can be specified independently. These regions are thus called *bivariant*. When two phases are at equilibrium, $F = 3 - 2 = 1$. If, say, T is specified, then the pressure is fixed. For example, if liquid and vapor are in equilibrium at a given T, then the pressure must be the equilibrium vapor pressure. Such two-phase regions are thus called *univariant* and are represented by lines on Fig. 1. When three phases are in equilibrium, $F = 0$, the system is *invariant*, and the state is represented by a triple point in Fig. 1.

In a two-component system, $C = 2$ and $F = 4 - P$. When we consider a T-X phase diagram at a constant pressure, however, we have already eliminated one degree of freedom. Hence, for an isobaric T-X diagram, $F = 3 - P$. The variables of interest are now T and the compositions of the phases. In a single-phase area, $F = 3 - 1 = 2$. Hence, T and composition can be independently specified, and the system is bivariant. When two phases are in equilibrium, $F = 1$. If, say, T is specified, then the compositions of both phases are fixed by the ends of the tie-line. When three phases are at equilibrium, the system is invariant. That is, the compositions of all three phases as well as the temperature are fixed. This gives rise to eutectic-type and peritectic-type invariants.

It can thus be seen how the topology of phase diagrams is determined by the phase rule.

4. TERNARY PHASE DIAGRAMS

Only a very brief introduction to isobaric ternary T-X diagrams can be given here. For further discussion see Pelton (1983, 1991) and Prince (1966).

4.1. Ternary Composition Triangle

In a ternary system with components A, B, C, the sum of the mole fractions is unity: $X_A + X_B + X_C = 1$. Hence, there are two independent composition variables. A representation of composition, symmetrical with respect to all three components, may be obtained with the equilateral "composition triangle" as shown in Fig. 11(a) for the LiF-NaF-KF system. Compositions at the corners of the triangle correspond to the pure components. Along the edges of the triangle are found compositions corresponding to the three binary subsystems LiF-NaF, LiF-KF, and NaF-KF. Lines of constant mole fraction X_{LiF} are parallel to the NaF-KF edge, while lines of constant X_{NaF} and X_{KF} are parallel to the LiF-KF and LiF-NaF edges, respectively. For example, at point *a* in Fig. 11(a), $X_{\mathrm{LiF}} = 0.06$, $X_{\mathrm{NaF}} = 0.23$, and $X_{\mathrm{KF}} = 0.71$.

Similar equilateral composition triangles can be drawn with coordinates in terms of weight percent of the three components.

4.2 Ternary Space Model

A ternary temperature-composition "phase diagram" at constant total pressure may be plotted as a *three-dimensional space model* within a right triangular prism with the equilateral composition triangle as base and temperature as vertical axis. Such a space model for the simple eutectic ternary system LiF-NaF-KF is illustrated in Fig. 11(b). On the three vertical faces of the prism are found the

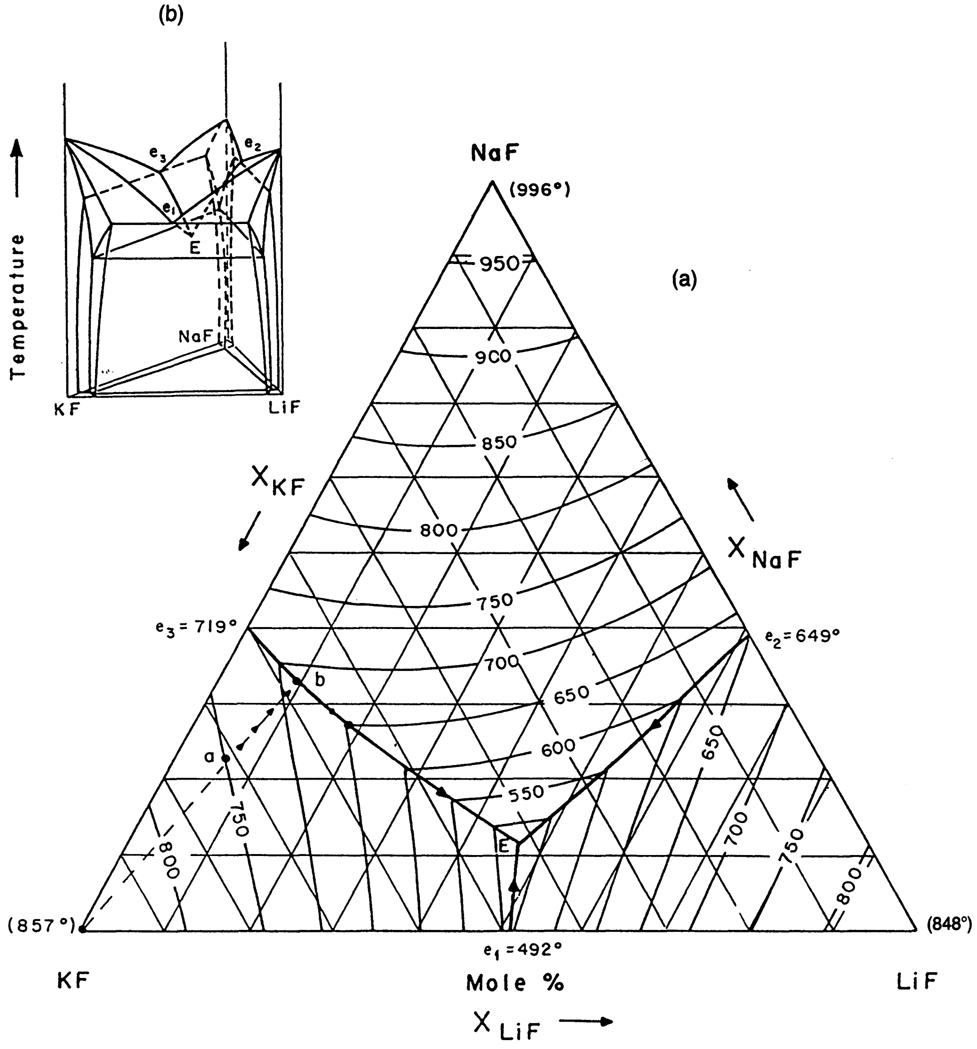

FIG. 11. (a) Polythermal projection of the liquidus surface of the LiF-NaF-KF system. Temperature in °C (Levin *et al.*, 1964.) (b) Perspective view of ternary space model of a simple eutectic system. ϵ_1, ϵ_2, and ϵ_3 are the binary eutectics and *E* is the ternary eutectic. The base of the prism is the equilateral composition triangle. (Reprinted from Pelton, 1983.)

phase diagrams of the three binary subsystems, LiF-NaF, LiF-KF, and NaF-KF, which in this example are all simple eutectic binary systems. The binary eutectic points are at e_1, e_2, and e_3. Within the prism are seen three *liquidus surfaces* descending from the melting points of pure LiF, NaF, and KF. Compositions on these surfaces correspond to compositions of liquids in equilibrium with LiF-, NaF-, and KF-rich solid phases.

The NaF and KF liquidus surfaces in Fig. 1(b) intersect along the line e_3E. Liquids with compositions along this univariant "valley" are therefore in equilibrium with NaF-rich and KF-rich solid phases simultaneously. The three univariant lines meet at the *ternary eutectic point E* at which the temperature and the compositions of all four phases in equilibrium are fixed.

In a 3-component system at constant pressure, the phase rule, Eq. (7), reduces to $F = 4 - P$. Therefore, for a liquid in equilibrium with one solid, $F = 2$. Hence, liquiduses are bivariant surfaces. The composition of a liquid in equilibrium with two solids is represented by a univariant line, and liquid can exist in equilibrium with three solids at a ternary eutectic invariant point.

4.3 Polythermal Projections of Liquidus Surfaces

A two-dimensional representation of the ternary liquidus surface may be obtained as an orthogonal projection upon the base composition triangle. Such a *polythermal projection* of the liquidus of the LiF-NaF-KF system is shown in Fig. 11(a). This is a simple eutectic ternary system. The constant-temperature lines in Fig. 11(a) are called *liquidus isotherms*. The univariant valleys are shown as the heavier lines. By convention, the arrows indicate the directions of decreasing temperature along these lines.

Let us consider the sequence of events that occur during the equilibrium cooling of a liquid of overall composition *a* in Fig. 11(a). Point *a* lies within the *field of primary crystallization* of KF. That is, it lies within the composition region in Fig. 11(a) in which KF-rich solid will be the first solid to precipitate upon cooling. As the liquid is cooled, the KF liquidus surface is reached at $T = 750$ °C. A solid KF-rich phase begins to precipitate at this temperature. Now, in this particular system, NaF and LiF are nearly insoluble in solid KF so that the solid phase is virtually pure KF. [Note that this fact cannot be deduced from Fig. 11(a) alone]. Therefore, as solidification proceeds, the liquid becomes depleted in KF, but the ratio $X_{\mathrm{NaF}}/X_{\mathrm{LiF}}$ in the liquid remains constant. Hence, the composition path followed by the liquid (its *crystallization path*) is a straight line passing through point *a* and projecting to the KF corner of the triangle. This crystallization path is shown in Fig. 11(a) as the line *ab*. (Note that in the general case, in which a solid solution rather than a pure component or stoichiometric compound is precipitating, the crystallization path will not be a straight line.)

When the composition of the liquid has reached point *b* in Fig. 11(a) at $T \approx 680$ °C, the primary crystallization of KF is complete. Upon further cooling, the liquid composition follows the univariant valley from *b* to *E* while LF- and NaF-rich solids coprecipitate as a binary eutectic mixture. When the liquidus composition attains the ternary eutectic composition *E* at $T = 463$ °C, the invariant *ternary eutectic reaction* occurs:

$$\text{liquid} \rightarrow s_1 + s_2 + s_3, \qquad (8)$$

where s_1, s_2, and s_3 are the three solid phases and where the compositions of all four phases, as well as T, remain fixed until all liquid is solidified.

As another more complex example, the polythermal liquidus projection is shown in Fig. 12 for the $CaO\text{-}Al_2O_3\text{-}SiO_2$ system. Liquidus surfaces, with isotherms, are seen for several primary crystalline phases. The compositions of the solid compounds are shown in Fig. 12 by points. For example, $CaSiO_3$ (pseudowollastonite) is a *binary compound* (since its composition is in the $CaO\text{-}SiO_2$ binary system), which melts at 1540 °C. For any liquid with composition in the field labeled "pseudowollastonite," $CaSiO_3$ will be the first solid to precipitate upon cooling. Anorthite, $CaAl_2Si_2O_8$, is a *ternary compound* which melts congruently at 1555 °C.

The liquidus surfaces for the various solid phases in Fig. 12 intersect along univariant lines. The arrows shown on these lines indicate the direction followed by the liquid composition during cooling in equilibrium with both solid phases. The univariant lines meet at invariant points. If the arrows on all three lines converge at such a point, then the point is a *ternary eutectic point*. If one or more arrows lead away from the point, then the point is a *ternary peritectic point*.

4.4 Ternary Isothermal-Isobaric Sections

If the solid phases in equilibrium with the liquid are stoichiometric, or nearly stoichiometric compounds, then a polythermal liquidus projection as in Figs. 11(a) and 12 gives complete information on the ternary space model. However, when solid solutions are present, the liquidus projection does not give information on the compositions of the solid phases. This information can be conveyed by a series of *isothermal sections*, which are constant-temperature slices through the space model.

An isothermal section at 25 °C of the Al-Zn-Mg system is shown in Fig. 13. Such isothermal sections follow strict topological rules. With three components, at constant T and pressure, the phase rule, Eq. (7), reduces to $F = 3 - P$. Single-phase regions are thus

bivariant ($F = 2$). These are shown as the black regions in Fig. 13. When two phases are in equilibrium, $F = 1$, and a tie-line results. These tie-lines together form two-phase regions. For example, in Fig. 13, a set of tie-lines joins the δ-phase and τ-phase regions. For an overall composition on any one of these tie-lines a δ-phase alloy with composition at one end of the tie-line is in equilibrium with a τ-phase alloy whose composition is at the other end. When three phases are at equilibrium, $F = 0$ and the compositions of all three phases are fixed. Three-phase regions are represented by *tie-triangles* as shown in Fig. 13. For an overall composition inside such a triangle, three phases are present at equilibrium, and their compositions are given by the corners of the triangle.

5. OTHER KINDS OF PHASE DIAGRAMS

The types of phase diagrams discussed in the preceding sections, and exemplified in Figs. 1 through 13, are the most commonly encountered. However, there are many other useful types of phase diagrams.

Vertical sections, known as *isopleths*, through a ternary space model like Fig. 11(b), are often a convenient method of representing ternary equilibria. In systems of four or more components, many techniques of presenting two-dimensional sections or projections have been proposed. For a discussion of these, see Prince (1963), Palatnik and Landau (1964), Prince (1966), and Hillert (1985).

Many types of phase diagrams result when the chemical potentials of components are

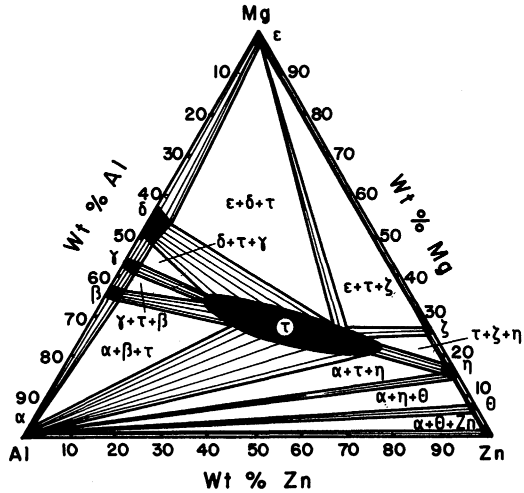

FIG. 13. Ternary isothermal section of the Al-Zn-Mg system at 25 °C (after Koster and Dullenkopf, 1936, reprinted from Pelton, 1983).

used as axis variables or are held constant. The chemical potential of a gas is easily controlled by fixing its partial pressure. Hence, the most useful and common phase diagrams of this class are those with partial pressures of gases as variables.

For example, Fig. 14 shows a *predominance diagram* of the Cu-S-O system at 1000 K. The axes are the equilibrium SO_2 and O_2 partial pressures. The diagram is divided into areas or domains of stability of the various solid Cu-containing compounds. The conditions for coexistence of two and three solids are indicated respectively by the lines and triple points on the diagram. Such diagrams have many applications in hot corrosion, roasting, chemical vapor deposition, etc. It can be seen that these diagrams obey the same topological rules of construction as *P-T* diagrams of one-component systems as in Fig. 1.

Another type of predominance diagram, which again obeys the same rules of construction, is shown in Fig. 15. This diagram indicates which solid Fe-containing phases are stable as a function of equilibrium oxygen partial pressure and temperature when the partial pressure of SO_2 is held constant.

Predominance diagrams, their thermodynamic calculation, and their extension to systems of several components have been discussed by Bale *et al.* (1986) and Bale (1990).

In Fig. 16 is shown a *chemical-potential–composition phase diagram* for the Fe-Cr-O system at 1300 °C. This is an isothermal plot of the equilibrium oxygen pressure vs the molar metal ratio, $n_{Cr}/(n_{Fe} + n_{Cr})$, where n_i = number of moles of *i*. The diagram consists of single-phase areas, two-phase regions with

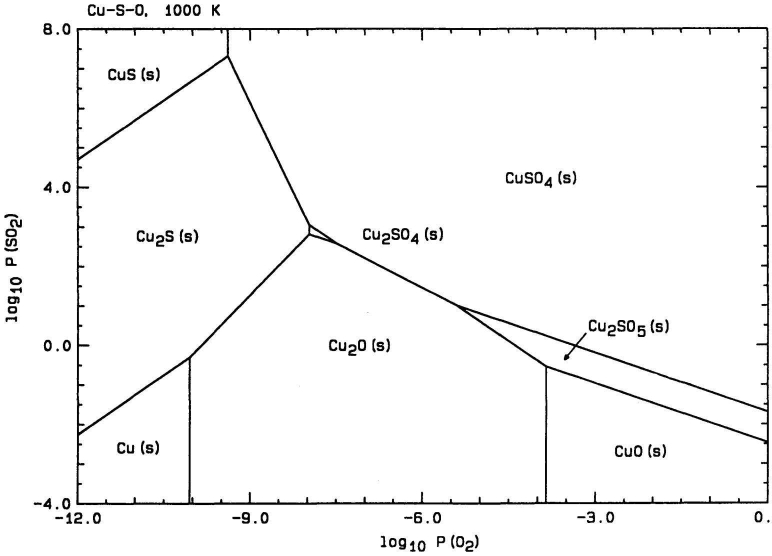

FIG. 14. Predominance diagram, $\log p_{SO_2}$ vs $\log p_{O_2}$ (atm) at 1000 K for the Cu-S-O system (Bale *et al.*, 1986).

horizontal tie-lines (to which the lever rule applies), and three-phase eutectic-type and peritectic-type invariants. That is, topologically the diagram obeys the same rules of construction as binary *T-X* or *P-X* diagrams.

Many other phase diagrams can be drawn which have the same topologies as either one-component *P-T* diagrams, binary *T-X* and *P-X* diagrams, or ternary isothermal sections. Such phase diagrams and their classification have been discussed by Pelton and Schmalzried (1973).

6. THERMODYNAMIC ORIGIN OF PHASE DIAGRAMS

In this section we briefly discuss the thermodynamic origin of phase diagrams. This subject is treated in more detail by Pelton (1991). A basic knowledge of solution thermodynamics is required for this section. The principles are covered in THERMODYNAMICS, EQUILIBRIUM and by Pelton (1991).

Every system is characterized by a Gibbs energy function. The equilibrium state of the system is the state with minimum Gibbs energy. The isobaric *T-X* phase diagram of the Ge-Si system is shown in the lowest panel of Fig. 17. In the upper three panels of Fig. 17 the molar Gibbs energies of the solid and liquid phases, g^s and g^l, at three temperatures are shown to scale. As illustrated in the top panel, g^s varies with composition between the standard molar Gibbs energies of pure solid Ge and pure solid Si, $g^{0(s)}_{\mathrm{Ge}}$ and $g^{0(s)}_{\mathrm{Si}}$, while g^l varies between the standard molar Gibbs energies of the pure liquid components, $g^{0(l)}_{\mathrm{Ge}}$ and $g^{0(l)}_{\mathrm{Si}}$.

The quantities Δg^s_m and Δg^l_m are the molar Gibbs energies of mixing of the solutions. Each of these is equal to an ideal mixing term, $RT(X_1 \ln X_1 + X_1 \ln X_2)$, plus an excess term, g^E:

$$\Delta g_m = RT(X_1 \ln X_1 + X_2 \ln X_2) + g^E, \tag{9}$$

where X_1 and X_2 are the component mole fractions. The ideal mixing term is negative and is calculated statistically from the entropy of a random distribution of Ge and Si atoms over the lattice positions (see STATISTICAL MECHANICS, CLASSICAL).

As shown in the top panel of Fig. 17, the difference between $g^{0(l)}_{\mathrm{Si}}$ and $g^{0(s)}_{\mathrm{Si}}$ is equal to the standard molar Gibbs energy of fusion (melting) of pure Si, $\Delta g^0_{f(\mathrm{Si})} = g^{0(l)}_{\mathrm{Si}} - g^{0(s)}_{\mathrm{Si}}$. Similarly for Ge, $\Delta g^0_{f(\mathrm{Ge})} = g^{0(l)}_{\mathrm{Ge}} - g^{0(s)}_{\mathrm{Ge}}$. The Gibbs energy of fusion of a pure component may be written as

$$\Delta g^0_f = \Delta h^0_f - T\Delta s^0_f, \tag{10}$$

where Δh^0_f and Δs^0_f are the standard molar enthalpy and entropy of fusion.

Since to a first approximation, Δh^0_f and Δs^0_f are independent of T, Δg^0_f is approximately a linear function of T. If $T > T^0_f$, then Δg^0_f is negative. If $T < T^0_f$, then Δg^0_f is positive. Hence, as seen in Fig. 17, as T decreases, the g^s curve descends relative to g^l. At 1500 °C, $g^l < g^s$ at all compositions. Therefore, by the principle that a system always seeks the state of minimum Gibbs energy at constant T and

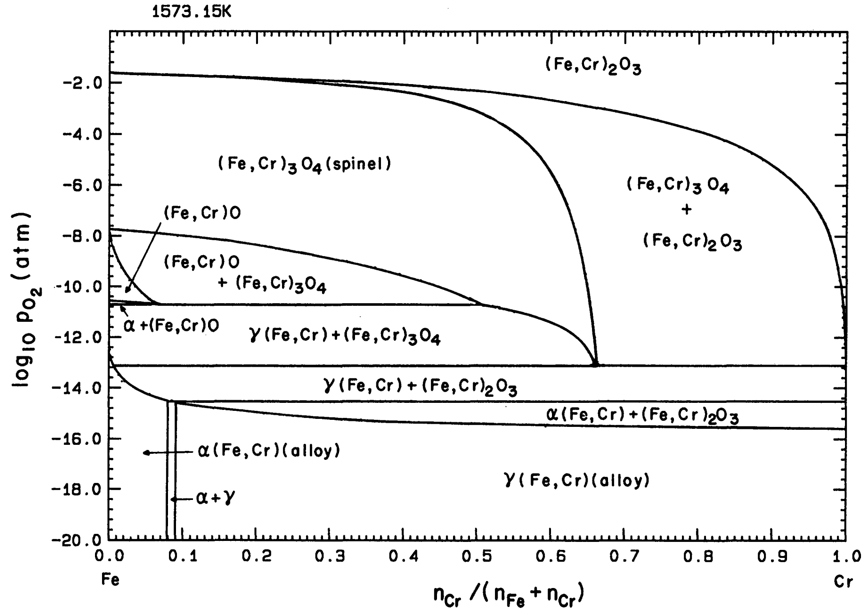

FIG. 16. Phase diagram of $\log p_{O_2}$ vs molar metal ratio for the Fe-Cr-O system at 1300 °C (Pelton and Schmalzried, 1973).

P, the liquid phase is stable at all compositions at 1500 °C.

At 1300 °C, the curves of g^s and g^l cross. The line P_1Q_1, which is the common tangent to the two curves, divides the composition range into three sections. For compositions between pure Ge and P_1, a single-phase liquid is the state of minimum Gibbs energy. For compositions between Q_1 and pure Si, a single-phase solid solution is the stable state. Between P_1 and Q_1, a total Gibbs energy lying on the tangent line P_1Q_1 may be realized if the system adopts a state consisting of two phases with compositions at P_1 and Q_1 and with relative proportions given by the lever rule. Since the tangent line P_1Q_1 lies below both g^s and g^l, this two-phase state is more stable than either phase alone. Furthermore, no other line joining any point on the g^l curve to any point on the g^s curve lies below the line P_1Q_1. Hence, this line represents the true equilibrium state of the system, and the compositions P_1 and Q_1 are the liquidus and solidus compositions at 1300 °C.

As T is decreased to 1100 °C, the points of common tangency are displaced to higher concentrations of Ge. For $T < 937$ °C, $g^s < g^l$ at all compositions. In this way, the lens-shaped Ge-Si phase diagram is generated.

If both Δg_m^l and Δg_m^s are ideal [i.e., if the g^E term in Eq. (9) is zero for both phases], then a lens-shaped two-phase region always results. However, in most systems, even approximate ideal behavior is the exception. Curves of g^s and g^l for a hypothetical system A-B are shown schematically in Fig. 18 at a constant temperature below the melting points of pure A and B such that the solid state is the stable state for both pure components. However, in this system $g^{E(l)} < g^{E(s)}$, so that g^s presents a flatter curve than does g^l and there exists a central composition region in which $g^l < g^s$. Hence, there are two common tangent lines, P_1Q_1 and P_2Q_2. Such a situation gives rise to a phase diagram with a minimum in the two-phase (solid + liquid) region similar to the diagram of Fig. 5.

Other forms of the Gibbs energy curves can give rise to phase diagrams with regions of immiscibility, eutectic-type and peritectic-type invariants, etc. The treatment can be extended to multicomponent systems.

6.1 Models of Solutions—Regular Solution Theory

The phase diagram of a system is determined by the thermodynamic properties of the phases which, in turn, depend upon their structure and bonding. To illustrate this re-

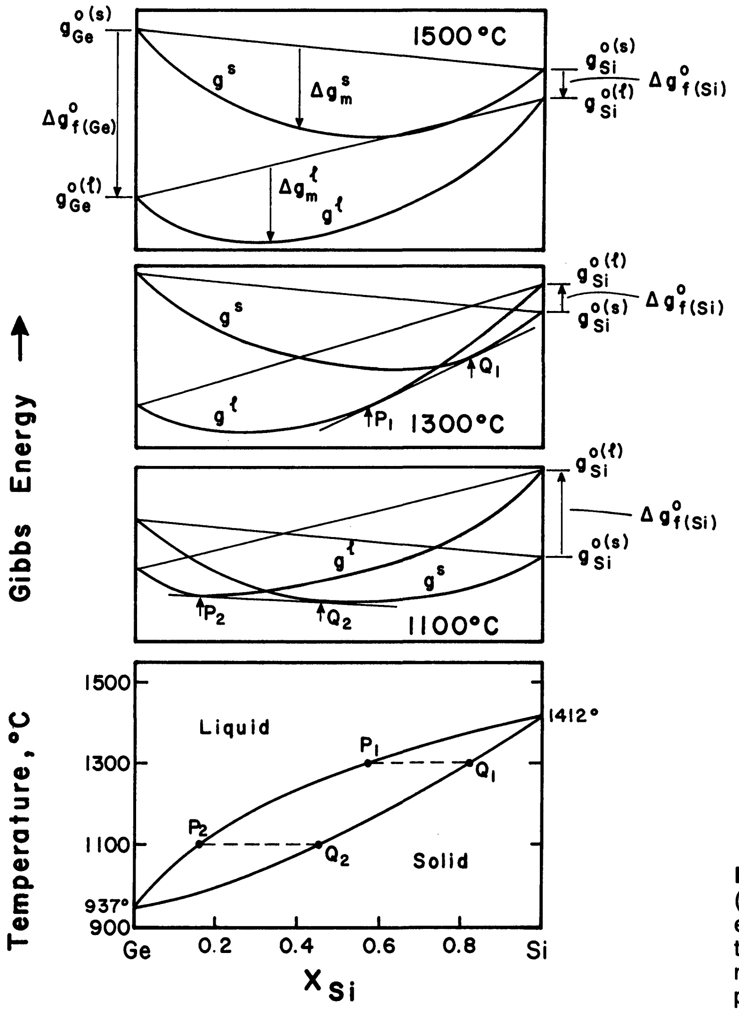

FIG. 17. The Ge-Si phase diagram (after Hansen, 1958) and Gibbs energy-composition curves at three temperatures illustrating the common tangent construction (reprinted from Pelton, 1983).

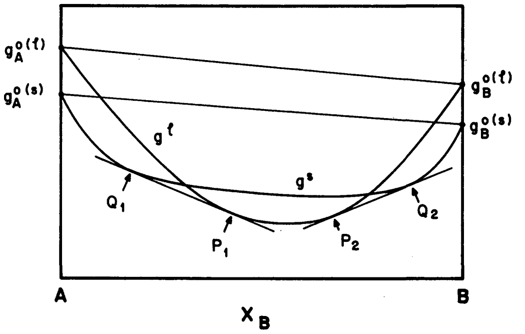

FIG. 18. Isothermal Gibbs energy- composition curves for solid and liquid phases in a system *A-B* in which $g^{E(l)} < g^{E(s)}$. A phase diagram with a minimum in the (solid + liquid) two-phase region results.

lationship, we shall briefly discuss a very simple solution model, that of a "regular" solution.

Consider a binary solution formed of atoms or molecules of the components *A* and *B* that mix substitutionally and nearly randomly. The entropy of mixing will then be nearly ideal and will give rise to the ideal mixing term in Eq. (9).

We now assume that the bond energies ϵ_{AA}, ϵ_{BB}, and ϵ_{AB} of nearest-neighbor pairs of atoms or molecules are independent of temperature and composition and that the average nearest-neighbor coordination number, *Z*, is also constant. Finally, we assume that the excess Gibbs energy of mixing, g^E, results mainly from the change in the total energy of nearest-neighbor pair bonds.

In one mole of solution there are $N^0Z/2$ nearest-neighbor pair bonds, where N^0 is Avogadro's number. Since the distribution is assumed to be random, the probability that a given bond is an A-A bond is equal to X_A^2. The probabilities of B-B and A-B bonds are, respectively, X_B^2 and $2X_AX_B$. The molar excess Gibbs energy of mixing is then equal to the sum of the energies of the nearest-neighbor bonds in one mole of solution, less the energy of the A-A bonds in X_A moles of pure A and the energy of the B-B bonds in X_B moles of pure B:

$$\begin{aligned} g^E &= (N^0Z/2)(X_A^2\epsilon_{AA} + X_B^2\epsilon_{BB} + 2X_AX_B\epsilon_{AB}) \\ &\quad - (N^0Z/2)(X_A\epsilon_{AA}) - (N^0Z/2)(X_B\epsilon_{BB}) \\ &= (N^0Z)[\epsilon_{AB} - (\epsilon_{AA} + \epsilon_{BB})/2]X_AX_B \\ &= \omega X_AX_B, \end{aligned} \tag{11}$$

where ω is a constant, and where the relation $X_A + X_B = 1$ has been used in the simplification of Eq. (11).

If A-B bonds are stronger than AA and BB bonds, then $\epsilon_{AB} < (\epsilon_{AA} + \epsilon_{BB})/2$ and $\omega < 0$, and $g^E < 0$. That is, the solution is rendered more stable. If the A-B bonds are relatively weak, then the solution is rendered less stable since $\omega > 0$ and $g^E > 0$.

In Fig. 19, several phase diagrams are shown, calculated for a hypothetical system A-B containing a solid and a liquid phase with melting points of $T^0_{f(A)} = 800$ K and $T^0_{f(B)} = 1200$ K and with entropies of fusion of both A and B set to 10 J/mol K, which is a typical value for metals. The solid and liquid phases are both regular, with temperature-independent excess Gibbs energies:

$$g^{E(s)} = \omega^s X_AX_B \quad \text{and} \quad g^{E(l)} = \omega^l X_AX_B.$$

The parameters ω^s and ω^l have been varied systematically to generate the various panels of Fig. 19.

In panel (n) both phases are ideal. Panels (l)–(r) exhibit minima or maxima depending upon the sign and magnitude of $g^{E(l)} - g^{E(s)}$. In panel (h) the liquid is ideal, but positive deviations in the solid give rise to a solid-solid miscibility gap. That is, A-B bonds are energetically so unfavorable that $g^{E(s)}$ becomes so positive that the solid solution splits into an A-rich phase and a B-rich phase.

On passing from panel (h) to panel (c), an increase in $g^{E(s)}$ results in a widening of the miscibility gap so that the solubility of A in solid B and of B in solid A decreases. Panels (a)–(c) illustrate that negative deviations in the liquid cause a relative stabilization of the liquid with resultant lowering of the eutectic temperature.

If the negative deviations in the liquid phase are sufficiently large, then the liquid solution will adopt a structure in which the number of A-B nearest-neighbor pairs in greater than the value $2X_AX_B$ for random mixing. Such *short-range ordering* is not predicted by the simple regular solution model, but can be taken into account by more sophisticated models such as the quasichemical model (Pelton and Blander, 1986).

6.2 Thermodynamic-Phase Diagram Optimization

In recent years, the development of solution models, numerical methods, and computer software has permitted a quantitative application of thermodynamics to phase-diagram analysis. For a great many systems it is now possible to perform a simultaneous critical evaluation of available phase-diagram measurements and of available thermodynamic data (calorimetric data, measurements of chemical activities, etc.) with a view to obtaining optimized equations for the Gibbs energies of each phase that best represent all the data.

The phase diagram can be calculated from these thermodynamic equations, and so one set of self-consistent equations can describe all the thermodynamic properties and the phase diagram. This technique of analysis greatly reduces the amount of experimental information needed to characterize a system fully. All data can be tested for internal consistency. The data can be interpolated and extrapolated more accurately, and metastable phase boundaries can be calculated. All the thermodynamic properties and the phase diagram can be represented and stored by means of a small set of coefficients. Finally and most importantly, it is often possible to estimate the thermodynamic properties and phase diagrams of ternary and higher-order systems from the assessed parameters for their binary subsystems. The *Calphad Journal* (Pergamon Press) is an in-

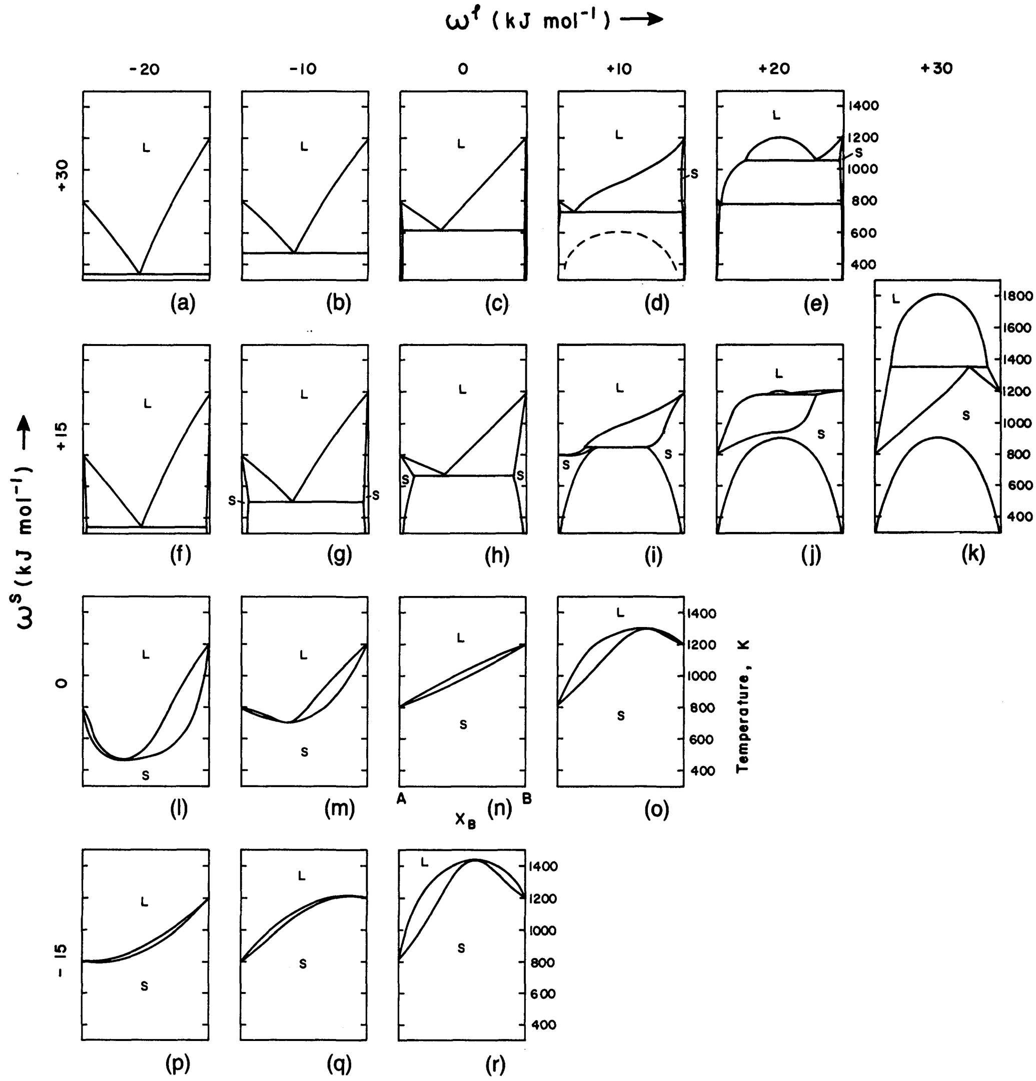

FIG. 19. Topological changes in the phase diagram for a system *A*-*B* with regular solid and liquid phases, brought about by systematic changes in the regular solution parameters ω^s and ω^l. Melting points of pure *A* and *B* are 800 and 1200 K. Entropies of fusion of both *A* and *B* are 10.0 J/mol K (Pelton and Thompson, 1975). Dotted curve in panel (d) is metastable liquid-liquid miscibility gap. (Reprinted from Pelton, 1983.)

ternational journal devoted to publishing this type of work.

7. GLASS FORMATION

In certain liquids, such as molten SiO_2, the nature of the chemical bonds is such that solidification to form an ordered crystal structure upon cooling the melt is a relatively slow process. Consequently, if such melts are cooled quickly, the disordered liquid structure will be frozen in, and the result at room temperature will be an *amorphous, glassy,* or *vitreous* phase, which can be considered to be a supercooled liquid. Glasses, being nonequilibrium phases, do not appear on equilibrium phase diagrams. Nevertheless, the equilibrium phase diagram is very useful in understanding the microstructure of materials with a glassy phase. For example, suppose that a CaO-SiO_2 melt of overall composition $X_{SiO_2} = 0.53$ (see Fig. 7) is annealed at 1500 °C and then quenched. The equilibrium phases at 1500 °C will be $CaSiO_3$ and liquid of composition $X_{SiO_2} = 0.57$ with the relative amounts given by the lever rule: (moles $CaSiO_3$)/(moles liquid) = (0.57 − 0.53)/(0.53 − 0.50) = 1.33. Upon rapid quenching, the entire liquid phase becomes a glass, and at room temperature we have (moles $CaSiO_3$)/(moles glass) = 1.33.

Most liquids, even metals, will form an amorphous phase if the quenching rate is sufficiently rapid. Generally, when a liquid is quenched to form a glass, the physical properties, such as viscosity, change from values typical of a liquid to values typical of a solid over a relatively narrow range of temperature about an average or *glass transition temperature* that depends upon the cooling rate. Glass formation is discussed in AMORPHOUS MATERIALS, STRUCTURE OF, and GLASSES.

8. ORDER-DISORDER TRANSITIONS

In solid solutions, long-range ordering can occur. For example, in the Ag-Mg system, a transformation occurs at approximately 392 °C at the composition Ag_3Mg from a low-temperature form with long-range ordering (superlattice formation) to a high-temperature form in which Ag and Mg are randomly distributed over the lattice sites. Unlike first-order phase transformations such as solidification, or the transformation between two different crystal structures, such *order-disorder transformation* can occur by atomic rearrangement over distances of the order of atomic dimensions.

A type of order-disorder transformation of importance in ferrous metallurgy is the magnetic transformation. Below its *Curie temperature* of 769 °C, Fe is ferromagnetic. Above this temperature it is not. The transformation involves a change in ordering of the atomic spins and is not first order. Additions of alloying elements will change the temperature of transformation as shown in Fig. 9.

For further discussion see ORDER-DISORDER TRANSITIONS and Pitsch and Inden (1991). Magnetic transformations are discussed by Miodownik (1982) and Inden (1982).

9. INTERFACIAL EFFECTS

In Sec. 6 it was shown that equilibrium between phases results from a minimization of the total Gibbs energy of the system. If a homogeneous solution is slowly cooled, a second phase will begin to precipitate at a temperature below which the formation of a second phase lowers the total Gibbs energy. In Sec. 6, however, it was assumed that the Gibbs energy associated with the formation of the interface between the phases is negligible. This is usually a good assumption unless the precipitating particles are very small. In the case of very small precipitates, however, the interfacial area is so large that the interfacial Gibbs energy cannot be ignored. An interface is a region in which the continuity of the structure and the bonding is interrupted. The Gibbs energy associated with the formation of an interface is thus positive. If the precipitates are very small, then, the precipitation temperature will be lowered below the value shown in the equilibrium phase diagram.

A further positive contribution to the Gibbs energy of forming a second phase arises if the interface is *coherent*, that is if there is a matching of the crystal structures across the interface. Since the lattice parameters of the two phases are not identical, such coherency gives rise to a positive strain energy which will also influence the phase equilibrium.

The existence of a strain energy in the region near the interface can result in concentration gradients in this region, since the formation of such gradients will partially decrease the strain energy. An applied stress on the sample can also affect the phase equilibria, as well as the kinetics of precipitation, because of interaction between the applied and coherency stress fields. For discussions of these topics, the reader is referred to Wagner and Kampmann (1991) and Purdy (1991).

GLOSSARY

Azeotrope: An extremum in a liquid + vapor two-phase region.

Binary System: A system of two components.

Bivariant: Having a variance of two.

Component: One of the chemical species required to define the composition of a system.

Congruent Melting: Melting to form a liquid of the same composition as the solid.

Conode: See **Tie-Line**.

Consolute Point: The summit of a miscibility gap. See also **Critical Point**.

Critical Point: A point on a phase diagram at which the properties of two phases become identical and a two-phase region ends.

Critical Pressure: The pressure at a critical point.

Critical Temperature: The temperature at a critical point.

Crystallization Path: The locus followed by the liquid composition during equilibrium cooling.

Equilibrium: A state of minimum free energy. A system at equilibrium is unchanging even over an infinite amount of time.

Eutectic Composition: The (constant) composition of the liquid during a eutectic reaction.

Eutectic Reaction: An invariant reaction during which, upon cooling, a liquid solidifies at constant temperature to give two solids (in a binary system), three solids (in a ternary system), etc.

Eutectic Temperature: The (constant) temperature at which a eutectic reaction occurs.

Eutectoid Reaction: An invariant reaction during which, upon cooling, a solid dissociates, at constant temperature, to two (or more) different solids.

Incongruent Melting: Melting (in a peritectic reaction) to form a liquid plus a solid of another composition.

Invariant: Having a variance of zero.

Isopleth: A constant-composition section through a multicomponent phase diagram.

Lever Rule: The rule by which the relative amounts of two phases existing at equilibrium can be calculated from a phase diagram.

Liquidus: The surface on a phase diagram giving the composition of the liquid phase in equilibrium with a solid phase.

Miscibility Gap: A region on a phase diagram in which two liquid phases (or two solid phases of the same crystal structure) are in equilibrium.

Mole Fraction: A composition variable. The mole fraction X_i of component i is equal to $n_i/\Sigma n_j$ where Σn_j is the sum over all the components.

Monotectic Reaction: An invariant reaction during which, upon cooling, a liquid reacts at constant temperature to give another liquid and one (or more) solids.

Nonstoichiometric Compound: A compound that exists as a single phase over a range of composition.

Peritectic Reaction: An invariant reaction during which, upon cooling, a liquid and one (or more) solids react, at constant temperature, to give one (or more) other solids. See also **Incongruent Melting**.

Phase: A region of a system of uniform physical and chemical properties.

Primary Solid: The first solid phase to crystallize upon equilibrium cooling of a single-phase liquid. Also called *pro-eutectic solid*.

Solidus: The surface on a phase diagram giving the composition of a solid phase in equilibrium with a liquid phase.

Solvus: The surface on a phase diagram giving the composition of a solid phase in equilibrium with another solid phase.

Space Model: The three-dimensional temperature-composition phase diagram of a ternary system.

Stoichiometric Compound: A compound of fixed composition.

Ternary System: A system of three components.

Tie-Line: A straight line on a phase diagram whose ends give the compositions of two phases at equilibrium. Also called *Conode*.

Tie-Triangle: A triangle on a phase diagram whose corners give the compositions of three phases at equilibrium.

Triple Point: At invariant point on a phase diagram at which three phases are at equilibrium.

Univariant: Having a variance of one.

Variance: The number of variables (temperature, pressure, compositions of the phases) which can and must be specified in order to completely specify the state of a system.

INTRODUCTION

Among the most fundamental notions about the physical world is the existence of matter in different phases. H_2O molecules, for example, can exist as either gas (water vapor), liquid (water), or crystals (ice, snow). The processes by which matter transforms from one phase to another are at the basis of numerous phenomena that either occur naturally or play a technologically important role. Of equal fundamental importance is the notion of phase coexistence (Stanley, 1971; Gunton *et al.*, 1983). The temperature of a block of ice rises as it is heated up until it reaches the melting temperature. Further addition of heat energy does not raise the temperature but is used to transform the ice crystal into water at constant temperature. Only after all the ice is melted does additional added heat raise the temperature further. The coexistence of water and ice is an example of phase coexistence for which numerous examples can be found in everyday life. In addition to the melting and freezing cycle, the evaporation and condensation cycle is commonly observed.

A further kind of phase coexistence can be found when the same chemical adopts different crystalline or amorphous structures, with sometimes very different properties. A well-known example is the element carbon, which can exist as amorphous carbon, diamond, graphite, or the recently discovered fullerenes. These different phases can coexist as evidenced by diamond crystals embedded naturally in carbon.

So far, only single-component systems have been considered, and their phase behavior is described in the first section below. If one considers two-component or multicomponent systems, the phase diagrams become rapidly more complex, and the possible combinations of coexisting phases grow rapidly in number. One example that is treated below is mixtures of two fluids. Crudely, fluid mixtures can be categorized as either miscible, like water and alcohol, or immiscible, like water and oil. There are well-known examples of binary fluids (say *A* and *B*), however, which at high temperatures are miscible and at low temperatures separate into two phases that coexist. One of the two phases is rich in fluid *A* and the other in fluid *B*. The above situation describes a system with an upper critical temperature, but many examples are known where the reverse occurs, i.e., at low temperatures a single phase exists and as the temperature is raised the physical system undergoes phase separation. This is described by a lower critical temperature. The phase separation can take place in a variety of binary mixtures ranging from liquids, polymers (de Gennes, 1979), and complex fluids (Safran and Clark, 1987) to glasses (Cahn and Charles, 1965) and metal alloys (Komura and Furukawa, 1988). In such sys-

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

tems, the phase-separation process can be induced by changing thermodynamic variables, such as temperature, pressure, or volume rapidly. How the phase-separation process occurs and how it might be controlled can affect the material properties considerably and be thus of great technological importance. Examples of phase diagrams of multicomponent systems are shown in Sec. 1.2.

A system that has been rapidly quenched from a one-phase equilibrium state to a point in the phase diagram where two phases coexist in a new equilibrium is at first in a state far from equilibrium. The processes by which the system evolves into its thermodynamic state of coexisting phases are called phase separation (Gibbs, 1948). The two main mechanisms are nucleation and growth, and spinodal decomposition. The path between the initial one-phase equilibrium and the final state of coexistence determines which one of these two mechanisms takes place. Under most circumstances, this path goes through a first-order phase-transition point, and nucleation and growth is observed. Such a phase transition is called first order or discontinuous, because even for an infinitesimally small change in parameter space, the two coexisting phases have a finite difference in composition. There are singular points in thermodynamic phase space, however, where a system can enter the two-phase region continuously, and if the final state is close enough to such a critical point the difference in composition between the two phases can become vanishingly small. Here the phase-separation process is called second order.

1. PHASE DIAGRAMS

1.1 One-Component Systems

The phases of a system with a single component can be described by an equation of state that relates thermodynamic variables, such as temperature, volume, and pressure. For a one-component system, three variables uniquely define all the possible phases. The equation of state defines a surface in the three-dimensional parameter space on which each point defines an equilibrium state. In Fig. 1, projections of the pressure/volume/temperature surface are shown schematically for what could be for instance a gas like argon. The projection onto the temperature–pressure plane has three well-known regions separated by lines. The region of the solid is separated from the liquid by the fusion curve and from the gas by the sublimation curve. These curves represent states where two or even three adjoining phases coexist.

Liquid and gas are separated by the vapor-pressure curve. This line terminates at a critical point, which is of great interest. In its

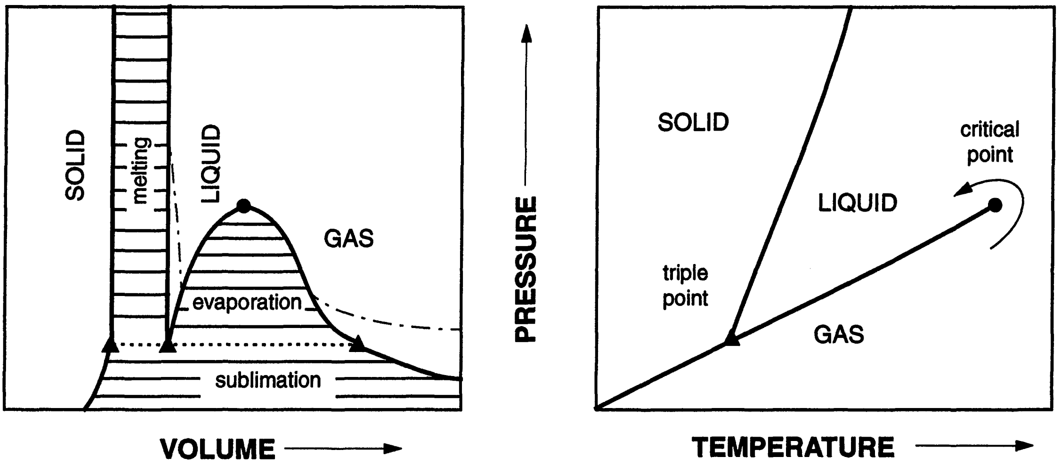

FIG. 1. Projections of the *PVT* surface of a one-component system that can exist in three different states, solid, liquid, and gas. The solid curves represent coexisting phases. The tricritical point is a point where all the phases coexist, and at the critical point two coexisting phases (gas and liquid) become identical.

vicinity, the gas and the liquid phases can be arbitrarily similar, and one can change the state of the system continuously from the gas to the liquid without crossing a phase-transition line, as indicated by the arrow. All the points on the various curves are first-order transition points. The phases coexisting on these lines are clearly distinguishable. The critical point is an exception. On approaching this point along the vapor-pressure curve, the gas and the liquid phases become less and less distinguishable and become ultimately identical. This point is also called a second-order phase-transition point. The search for a similar end point on the fusion curve has been in vain so far, and theoretical arguments have been made precluding its existence.

A further point of interest in this projection is the intersection of the three curves, which is a triple point. At this well-defined temperature and pressure, three phases of the substance coexist.

Another instructive projection is that onto the pressure/volume plane. Here the vapor-pressure curve (the gas-liquid coexistence curve) has the shape of a hump with the critical point at the top. As one reduces the volume of the system at constant temperature, the gas is compressed, and the pressure increases until the gas-liquid curve is reached, as indicated by the dashed-dotted line. Further volume reduction does not increase the pressure. Liquid droplets start to condense, and further reduction of the volume transforms more of the gas phase into the liquid phase. The horizontal lines under the coexistence curve are called tie-lines. After all the gas has been compressed to liquid, the pressure inside the liquid will increase rapidly until the coexistence between liquid and solid is reached.

The phase diagram in Fig. 1 is for illustrative purposes only. Real phase diagrams, even for one-component systems, can be much more complex. The phase diagram for helium has additional phases, such as the superfluid phase and associated with it a special point called λ point where the normal fluid, the superfluid, and the gas coexist. The phase diagram of water and ice is also of great complexity. For this single-component system, eight different crystalline structures and eight different triple points are known. Various ice phases can coexist with each other or with water. Interestingly, only one phase of liquid water is known.

The concepts described above for very familiar states of matter can be found in a multitude of dissimilar physical systems. Changing the temperature of certain materials can change them from being nonmagnetic to magnetic, conducting to superconducting, metallic to insulating. The same liquid-crystalline material can exist in a number of different structures depending on temperature.

1.2 Multicomponent Systems

An example of a two-component system is shown in Fig. 2. It is the schematic phase diagram of a mixture of a polymer and a liquid crystal (Doane *et al.*, 1986; Smith, 1993). At high temperatures, the two mix at all proportions. The pure liquid-crystalline material has a transition between an isotropic and a nematic state at a temperature T_{NI}. In the nematic phase, the liquid-crystalline molecules have orientational order but lack the translational order found in crystalline structures. At temperatures below T_{NI}, there

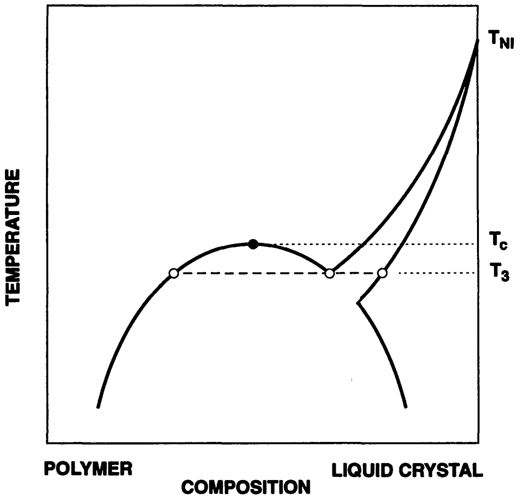

FIG. 2. Phase diagram for a mixture of a polymer and a liquid crystal in the temperature-composition space. T_{NI} is the nematic-to-isotropic transition temperature of the pure liquid-crystalline material. T_c is a critical point where the polymer-rich phase and the liquid-crystalline–rich phase become identical. T_3 is the temperature where three phases coexist, a polymer-rich phase and two liquid-crystalline–rich phases, one where the liquid crystal is isotropic and one where it is nematic.

are several regions of coexistence between two phases. Depending on composition and temperature, the two phases can be both isotropic or one can be isotropic and the other nematic. At one particular temperature T_3, three phases coexist. One is rich in polymer, and the two others are rich in liquid crystal. In the two latter phases, the liquid-crystalline material is in the isotropic or nematic phase, respectively. In addition, this phase diagram shows a critical point at T_c.

Figure 2 displays only a portion of the full phase diagram. At very high temperatures, there is a vapor phase, and at low temperatures the polymer can crystallize and the liquid crystal can assume a number of different structures with increasing degree of crystalline order. In addition, pressure and volume have to be considered as possible degrees of freedom for a full description in this case.

1.3 Thermodynamic Principles

Phase diagrams are based on thermodynamic principles and describe the conditions under which various phases of matter can coexist. The processes by which matter changes from a single-phase to a two-phase state upon sudden changes of parameters are called phase separation.

Of particular interest for the description of two fundamentally different mechanisms by which phase separation can occur are two-component fluid systems. These systems have been studied extensively and lend themselves readily for comparison between experiment and theory. The free energy of a mixture of two fluids, *A* and *B*, consists in its simplest form of two terms, an entropic term that favors disorder or mixing of the molecules *A* and *B*, and an enthalpic term that favors the proximity of similar molecules. The expression for the free energy of a mixture of two polymers has been provided by Flory and Huggins (Flory, 1953):

$$F = \frac{\phi \ln(\phi)}{N_A} + \frac{(1 - \phi)\ln(1 - \phi)}{N_B} + \chi\phi(1 - \phi), \tag{1}$$

where ϕ is the volume fraction of polymer *A* and $1 - \phi$ the volume fraction of polymer *B*. The terms N_A and N_B are the polymerization indices or number of monomers in chains *A* and *B*, and χ is the Flory interaction parameter. It has the following temperature dependence:

$$\chi(T) = a/T + b. \tag{2}$$

The free energy is plotted schematically in Fig. 3 as a function of composition for two different temperatures corresponding to two different values of χ. At temperatures above a certain critical temperature T_c, the free energy has a single minimum and the two components *A* and *B* mix at all compositions. Separating mixture 1 into two mixtures at slightly higher and lower concentrations would increase the total free energy, and the two phases could achieve a state of lower energy by remixing. This is the case for the upper curve in Fig. 3. An example of this is a mixture of water and ethanol at room temperature, for instance. As one lowers the temperature of the *A*/*B* mixture below T_c, however, the free energy has two minima and the state of the mixture depends on its global composition. Three thermodynamically different regions can be distinguished. The phase behavior of the mixture depends on the sign

FIG. 3. Free energy as a function of composition for a two-component mixture. The upper curve is a high-temperature single phase, whereas the lower curve is at low temperatures where two phases coexist. Three regions (stable, unstable, and metastable) as well as various hypothetical samples (1–6) and their stability behavior are described in the text.

of the second derivative of the free energy. Very dilute mixtures, indicated by 2 and 3, behave like the high-temperature mixtures described above. They are miscible and form a single stable phase. Mixtures with compositions in the unstable region, where the second derivative of the free energy is negative, spontaneously separate into two coexisting phases. A mixture prepared at these compositions, as indicated by 4 in Fig. 3, can have a lower global free energy by forming domains of different compositions. One of the phases is rich in component A and the other in component B. Between the unstable and the stable regions is a metastable region. Here the second derivative of the free energy is positive and small separations in composition do not lower the overall free energy, as shown for mixture 5. Formation of a domain on the other side of the maximum in the free-energy curve, however, leads to a globally lower free energy. This is shown schematically for mixture 6. This region of the phase diagram is thus metastable. It takes a triggering event such as nucleation to induce phase separation.

The transition from a single-minimum free-energy curve to one with two minima is common to phase transitions. Even though such free-energy curves help us to understand the cause of the phase transition, they are not very convenient if one is interested in the phase behavior of a given system. A complete description of the temperature dependence would require many of these curves. The important points are the inflection points, defined by the condition

$$\frac{\partial^2 F}{\partial \phi^2} = 0, \tag{3}$$

and the points separating the metastable from the stable compositions, given by

$$\left.\frac{\partial F}{\partial \phi}\right|_{\phi_1} = \left.\frac{\partial F}{\partial \phi}\right|_{\phi_2}. \tag{4}$$

A plot of these points as a function of temperature is shown in Fig. 4. It is important to note that both Figs. 3 and 4 are for model systems, with symmetry about the 50% composition line. For most real systems, the curves are asymmetric, with the maximum coexistence temperature occurring at a composition different from 50%. In Fig. 4, the three regions in the temperature-composition diagram are clearly visible. They are separated by two lines, the coexistence curve, also called binodal curve, and the spinodal curve, or stability limit. Crossing these lines induces phase separation in a sample that was originally in a single-phase state at high temperatures. The process by which the separation occurs is fundamentally different depending on whether the quench point in the temperature/composition is in the metastable region (nucleation and growth) or the unstable region (spinodal decomposition). The volumes of the coexisting phases will not necessarily be identical. An illustration of this is given in Fig. 5. Here three samples were prepared at compositions corresponding to points 1, 2, and 3 in Fig. 4. In the one-phase region, $T > T_c$, no meniscus is observed within the sample. After a quench into the unstable region (sample 1) or the metastable region (samples 2 and 3), phase separation starts. Immediately after the mixtures are quenched, they are in a highly dispersed, nonequilibrium state that has a milky appearance (Fig. 5, sample 1, $T < T_c$, immediately after quench). Under the influence of gravity, the coexisting phases are allowed to settle. In sample 1, the A-rich and B-rich phases occupy equal volumes whereas for the off-critical samples the minority phases occupy a smaller volume. The three samples in Fig. 5 have reached their new equilibrium. Both processes are explained in detail in Secs. 2 and 3. Samples at different compositions will separate into phases with compositions at the same coexistence-curve values, if quenched to the same temperature.

2. NUCLEATION AND METASTABLE STATES

A system quenched into the region between the coexistence curve and the spinodal curve is thermodynamically metastable. For short enough times, it will not demix, but remain as a one-phase system. Very small fluctuations in concentration, such as those due to thermal activity, will decay as if the mixture were in thermodynamic equilibrium. In such a supersaturated mixture, a nucleation process is needed to initiate formation of a region having a composition of the coexisting minority phase. This nucleation process can

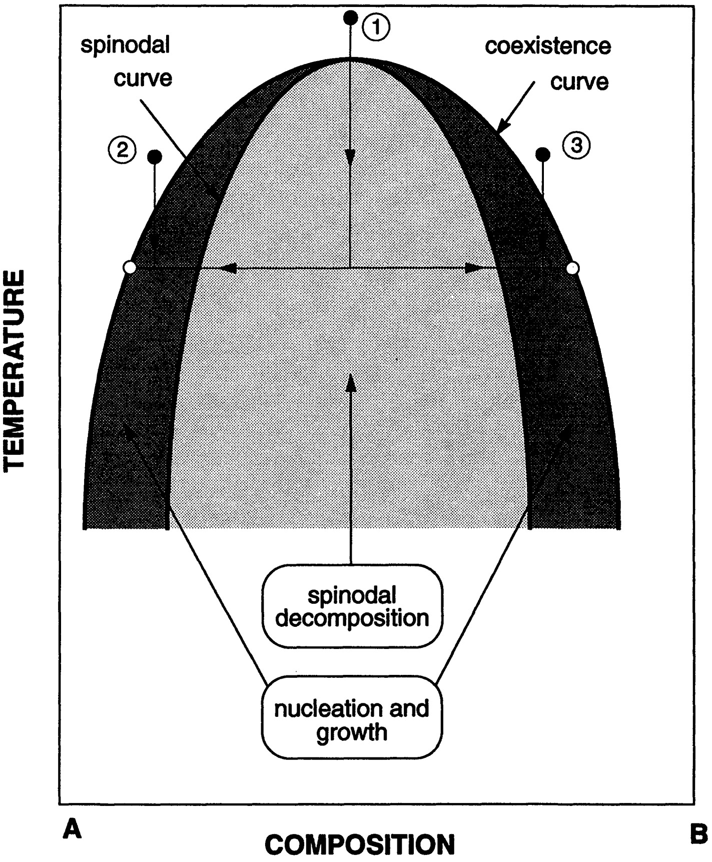

FIG. 4. Coexistence and spinodal curves for a two-component mixture in the temperature-composition space. The phase-separation process of sample 1 is called spinodal decomposition, whereas samples 2 and 3 undergo nucleation and growth.

be either heterogeneous or homogeneous. A heterogeneous process is induced by a third component, such as a contaminant or dirt in the bulk mixture, or a surface. This third component can locally decrease the free energy required for molecules of the minority phase to aggregate and create a domain of composition different from that of the initial mixture. During homogeneous nucleation, thermal fluctuations alone can cause the minority phase to nucleate without the presence of a third component. Far away from the spinodal curve, heterogeneous nucleation will dominate, whereas in the vicinity of the spinodal, the system is close enough to being thermodynamically unstable that thermal fluctuations can cause nucleation.

Once a droplet of the minority phase has been formed, it can evolve in two different ways. It can either grow by accreting more material from its supersaturated environment, or it can shrink and redissolve. The radius of the nucleated droplet determines which route it is likely to take.

Gibbs (1948) was among the first to recognize that a balance of competing effects leads to a critical droplet radius. Deep quenches or large supersaturation of the mixture favor the growth of a droplet. The deeper the quench, the more energy that can be gained by growth of the minority phase. Surface tension (interfacial free energy) is comparatively more costly for small droplets and opposes their existence. For every value of the supersaturation, there is a critical radius R_c. Droplets with a radius greater than R_c grow, and those with a smaller radius shrink. The critical radius depends on temperature, composition, and time elapsed since the system was quenched (see below).

Figure 6 shows a series of photomicrographs of quenched lead (Pb) and tin (Sn) mixtures (Hardy and Voorhees, 1988). The Sn-rich domains were held at 185 °C for varying periods of time. As time elapsed, the average particle size increased and the number of particles decreased, i.e., particle coarsening occurs.

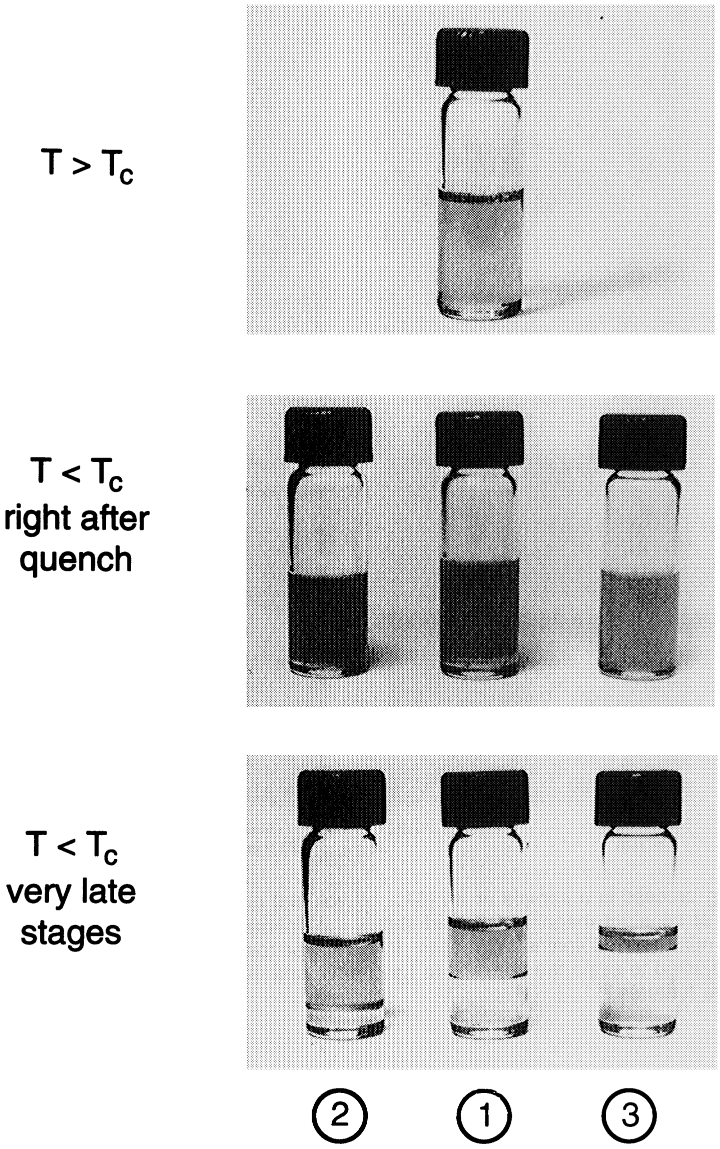

FIG. 5. Mixtures of two liquids at various compositions and temperatures. The mixture in the top vial is at a temperature above the critical temperature T_c and is in a single phase. Samples 1, 2, and 3 are prepared at compositions corresponding to the samples schematically depicted in Fig. 4. Immediately after being quenched to a lower temperature corresponding to a point in the two-phase region of the phase diagram, all three samples have a cloudy appearance. Many small domains of the two phases coexist, and with time these domains coalesce and coarsen. Finally, after the heavier phase has settled under gravity a meniscus appears separating the two coexisting phases. Note that for sample 1 the meniscus is in the middle (equal volumes of the two coexisting phases), whereas in samples 2 and 3 the volumes are unequal. These mixtures correspond to fluid *A* in Fig. 4 having a lower density than fluid *B*.

2.1 Free Growth

Droplets in a supersaturated environment are depicted schematically in Fig. 7. Here the *B* material is the minority component. Immediately after having been nucleated, each droplet is surrounded by the same composition ϕ_0, which is related to the supersaturation Δ by

$$\Delta = (\phi_0 - \phi_A)/(\phi_B - \phi_A). \tag{5}$$

As long as the degree of supersaturation does not change, there will be a concentration gradient, called the depletion layer, favoring diffusion of material to droplet, where it accumulates. This leads to growth of the droplets (first and second frames in Fig. 7). At the same time as the droplets grow, their depletion layers also grow since the total amount of materials *A* and *B* must be conserved. If the depletion layers of individual droplets do not overlap, so-called free growth is observed, with no interactions between droplets. Under these conditions, the radius of any droplet that has been nucleated with a radius greater than R_c will grow asymp-

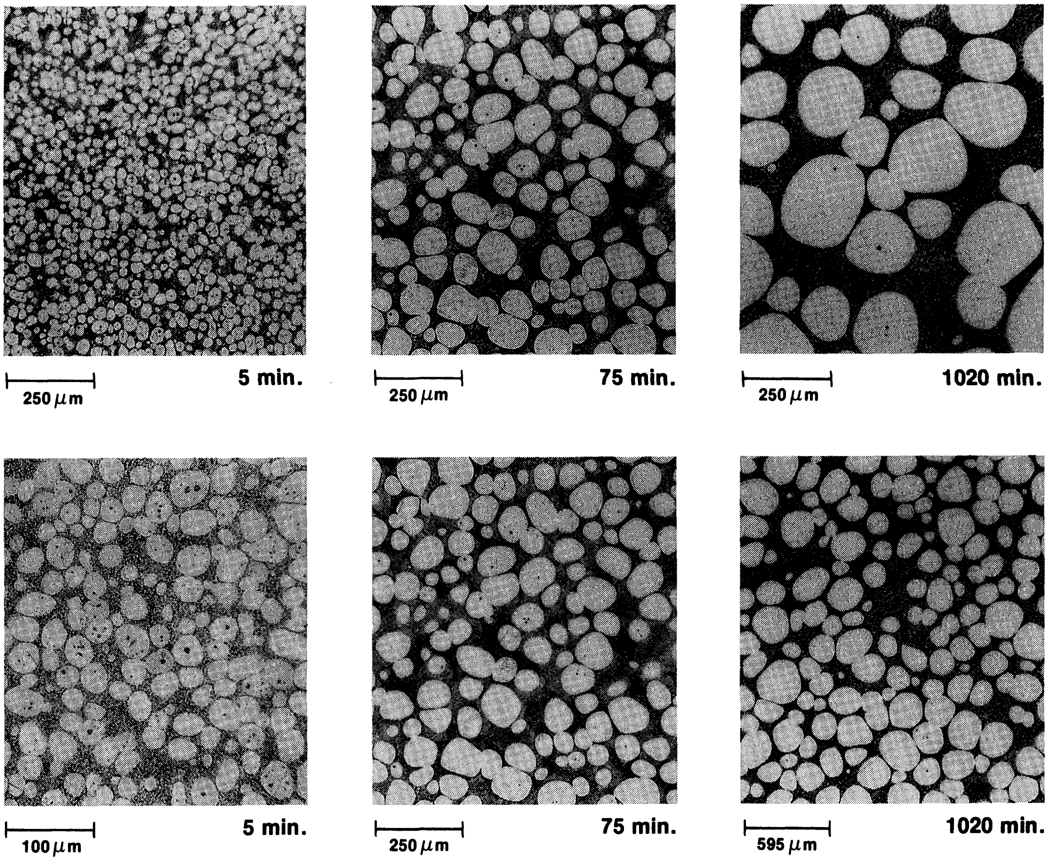

FIG. 6. Micrographs of the coarsening process in a sample of Sn (64% by volume) and Pb over a 17-h period at 185°C. The top row of pictures is at constant magnification and shows the coarsening process, where the average domain size grows and the number of domains decreases. In the lower row, the same micrographs are shown but with a magnification adjusted to scale the domains to have the same average size. Interestingly, the pictures show the same qualitative features.

totically as the square root of time. An example of this is shown in Fig. 8. Here the radii of droplets nucleated in a mixture of two polymers are shown as a function of time. The mixture had been quenched from a temperature in the one-phase region to five different temperatures in the metastable region, and the sizes of the droplets were measured by light scattering. The temperature differences ΔT cited are the depths below the coexistence curve. All the quenches were into the metastable region, since the spinodal curve lies about 1.2° below the coexistence curve for the composition used in the experiment. The radii are given in units of the critical radius, and the time is also in dimensionless units. Note that even though the raw data do not fall on a single curve, this scaled representation of the data supports the idea that a generalized dimensionless description of the growth phenomenon can be found. The slope of the experimental data is in agreement with the above-mentioned square-root growth law.

2.2 The Lifshitz–Slyozov–Ostwald Evaporation–Condensation Mechanism

The free-growth regime lasts only as long as the growing droplets are surrounded by a constant supersaturation layer. As more and more material diffuses through the depletion layers and accretes onto the droplets, the size of the depletion layers grows (see Fig. 7). Eventually, the depletion layers of neighboring droplets overlap, and competition for material from the supersaturated medium sets in, leading to a decrease of the level of supersaturation (third panel of Fig. 7). This, in turn, increases the droplet critical radius R_c. Small droplets stop growing and can even become subcritical in size, leading to their evaporation as indicated for droplet 1 in Fig. 7. This process is called the evaporation–condensation mechanism. This leads to the late-stage regime of coarsening shown in the fourth panel of Fig. 7, where the supersaturation has vanished. Diffusion due to concentration gradients ceases, but processes reducing the surface free energy can lead to further changes in the droplet size distribution. In one such mechanism, diffusion of droplets and their collisions allows them to coalesce, thus reducing the total surface free energy. Coarsening processes that lead to reduction of the interfacial area are also known as Ostwald ripening.

An important feature during all phases of coarsening is that diffusion is normal, i.e., in the direction of a concentration gradient. This is fundamentally different from the case for spinodal decomposition, which is discussed in Sec. 3.

Interestingly, the late-stage coarsening laws do not depend on whether the coarsening occurs via evaporation, diffusion, and condensation of material molecule by molecule (as might happen in a metal alloy) or by global diffusion and collision of macroscopic droplets (as can happen in fluids). A significant

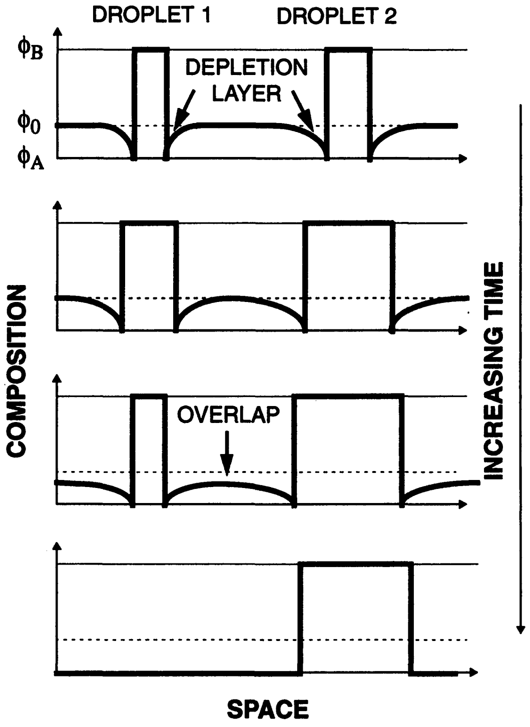

FIG. 7. Growth of droplets as a function of time in a supersaturated medium in the nucleation and growth regime. The average composition of the sample is ϕ_0, and the compositions of the coexisting phases are ϕ_A and ϕ_B, respectively. Droplet 2 is growing as a function of time, whereas droplet 1 is first growing and then shrinking.

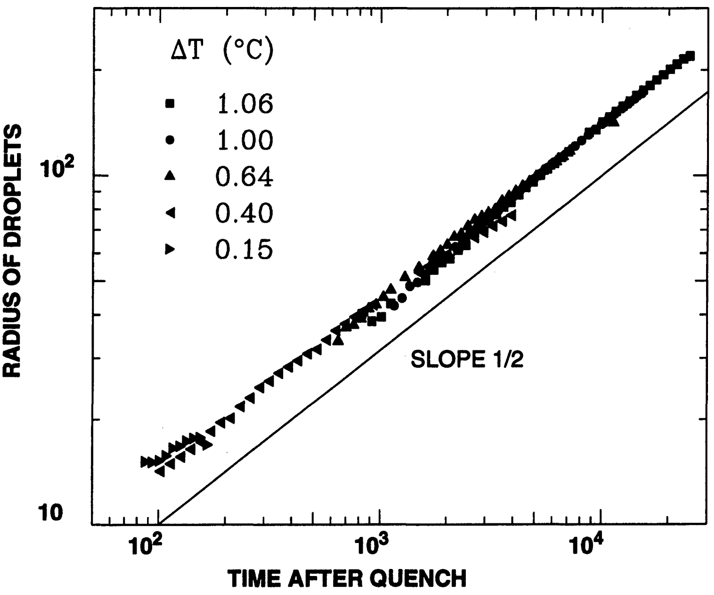

FIG. 8. The average radius of droplets of the minority phase in a phase-separating polymer mixture as a function of time for several quench depths in the metastable region of the phase diagram. A line of slope $\frac{1}{2}$ is shown for comparison.

theoretical body based both on analytical work and on numerical simulations predicts that such a system asymptotically evolves toward a polydisperse distribution of droplets. The breadth of the distribution is about 50%, and the average droplet size grows as the $\frac{1}{3}$ power of time. A full pictorial description of the various phases of the coarsening in the metastable region is shown in Fig. 9 [for details see Cumming *et al.* (1992)]. Here the evolution of the radii of individual droplets that have been "nucleated" at early times has been calculated using the differential equation proposed by Lifshitz and Slyozov (1961):

$$\frac{dR}{dt} = \frac{D}{R}\left[\Delta - \frac{\alpha}{R}\right]. \tag{6}$$

Here D is a diffusion coefficient, and α is the thickness of the interface between the droplet and the surrounding medium. Note that the absence of new droplets after time $t = 6$ is arbitrarily assumed. This case might describe a situation in which droplets are nucleated around nucleation centers of a third material (heterogeneous nucleation). Four regimes are observed. The nucleation process is assumed to be heterogeneous, since no new droplets are nucleated after a reduced time of 6. Only droplets with a radius greater than R_c (assumed to be unity here) are nucleated. After nucleation, the droplets grow as the square root of time during the free-growth regime. An interesting phenomenon is observed in this regime. An originally polydisperse distribution of droplets becomes more monodisperse. This monodispersity disappears, however, after the transition regime to the late-stage Lifshitz–Slyozov–Ostwald coarsening. The duration of the free-growth regime depends on the degree of the original supersaturation. Free growth lasts longer for deep quenches.

During the last phase, the smallest droplets become subcritical and evaporate rapidly, returning material to the majority phase, which is the source of growth of the largest droplets. This ongoing process keeps the size distribution quite broad.

2.3 Advanced Issues

The theoretical framework evoked above has been known to fail to predict correctly the quantitative features of particle size distributions. Figure 10 (Marder, 1987) shows a compilation of a number of experimentally obtained particle size distributions. It is found that the distributions are broader than the distribution predicted by Lifshitz and Slyozov (dashed line).

This failure has been attributed to the neglect of spatial distributions and interactions of the droplets that can play an important role

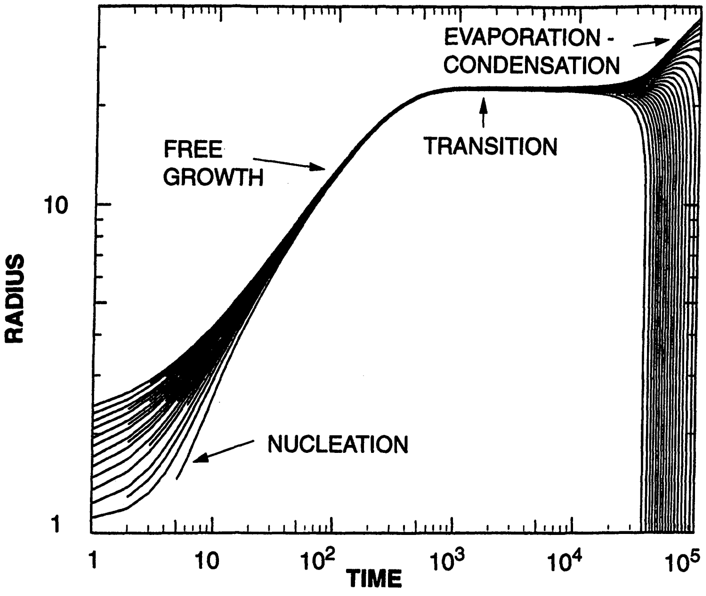

FIG. 9. Model curves obtained from numerical integration of a differential equation [Eq. (6)] proposed by Lifshitz and Slyozov. The various stages of the phase-separation process are shown. The nucleation process was halted artificially after times $t = 6$, which mimics a fast heterogeneous nucleation process at early times. During the free-growth period, the slope of the curves approaches $\frac{1}{2}$, whereas at late times an asymptotic slope of $\frac{1}{3}$ is found.

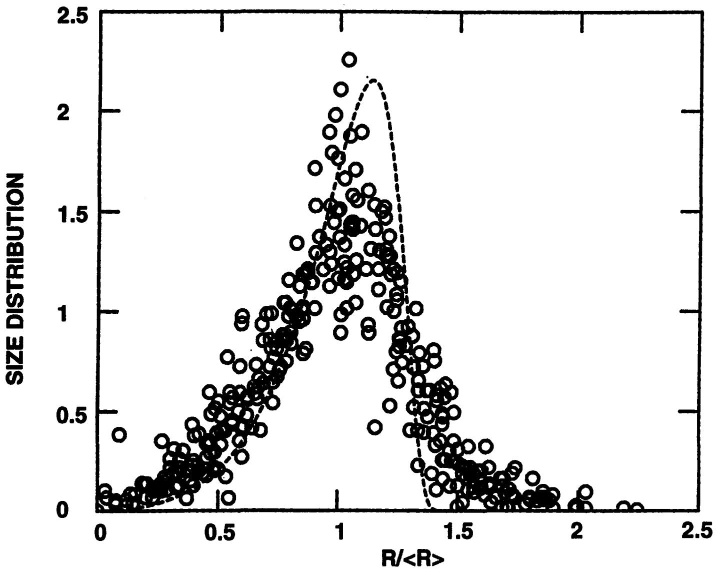

FIG. 10. Experimentally observed size distributions in a variety of phase-separating systems. For comparison, the distribution predicted by Lifshitz and Slyozov for the late-stage evaporation–condensation regime in Fig. 9 is shown (dashed line). [Adapted from Marder (1987).]

during the coarsening mechanism (Voorhees and Glicksman, 1984; Voorhees, 1992). The simplified theory predicts that all particles of a given size grow at the same rate, since only the global, mean supersaturation counts. This mean-field picture may be a good approximation for dilute systems, but in denser systems it is clear that a particle of a given radius will have a different evaporation rate depending on whether it is next to a large or a small sphere. These effects of spatial distributions around given particles are difficult to treat in analytical theories. They are currently investigated by means of large-scale numerical simulations.

3. SPINODAL DECOMPOSITION AND UNSTABLE STATES

Spinodal decomposition is the phase-separation process that occurs when a binary system is quenched from the one-phase region into the thermodynamically unstable two-phase region (see Fig. 4). A convenient way of observing this experimentally is to prepare a mixture at the critical composition where the spinodal curve and the coexistence curve coincide. For off-critical quenches, any trajectory at constant composition from the one-phase region into the two-phase region is always through a region of metastability, where the above-described nucleation and growth mechanisms can occur. In an off-critical quench, phase separation could begin locally, leading to composition inhomogeneities before spinodal decomposition begins.

Thermodynamic considerations dictate that a mixture of molecules A and B that is quenched rapidly into the unstable region separates into two different phases with compositions prescribed by the coexistence curve. Since the interfacial energy between these two phases should tend toward minimal value, the ultimate equilibrium state of a phase-separated fluid mixture in a test tube will have the denser phase at the bottom and the lighter phase on top of it with a meniscus separating the two. The scenario by which this final state is reached can be divided into at least three stages, as shown in Fig. 11. During the early, linear-stage regime, composition fluctuations with long enough wavelength will be amplified spontaneously. During this phase, the wavelength of the fluctuations, $L_m(0)$, is time independent, as explained below. During a second, or intermediate, regime, both the amplitude and the wavelength of the composition fluctuations grow. Finally, domains form with constant compositions given by the coexistence-curve values, ϕ_A and ϕ_B. Thermodynamically, the mixture is at its equilibrium point. Interfacial tension, however, drives further coarsening during the late-stage regime. These three regimes are discussed below in detail.

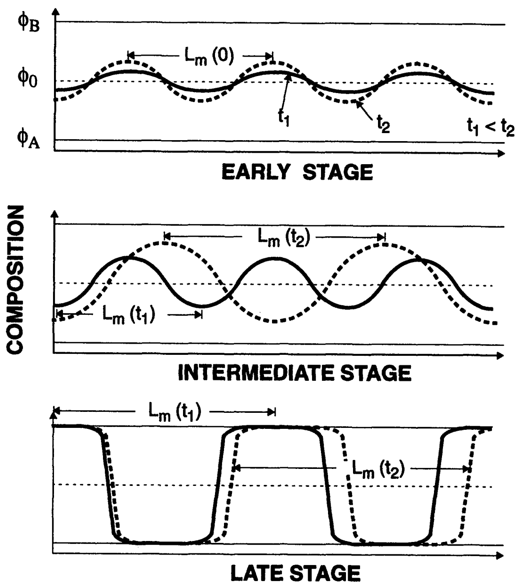

FIG. 11. Schematic description of the various stages of spinodal decomposition. $L_m(0)$ is the maximally unstable wavelength of a composition fluctuation.

The morphologies observed during the two phase-separation processes (nucleation and growth and spinodal decomposition) are quite different. Figure 12 shows photomicrographs of two different polymer mixtures undergoing phase separation. One of them (b) is prepared at an off-critical composition and has been quenched into the metastable nucleation and growth region of the phase diagram. The other (a) is at the critical composition, and it undergoes phase separation in the unstable, spinodal decomposition regime. The droplet morphology in the nucleation and growth region is obvious. Since in this case the sample was thick compared with the focal depth of the microscope, only the spheres close to the focal plane appear bright with a sharp interface. Droplets above or below the focal plane are out of focus and appear gray.

A spinodally decomposing sample (a) appears very different. This micrograph was taken during the intermediate stages where boundaries are not yet defined and only concentration gradients are present. There are

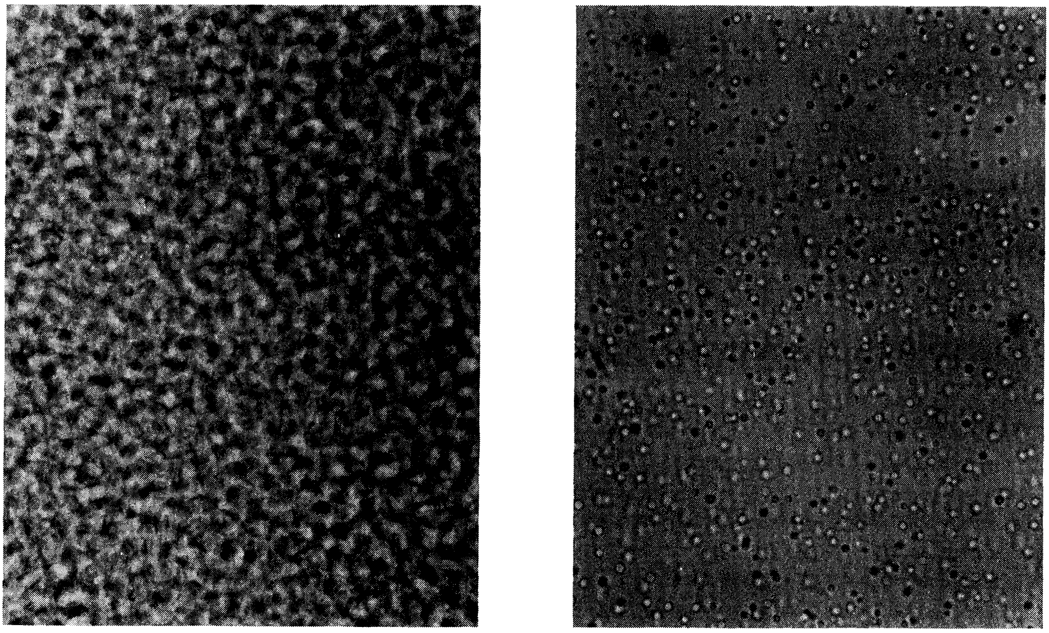

FIG. 12. Photomicrographs of two different polymer mixtures undergoing phase separation. The mixture shown in (a) was prepared at the critical composition and undergoes spinodal decomposition. The mixture shown in (b) was prepared at an off-critical composition and was quenched into the metastable region. Droplets of the minority phase nucleate and grow as a function of time.

no sharp interfaces to focus on, which explains the blurry image. More importantly, a characteristic length scale is apparent. This is even more evident in a Fourier transform, which has a ring pattern, indicative of a dominant length scale in the system. This dominant length is directly related to the maximally unstable wavelength q_m described below.

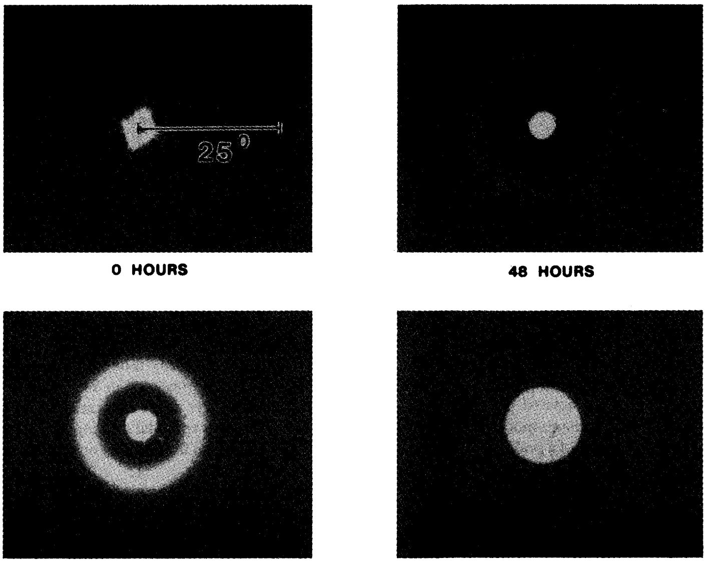
Since optical images of spinodally decomposing systems are not very easy to interpret, experimental work is typically done using light-scattering techniques (Goldburg, 1983; Hashimoto, 1988; Bates and Wiltzius, 1989; Cumming *et al.*, 1992). Figure 13 shows the time evolution of light scattered by a polymer blend undergoing phase separation. At time = 0, the sample is quenched from the one-phase region into the two-phase region. The 1-mm-thick sample is perfectly clear and does not scatter any light. The central spot is due to the laser beam directly passing through the sample without scattering. After 2 days, a ring of scattered light becomes visible. This ring is caused by fluctuations in the index of refraction (i.e., fluctuations in the concentration in the sample as schematically shown in Fig. 11). The most dominant fluctuations are those with a wavelength $L = \lambda/[2n \sin(\theta/2)]$. Here λ is the wavelength of the light, n is the index of refraction of the material, and θ is the scattering angle of the intensity maximum. As can be seen in Fig. 13, the ring becomes smaller and brighter in intensity as a function of time. This behavior reflects both an increase in the amplitude of the concentration fluctuations and a coarsening of the domains.

3.1 The Early Regime

Immediately after a quench, the thermodynamically favored state of a mixture is phase separation into two coexisting phases. This must occur, however, by transport of molecules A and B to the appropriate regions in space. From a thermodynamic point of view, a very finely divided arrangement of coexisting domains is the same as two macroscopic domains next to each other. The former arrangement of domains, however, has a huge interfacial area separating the two phases and a large energy cost associated with it. John Cahn (Cahn and Hilliard, 1958; Cahn, 1965), in seminal contributions, formalized these concepts and combined the thermodynamic free energy [Eq. (1)] with an interfacial energy into a functional form,

$$\frac{\Delta F}{k_B T} = \int \left(\frac{\phi \ln(\phi)}{N_A} + \frac{(1-\phi)\ln(1-\phi)}{N_B} + \chi(T)\phi(1-\phi) + r_p^2[\nabla\phi]^2 \right) dr, \qquad (7)$$

where r_p is the range of interactions in the



0 HOURS 48 HOURS

80 HOURS 240 HOURS

system and for polymer blends is of the size of the polymer chains. The phase separation in fluid system has to obey both a continuity equation,

$$\frac{\partial \phi}{\partial t} + \nabla J = 0, \tag{8}$$

for the mass flux density J, and a transport equation,

$$J = -D\nabla \mu, \tag{9}$$

relating J to the chemical potential μ via a mass diffusion coefficient D. Combining Eqs. (7)–(9) in reciprocal q space leads to the fundamental differential equation describing the phase-separation process in the unstable region,

$$\frac{\partial}{\partial t} \phi(q,t) = -Dq^2 \mu(q,t). \tag{10}$$

Unfortunately, this equation is highly nonlinear and analytically not soluble. Cahn's insight led him to develop a linear stability analysis of the differential equation. Rewriting the composition as

$$\phi(r,t) = \phi_0 + \delta\phi(r,t) \tag{11}$$

with $\delta\phi(r,t) \ll \phi_0$ and keeping only terms linear in $\delta\phi$, one finds a simpler differential equations for small fluctuations in composition:

$$\frac{\partial}{\partial t} \delta\phi = R(q)\delta\phi, \tag{12}$$

which has the solution

$$\delta\phi(q) = e^{R(q)t}. \tag{13}$$

The amplification factor $R(q)$ in the exponential has the following form:

$$R(q) = -Dq^2\left\{\frac{\partial^2 F}{\partial \phi^2} + 2q^2 r_p^2\right\}. \tag{14}$$

In the one-phase region (see Fig. 3), the second derivative of the free energy is always positive, and thus $R(q) < 0$ for all values of q. This means that spontaneous composition fluctuations of arbitrary wavelength decay exponentially, in agreement with our intuitive understanding of a system in thermodynamic equilibrium. In the two-phase region, however, $\partial^2 F/\partial\phi^2$ is negative for mixtures with compositions in the unstable region. For small enough values of q, the right-hand side of Eq. (14) is thus positive, leading to exponential growth of spontaneous fluctuations of those wavelengths as described by Eq. (13). Concentration fluctuations with a wavelength longer than a critical wavelength are unstable and grow as a function of time. Very short-wavelength fluctuations cannot grow, because they are too costly in terms of gradient or interfacial energy. Very long-wavelength fluctuations grow very slowly, because mass has to be transported over long distances. This makes it intuitively clear that there is an intermediate wavelength that grows at a maximal speed, the maximally unstable wavelength $L_m = 2\pi/q_m$. This wavelength depends on materials parameters and on the quench depth. For polymer blends, it can be expressed as follows (Binder, 1983; de Gennes, 1979):

$$q_m^2(t = 0) = \frac{3}{2R_G^2}\left(\frac{\chi - \chi_c}{\chi_c}\right), \tag{15}$$

where R_G is the radius of gyration, or size, of the polymer chains and χ_c is the value of the Flory parameter χ at the critical temperature. During the early stages, where the linear analysis applies, L_m is also independent of time. Part of this scenario is schematically depicted in the first panel of Fig. 11. One spontaneous spatial composition fluctuation with wavelength $L_m(0)$ grows as a function of time. Fluctuations with longer wavelength would also grow as a function of time, albeit more slowly, whereas very short-wavelength fluctuations would decay the same way as they would in the one-phase–equilibrium region of the phase diagram.

It is important to realize that this process is happening by "uphill" diffusion, i.e., against the concentration gradient. Uphill diffusion is the behavior opposite to "downhill" diffusion (in the direction of the concentration gradient as shown in Fig. 7).

Early stages of spinodal decomposition are difficult to observe experimentally. The composition fluctuations are small, and thus the scattering of light is weak. The early stages also evolve very rapidly, leaving little time to study them carefully. Nevertheless, a great deal of work has gone into extrapolating experimental data back to early times. This makes it possible to determine the typical unstable length scale soon after a sample has been quenched. The quench depth dependence of the measured length scales is found to be in good agreement with theoretical predictions. Qualitatively, it is found that the deeper the quench the shorter the unstable wavelengths. In addition to characteristic length scales, such an analysis also yields a quench-depth–dependent diffusion coefficient associated with the speed at which the composition fluctuations grow. The diffusion coefficients, which are formally negative quantities since the diffusion of material is against the concentration gradient, are quantitatively not understood.

3.2 The Intermediate Regime

As can be seen in Fig. 13, the maximally unstable wavelength and thus the characteristic domain size grow as a function of time. Typical data for fluid mixtures are shown in Fig. 14. The inverse of the domain size obtained from light scattering and direct visualization techniques is plotted as a function of time in reduced units. The units used in the scaling procedure are the natural time, $[Dq_m^2(t = 0)]^{-1}$, and length, $q_m^{-1}(t = 0)$, of the early-stage linear analysis. For the experiments shown in this figure, the scaling procedure is appropriate and yields a universal representation of the data. In experiments on spinodally decomposing polymer blends, systematic deviations from such universality have been found (Kedrowski *et al.*, 1993). For the reasons described above, data at very early stages, where the wave vector q_m is independent of time, are not available.

A complete theoretical understanding is still not available. This is a complicated nonlinear problem that poses a serious challenge to analytical work. The solid curve through the data in Fig. 14 is based on an empirical formula given by Furukawa (Komura and Furukawa, 1988). A number of numerical simulations have been performed on two- and three-dimensional models of these systems, and typical results are shown in Fig. 15 (Bortz *et al.*, 1974; Huse, 1986; Amar *et al.*, 1988). These are extensive Monte-Carlo simulations of domain growth in the two-dimensional spin-exchange model of a system of spins that can point either up or down. Such a system has a high-temperature phase where the spins are disordered and a low-temperature phase where they want to be organized in domains. In this particular model, the total number of up and down spins is conserved. The lattice of spins is shown at three different times, and the coarsening of the domains is apparent. The average domain size in this simulation grows as the $\frac{1}{3}$ power of time, which interestingly is the same exponent as that predicted for the disconnected dilute droplets observed in the Lifshitz–Slyozov model. The same power-law

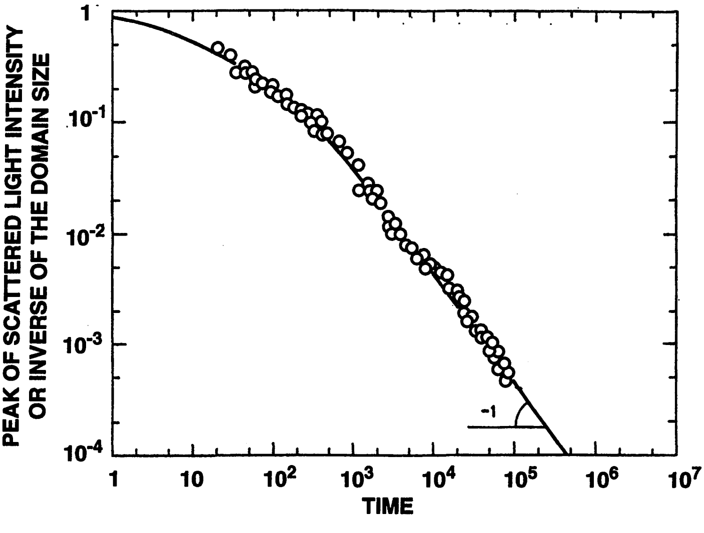

FIG. 14. The inverse domain size is plotted as a function of time for a variety of different liquid mixtures quenched to several temperatures in the unstable region. Both the domain sizes and the time have been scaled with appropriate scale factors. The asymptotic linear growth as a function of time is predicted for a growth of bicontinuous phases, where the growth mechanism happens via hydrodynamic flow. [Adapted from Beysens *et al.* (1988).]

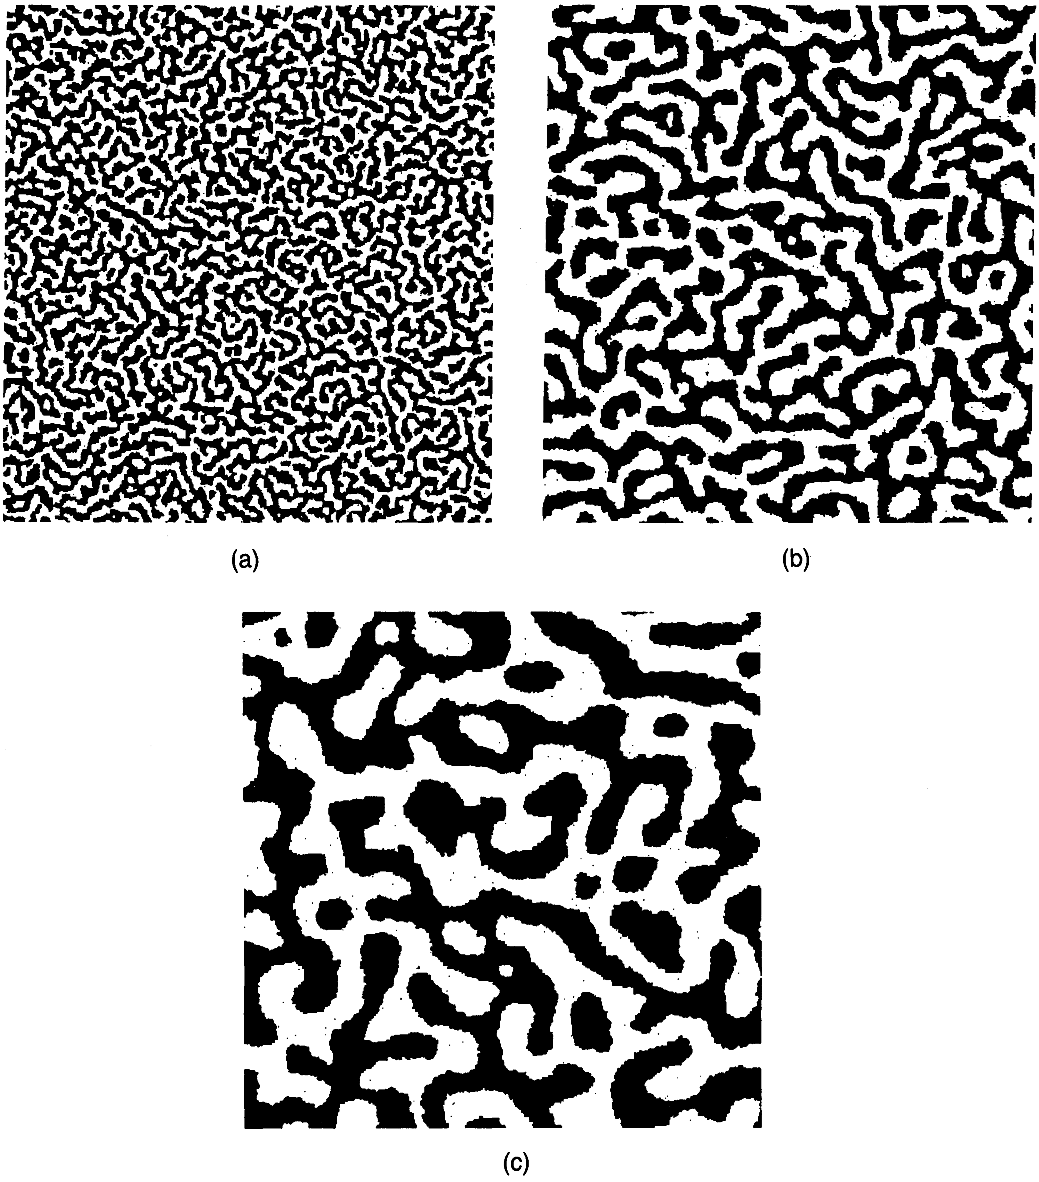

(a) (b)

(c)

FIG. 15. Numerical computer simulations of a two-dimensional spin-exchange model displaying the qualitative features of phase separation in physical systems. Here a given site can be occupied by either a spin up (white) or a spin down (black). The total number of up and down spins is conserved. Parts (a)–(c) are at increasing times. [From Amar *et al.* (1988).]

behavior has also been observed in three-dimensional simulations. This growth law has proven remarkably universal and independent of details of the models.

3.3 The Late-Stage Regime

Once the composition within the phase-separated domains has reached the values given by the coexisting curves (see Fig. 11), the only driving force is reduction of the interfacial energy. Some of the mechanisms described above lead to the $\frac{1}{3}$-power law behavior of the growth. As can be seen in Fig. 14 (Beysens *et al.*, 1987), however, in fluid mixtures at late stages a linear growth law (slope of -1) of domain size as a function of time is observed. In a very insightful paper, Siggia (1979) described the basic physical mechanism leading to this growth law. It hinges on the fact that in phase-separating mixtures with both phases topologically fully connected, fluid flow can occur throughout these bicontinuous phases. Analysis of the underlying hydrodynamic equations leads to the prediction for the linear growth law.

It has been shown experimentally and in simulations that during the late stages of domain coarsening the structures are self similar. That is, properly rescaled, the three panels in Fig. 15 have the same global properties. It is impossible to tell which are at earlier times and which at later. The self similarity is evidenced by structure factors or pair-correlation functions, which have a generalized form that depends only on a scaled spatial variable. In Fig. 16(a), several

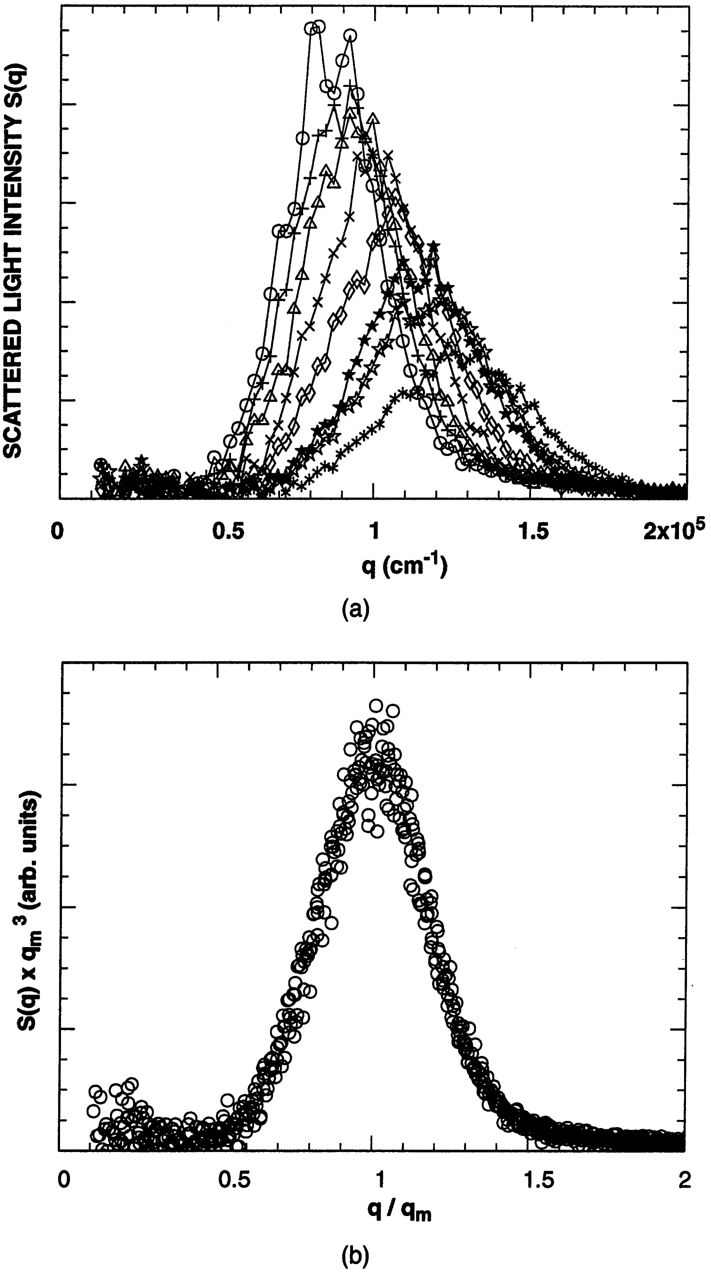

FIG. 16. (a) Light-scattering data for a polymer mixture undergoing spinodal decomposition for various times after the mixture has been quenched into the unstable region. The peak intensity is seen to increase with time (the earliest time is indicated by stars and the latest time by open circles) while its position decreases to smaller wave numbers. This indicates growth of spatial and compositional amplitude fluctuations. (b) The same data rescaled in a way appropriate to demonstrate self similarity of the time-dependent phase-separating structures. [Adapted from Kedrowski *et al.* (1993).]

such structure factors of phase-separating polymer blends are shown in their unscaled form. These are obtained from light-scattering measurements on samples similar to those shown in Fig. 13. In Fig. 16(b), the same structure factors are shown in a rescaled form. Superposition of the structure factors is in agreement with the concept of self similarity, which has been formalized by Furukawa in a scaling hypothesis.

4. CONCLUSIONS

Phase-separation phenomena can be broadly classified into two different categories depending on whether the processes occur in the thermodynamically unstable or metastable region of the phase diagram. Our insight both in nucleation and growth and in spinodal decomposition is based on work spanning well over a hundred years. Although the experimental and theoretical understanding is quite good, there are a number of issues that are not resolved. These include the quantitative understanding of nucleation barriers, the kinetics of phase separation, and finite-volume effects during late-stage coarsening. Most of the interest in the topic of phase separation has been driven by the challenging theoretical and experimental problems. There are some applications worth mentioning. Polymer-dispersed liquid crystals (PDLC) mentioned in Sec. 1.2 (Doane *et al.*, 1986; Smith, 1993) have emerged recently as switchable windows and even as candidates for flat-panel displays. PDLCs are made through a phase-separation process that results in a dispersion of micron-size droplets of liquid crystal trapped in a polymer matrix. An electric field can align the nematic textures inside the droplets, resulting in large changes in their scattering properties. It is possible to switch the optical appearance of a PDLC from transparent to milky white with reasonably small electric fields. The electro-optic properties of PDLCs depend largely on the morphology of the droplets formed during the phase-separation process. Predicting and controlling these morphologies is thus of great interest. In other applications, it can be desirable to tailor, e.g., the mechanical properties of a polymer blend by mixing various materials. Unfortunately, this results quite often in macroscopic phase separation of the components without the desired effect. A better understanding of the phase behavior and the separation processes could lead to better control.

GLOSSARY

Coarsening: Growth process of the minority-phase droplets during the nucleation and growth phase-separation process.

Coexistence Curve: Line separating the thermodynamically stable one-phase region of the phase diagram from the metastable two-phase region. Also known as binodal curve.

Critical Composition: Composition of a two-component mixture equal to the composition where the coexistence curve and the spinodal curve touch.

Critical Radius: Droplets of the minority phase smaller than the critical radius shrink and ultimately vanish from a phase-separating mixture. These droplets are also called subcritical.

Critical Temperature: Phase-separation temperature of a mixture prepared at the critical composition.

Depletion Layer: Region of lower concentration surrounding a droplet of the minority phase.

Liquid Crystal: Material with properties intermediate between those of liquids and crystals. Many different liquid-crystalline structures can be distinguished according to their degree of translational and/or orientational order.

Majority Phase: The phase in a two-component phase-separating mixture that occupies more volume than the minority phase.

Minority Phase: The phase in a two-component phase-separating mixture that occupies less volume than the majority phase.

Nucleation: Creation of a domain of the minority phase in a system undergoing phase separation in the metastable region of the phase diagram. The nucleation process can be heterogeneous, if it is induced by a third component, or homogeneous, if it is due to thermal fluctuations.

Self Similarity: Property of a system that changes, e.g., with time, but has qualitatively the same features if the dimensions are rescaled appropriately.

Spinodal Curve: Line separating the thermodynamically metastable two-phase region from the thermodynamically unstable two-phase region of the phase diagram.

Spinodal Decomposition: Phase-separation process in the unstable region of the phase diagram.

Supersaturation: Measure of the quench depth below the coexistence curve. See Eq. (5).

INTRODUCTION

The fundamental laws of nature governing the properties of matter possess distinguished symmetry properties: They are invariant with respect to translation in space and time, to rotations, and to inversions. The states of matter that we observe, however, usually do not display the full symmetries of the underlying basic principles. Rather, the atoms or molecules of a specific substance can be found in certain condensed phases consisting of enormously large numbers (typically 10^{23} cm^{-3}) of constituents, and these phases may be classified according to some specific symmetry transformation under which the system remains invariant (a subgroup of the original symmetry group; see Group Theory). In passing, we note that even the "fundamental" laws themselves, like the electroweak interaction and quantum chromodynamics, may have originated in the transition to a broken-symmetry state of an even more fundamental and more symmetric basic law. In this article, we shall be solely concerned with matter governed by the Schrödinger equation and electromagnetic forces.

The macroscopic properties of the phases of condensed matter, whose stability regimes are determined by the internal interactions of the particles involved, as well as by the

external conditions (temperature, pressure, electric and magnetic fields, etc.), can be very different. Upon a change of the external control parameters, the system may undergo a phase transition to a new macroscopic phase, thus lowering its total free energy (see THERMODYNAMICS, EQUILIBRIUM). Frequently, the internal energy of the system as a function of the control variables is minimized by the change of its thermodynamic phase, but there are also important cases where the driving force toward a new equilibrium state is a gain of entropy.

The stability of a particular phase and the implications of phase transitions are of course of prominent importance for applications and technology. Moreover, these issues provide a considerable intellectual challenge for their understanding in the framework of statistical mechanics (see STATISTICAL MECHANICS, CLASSICAL; STATISTICAL MECHANICS, QUANTUM). Accordingly, methods need to be developed in order to deal with a strongly interacting system containing a large number of particles, and near its stability boundary.

Fortunately, it is not necessary to study all the microscopic degrees of freedom in detail; instead it suffices to investigate the statistical mechanics of a few macroscopic entities (which, however, usually still poses a formidable task), namely the order parameter characterizing the specific phase transition and distinguishing the phases involved and its correlation functions, as well as the dependence on the external fields serving as control parameters (see CATASTROPHE THEORY).

Furthermore, near a critical point in the phase diagram the fluctuations of the order parameter become increasingly strong and long-range correlations emerge in the system, although the interactions of the particles are genuinely short ranged. Therefore, any approximate approach that neglects these fluctuations entirely, or merely treats them in some perturbative manner, is at least questionable.

On the other hand, because of the almost entirely collective behavior in the vicinity of a critical point, the microscopic details of the system become irrelevant there, and its long-wavelength (and low-frequency) properties tend to display *universality* (*q.v.*), i.e., in some asymptotic regime they depend solely on the symmetry and number of components of the order parameter, on the space dimension, and possibly on the long-range nature of the interactions. Historically, this emergence of universal behavior has provided one of the essential keys for a mathematical description and profound theoretical understanding of critical phenomena, in the framework of *renormalization-group* (RG) theory. In turn, the RG approach has laid a solid foundation for the striking phenomena of scale invariance and universality near second-order phase transitions.

Originally, RG concepts were developed in the context of elementary-particle quantum field theory. Within the theory of phase transitions and critical phenomena, scaling ideas had been developed before, but their sound justification was only provided when Wilson formulated a version of the RG approach designed to focus on the underlying structure of the nonlinear field theories involved, a procedure that also allowed for systematic and detailed calculations (Wilson and Kogut, 1974; Wilson, 1975). This considerable breakthrough has not only led to an enormous increase of the amount of knowledge and to a deeper understanding of the properties of condensed matter (see, e.g., Chaikin and Lubensky, 1995), but has in turn also provided important insights for the formulation and treatment of quantum field theories, from where it had originated (see UNIFIED FIELD THEORIES). For a thorough account of the historical development of the field, see CRITICAL PHENOMENA.

Remarkably, RG techniques, along with the ensuing notions of fixed points governing universal physical properties, relevant and irrelevant perturbations, the emphasis on the long-wavelength and low-frequency collective behavior, and the emergence of scaling laws have matured into a most important paradigm and tool well beyond the original realm of second-order phase transitions, and have found fruitful applications in a large variety of different fields of intensive current research (see Sec. 4).

1. PHASE TRANSITIONS

1.1 Phenomenology and Basic Concepts

At a phase transition, the free energy F (or some other appropriate thermodynamic potential; see STATISTICAL MECHANICS, CLASSI-

CAL) is a nonanalytic function of a control parameter. According to a standard classification scheme introduced by Ehrenfest, a phase transition is called of *n*th order if at least one of the *n*th derivatives of F is discontinuous or singular at the transition, while all the $(n - 1)$th derivatives are still continuous. In order to distinguish the different phases, a macroscopic *order parameter* ϕ is introduced, which is zero in one phase and finite in the other. If ϕ is given by the first derivative of the thermodynamic potential with respect to its conjugate external field h, its value will jump at a first-order transition; at a second-order transition, ϕ is to be a continuous function, but its derivatives will be singular or discontinuous.

To be specific, one may refer to a ferromagnetic material undergoing a second-order phase transition from the paramagnetic to the ferromagnetic phase at the critical (Curie) temperature T_c. The basic microscopic entities are the magnetic moments $\phi(\mathbf{x})$ at site $\mathbf{x}$, also called local order parameter (in this article, $\mathbf{x}$ denotes a d-dimensional vector referring to a point either in a discrete lattice or in a continuum). The macroscopic order parameter (the spontaneous magnetization) is then given by the thermal average $\phi = \langle\phi(\mathbf{x})\rangle$. In anisotropic crystals, the local order parameter may assume just the two values $\phi(\mathbf{x}) = \pm 1$ (referring to spin up and down, respectively). Accordingly, the (average) order parameter may point up or down. Whichever of the equivalent directions is chosen, the original discrete symmetry is spontaneously broken for $T < T_c$ [see Fig. 1(a)]. In cubic crystals, the order parameter may be a three-dimensional vector $\boldsymbol{\phi}(\mathbf{x})$, and point in an arbitrary direction. In this case, in the ordered phase a continuous (rotational) symmetry is broken.

The singularities in the vicinity of such continuous phase transitions generally assume the form of power laws, with certain *critical exponents* characterizing the transition. In case the temperature T serves as control parameter, with a second-order phase transition occurring at the critical temperature T_c, the most important examples of such power laws, and associated exponents, are the behavior of the order parameter near the critical point T_c [$\tau = (T - T_c)/T_c \ll 1$] [see Fig. 1(a)],

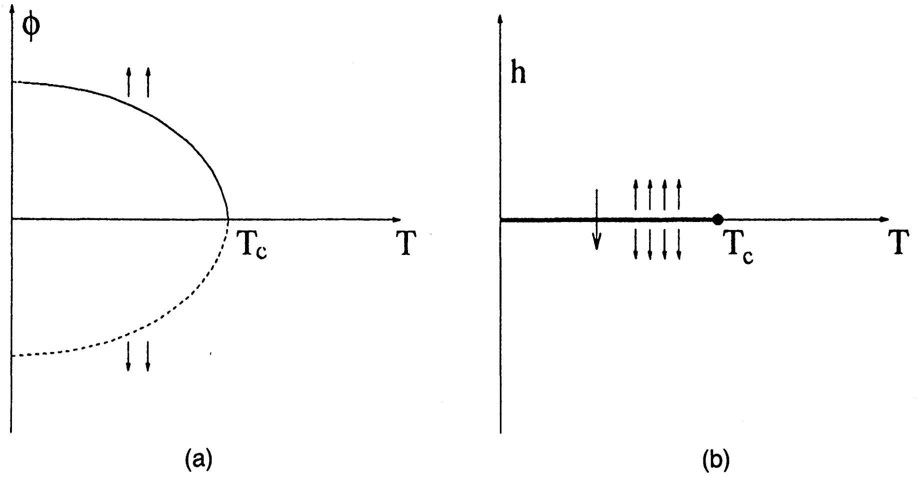
$$\phi \propto (-\tau)^{\beta} \quad \text{for } T < T_c, \tag{1}$$

the divergence of the isothermal susceptibility on approaching the critical point (from both sides of the transition),

$$\chi = \left(\frac{\partial \phi}{\partial h}\right)_T \propto |\tau|^{-\gamma}, \tag{2}$$

the power law for the critical isotherm,

$$h \propto \phi^{\delta} \quad \text{for } T = T_c, \tag{3}$$



(a) (b)

FIG. 1. (a) The order parameter ϕ of a ferromagnet for zero external field $h = 0$, as a function of the temperature T. ϕ sets in continuously at T_c and has at least two equivalent orientations. (b) Phase diagram (external field h vs temperature T) of a ferromagnet.

and the specific-heat singularity in the vicinity of T_c,

$$C_{h=0} \propto |\tau|^{-\alpha}. \tag{4}$$

Equation (2) leads to a most remarkable behavior of the order-parameter *correlation function,* defined as second cumulant (again, the brackets $\langle \ldots \rangle$ denote the thermal average)

$$G(\mathbf{x} - \mathbf{x}') = \langle \phi(\mathbf{x})\phi(\mathbf{x}') \rangle - \langle \phi \rangle^2 \tag{5}$$

(here translational symmetry has been assumed); namely from the fluctuation-response theorem in d dimensions,

$$\chi = \frac{1}{k_B T} \int d^d x G(\mathbf{x}), \tag{6}$$

it becomes apparent that a diverging susceptibility implies correlations of infinite range. This feature can be described by two additional critical exponents η and ν, for the power-law behavior of the correlation function precisely at the critical point,

$$G(\mathbf{x}) \propto \frac{1}{|\mathbf{x}|^{d-2+\eta}} \quad \text{for } T = T_c, \tag{7}$$

and the temperature dependence of the *correlation length* (measuring the spatial extent of the correlations) in the vicinity of T_c,

$$\xi \propto |\tau|^{-\nu}, \tag{8}$$

respectively. The growth of correlated regions upon approaching the critical point is illustrated in Fig. 2, where the spin-up/down configurations are plotted for a two-dimensional Ising model at different temperatures.

It turns out that for temperatures in the vicinity of T_c, the so-called *asymptotic region,* Eq. (7) may be generalized to the scaling form

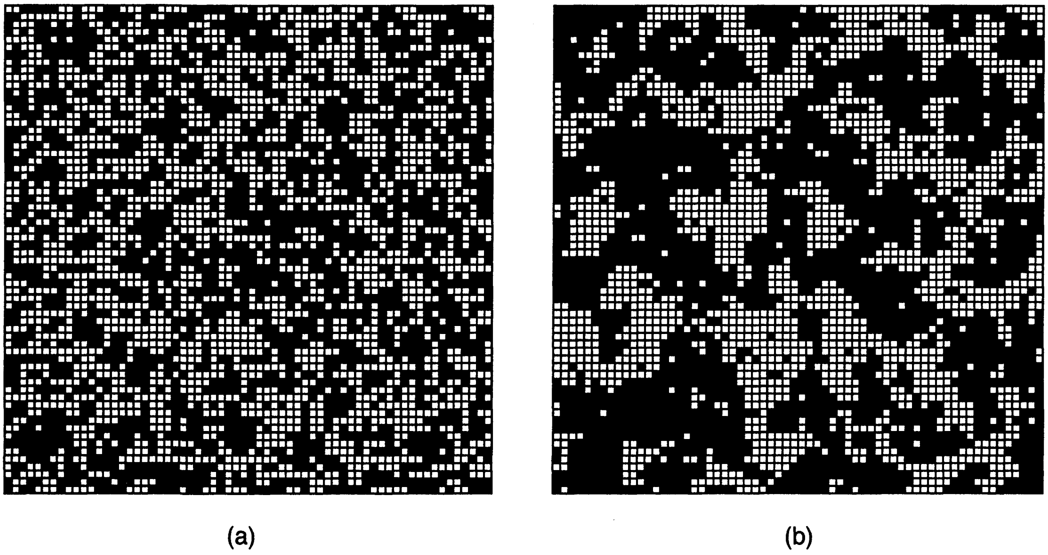
$$G(\mathbf{x},\tau) = \frac{1}{|\mathbf{x}|^{d-2+\eta}} \hat{G}_{\pm}(|\mathbf{x}|/\xi), \tag{9}$$

or, by introducing the Fourier transform of the correlation function, $G(\mathbf{k}) = \int d^d x G(\mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}}$,

$$G(\mathbf{k},\tau) = \frac{1}{|\mathbf{k}|^{2-\eta}} \hat{g}_{\pm}(|\mathbf{k}|\xi). \tag{10}$$

(The suffix "±" distinguishes between the cases $T > T_c$ and $T < T_c$.) The *scaling functions* $\hat{G}_{\pm}(y)$ and $\hat{g}_{\pm}(p)$ approach constant values in the limits $y \to 0$ and $p \to \infty$, respectively (see Sec. 1.4).

Near a critical point, where the only relevant length scale is set by the correlation



(a) (b)

FIG. 2. Correlated clusters in the two-dimensional Ising model (the black and white points correspond to the two possible states at each site i in the lattice) for two different temperatures: (a) far away from T_c in the disordered phase, and (b) near the critical point.

length ξ, the increasing size of correlated regions also causes a *critical slowing down* of the dynamics of the system. In fact, the characteristic frequency ω_c of the system is expected to obey a scaling law similar to Eq. (10), namely

$$\omega_c(\mathbf{k},\tau) = |\mathbf{k}|^z \hat{\Omega}_{\pm}(|\mathbf{k}|\xi), \tag{11}$$

with $\hat{\Omega}_{\pm}(p) \to \text{const}$ for $p \to \infty$, such that at the critical temperature

$$\omega_c(\mathbf{k},0) \propto |\mathbf{k}|^z \quad \text{for } T = T_c, \tag{12}$$

with the *dynamic critical exponent* z (Hohenberg and Halperin, 1977). For example, in the case of purely relaxational dynamics ω_c may be identified with the inverse relaxation time t_0^{-1}; thus by using Eq. (11) and $\Omega_{\pm}(p) \to p^{-z}$ for $p \to 0$, the temperature dependence of the relaxation time is found to be $t_0 \propto \xi^z \propto |\tau|^{-z\nu}$.

In addition, certain universal features of the thermodynamic phases themselves can sometimes be characterized by power laws also. Specifically, the cost in free energy Σ of creating a domain wall in a phase with broken symmetry is assumed to scale with its linear dimension L according to

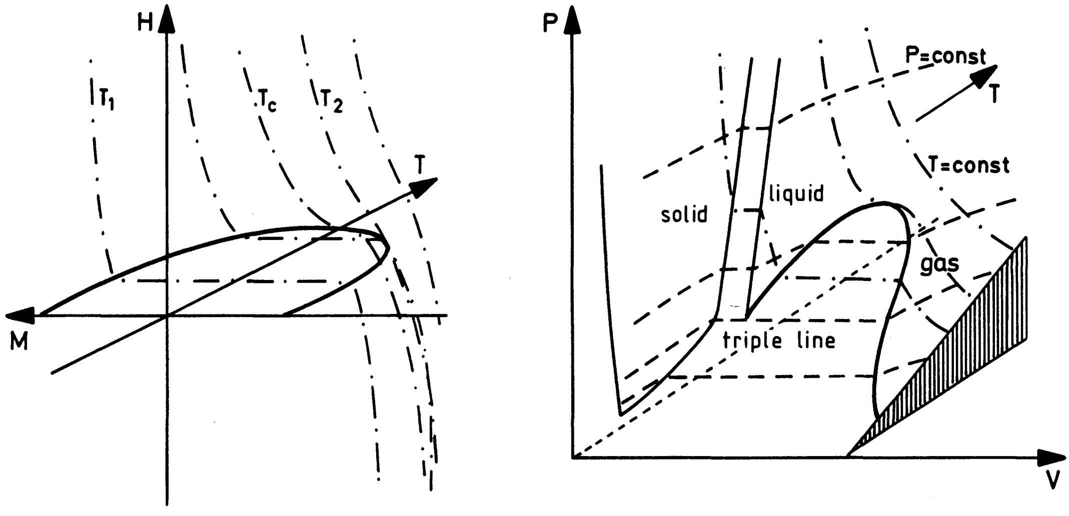
$$\Sigma = \sigma L^{\theta}, \tag{13}$$

where σ denotes the interfacial tension; a positive *stiffness exponent* θ means that long-range order is stable in the phase under consideration, whereas for $\theta < 0$ the system would spontaneously break up into domains (see, e.g., Fisher, 1993).

1.2 Examples

We have already referred to the phase transition from a paramagnetic to a ferromagnetic state, occurring at the Curie temperature T_c (in fact, the language used in this article is adopted from that particular physical realization). The order parameter is the macroscopic magnetization, χ is the magnetic susceptibility, and h the external magnetic field. A nonzero order parameter selects a particular direction; thus, depending on the Hamiltonian (see Sec. 2), the broken symmetry may be discrete (inversions) or continuous (rotations). At T_c, the order parameter sets in continuously [Fig. 1(a)], justifying the terminology "continuous transition." In anticipation of the comparison with the liquid–gas transition, we note, however, that reversing the external magnetic field for $T < T_c$ leads to a discontinuous change of sign of the magnetization [Fig. 1(b)]. The full phase diagram containing ϕ, h, and T is depicted in Fig. 3(a).

Probably the most familiar phase transitions are the solid–liquid and the liquid–gas



(a) (b)

FIG. 3. Comparison of the phase diagrams (a) of a ferromagnet, and (b) of a one-component gas/liquid/solid.

transitions [Fig. 3(b)]. For the latter, the density at the coexistence line minus the critical density may serve as an order parameter, which thus has a low- and high-density, i.e., a gas and liquid, branch. The associated external field is the pressure P, the (isothermal) compressibility κ would have to be identified with the order-parameter susceptibility, and the surface tension of the liquid defines the stiffness. At the critical point, where the isotherm as a function of P and V has an inflection point, one may observe the critical power laws as stated in Eqs. (1)–(4), (7), and (8) above (e.g., the divergence of κ becomes apparent in the phenomenon of critical opalescence near T_c).

In everyday life, the liquid–gas transition is usually observed at constant pressure well below P_c. As the system is heated up, the density changes discontinuously as a function of the temperature. Consequently, the liquid–gas transition is frequently referred to as being of first order, and the critical point as the end point of the transition line where the distinction between liquid and gas disappears. The analogy between the liquid–gas and the ferromagnetic transitions may be exhibited vividly if one encloses a fluid of critical density ρ_c in a so-called Natterer tube. For $T > T_c$, there is a uniform fluid phase, which splits up into a liquid and a gas phase if the system is cooled down below T_c. These phases appear separated by a meniscus.

At the liquid–solid transition, the translational symmetry is broken, and the order parameter may be chosen as the Fourier component of the density at a reciprocal-lattice vector of the solid; this transition does not terminate at a critical point, however [Fig. 3(b)]. Somewhat more subtle and diverse are structural transformations between different solid phases, where suitable components either of the displacement field or of the strain tensor appear as order parameters (see PHASE TRANSITIONS, STRUCTURAL); and furthermore the various ordered phases of liquid crystals (see LIQUID CRYSTALS, STRUCTURE OF). In the former, the order parameter may be the polarization or staggered polarization at ferroelectric or antiferroelectric phase transitions, or some quantity characterizing the orientation of molecular groups. At elastic transitions, it is a component of the strain tensor, specifying the deformation involved.

It should be noted that the phase diagrams of systems as different as ferromagnets and fluids look remarkably similar near their respective critical points (Fig. 3). Again, there is a very rich variety of magnetically ordered systems (e.g., antiferromagnets, ferrimagnets, helical phases), the order parameters of which may be of a rather complicated structure (see MAGNETIC ORDERING IN SOLIDS). A powerful tool to study the various phases of solids is neutron scattering, which directly measures the Fourier transform of the correlation function [Eq. (5)]. Moreover, time-dependent phenomena can be explored by inelastic scattering of neutrons and light, which renders the critical slowing down [Eq. (12)] of the collective excitations (see COLLECTIVE PHENOMENA IN SOLIDS) directly observable.

Finally, phase transitions to macroscopic quantum states, namely superfluidity and superconductivity, should be mentioned. The order parameter in these cases is a complex field Φ, which may be identified with a macroscopic wave function, and the broken symmetry is a gauge invariance with respect to the phase of Φ (see SUPERFLUIDITY: LIQUID HELIUM SYSTEMS; SUPERCONDUCTIVITY, LOW TEMPERATURE). Nature also allows for most interesting interplays between several kinds of phase transitions, which can lead to so-called multicritical points, and fairly complicated phase diagrams (see, e.g., SUPERCONDUCTIVITY, HIGH TEMPERATURE).

1.3 Universality

Near critical points, the topologies of the phase diagrams of such diverse systems as a liquid–gas mixture and a ferromagnetic material look amazingly similar (Fig. 3). Moreover, both in computer simulations of simplified models and in real experiments the critical exponents for the corresponding phase transitions turn out to be identical for a broad variety of physical systems, and to depend only on the number of components and symmetry properties of the order parameter, the space dimension, and possibly the character of the particle interaction, namely if it is long range (e.g., Coulomb or dipolar forces). This surprising feature is usually termed *universality*. The microscopic details of the strongly interacting many-particle system merely enter the prefactors of the ensuing power laws, and even ratios of such amplitudes are in fact universal numbers.

A clue for this most remarkable fact may be found in the divergence of the correlation length [Eq. (8)] at a continuous phase transition. Upon approaching T_c, ξ will asymptotically become the only relevant length scale in the system, dominating over all microscopic scales. Even though the phase transition itself is caused by some (usually short range) interactions of the microscopic constituents, the ensuing large fluctuations will markedly reduce all dependences on the degrees of freedom acting on short length scales, like the underlying crystal structure, the interaction range (as long as it is short), etc. Therefore, the system's thermodynamic properties near T_c should be entirely determined by global features such as its overall symmetry and large-scale properties (this is why long-range interactions, though possibly weak, may become important). In this regime, the system will behave strongly collectively, and one expects universal laws to apply for its low-wavelength and low-frequency excitations.

1.4 Scaling Laws

Another striking experimental feature near a critical point is the apparent *scale invariance* of physical properties (Fig. 4 illustrates this spectacular effect for the specific heat of helium-4 near the normal–superfluid transition). Again, this may be related to the diverging correlation length. The appropriate mathematical description for this phenomenon of scale invariance is that the free energy and the correlation functions assume the form of generalized homogeneous functions. In the case that the only relevant control parameters are the temperature and the external field, and using the definitions of the critical exponents (also called critical indices), one is thus led to the formulation of the *scaling hypotheses* for the singular part of the free energy:

$$F_s = A_\pm |\tau|^{2-\alpha} \hat{f}_\pm(h/|\tau|^{\beta\delta}), \tag{14}$$

and the correlation function, Eq. (9) [or Eq. (10)] (Fisher, 1974). In Eq. (14), the scaling function $\hat{f}_\pm$ approaches a constant value in the limit $h \to 0$.

There are various ways to make Eq. (14) plausible. First, it can be considered as a generalization of the mean-field results [see Sec. 2.3.1] to general critical exponents. Second, one may start from the observation that singularities are present only at $\tau = 0$ and $h = 0$. To what extent these become apparent depends on the separation from the critical point, τ, and on the value of $h/|\tau|^{\beta\delta}$, i.e., the ratio of the external field to the field equivalent of τ, namely $h_\tau = \phi^\delta = |\tau|^{\beta\delta}$. As long as $h \ll h_\tau$, the system is essentially in zero field, and $F_s \approx A_\pm|\tau|^{2-\alpha}\hat{f}_\pm(0) \propto |\tau|^{2-\alpha}$. On the other hand, when τ gets so small that $|\tau| \leq h^{1/\beta\delta}$, the system is manifestly in a finite field. Any further decrease of τ will then not lead to any changes: F_s remains at the value it acquired for $|\tau| = h^{1/\beta\delta}$, i.e. $A_\pm h^{(2-\alpha)/\beta\delta}\hat{f}_\pm(1)$; that is to say, in the limit $\tau \to 0$ one must have $\hat{f}_\pm(y)$

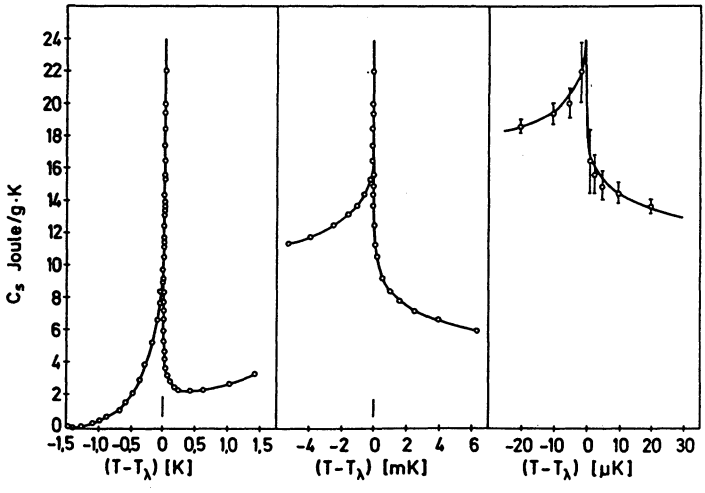


FIG. 4. Temperature dependence of the specific heat of helium-4 at the normal–superfluid phase transition, shown for successively reduced scales in the temperature variable (from Buckingham and Fairbank, 1961, p. 86).

$\rightarrow y^{(2-\alpha)/\beta\delta}$, in order to cancel the singular dependence of F_s on τ.

The scaling forms [Eqs. (14), (9), and (10)] incorporate the power laws [Eqs. (1)–(4), (7), and (8)]; moreover, by taking suitable derivatives with respect to τ and h, several *scaling relations* connecting the different critical indices may readily be obtained, namely

$$\alpha = 2 - \beta(\delta + 1), \tag{15}$$

$$\gamma = \beta(\delta - 1) = \nu(2 - \eta). \tag{16}$$

Relations of the type in Eqs. (14) and (9) are called *scaling laws*, because they are invariant under the following scale transformations:

$$\begin{aligned} &x \rightarrow x/b, \quad \xi \rightarrow \xi/b, \\ &\tau \rightarrow \tau b^{1/\nu}, \quad h \rightarrow h b^{\beta\delta/\nu}, \\ &F_s \rightarrow F_s b^{(2-\alpha)/\nu}, \quad G \rightarrow G b^{(d-2+\eta)/\nu}. \end{aligned} \tag{17}$$

If, in addition, one assumes that underlying these scale transformations there is a microscopic elimination procedure mapping the original system with lattice constant a and N sites to a new one with the same lattice constant a, but a reduced number Nb^{-d} degrees of freedom, one has

$$\frac{F_s(\tau,h)}{N} = b^{-d}\frac{F_s(\tau b^{1/\nu}, h b^{\beta\delta/\nu})}{Nb^{-d}}, \tag{18}$$

which in turn implies the *hyperscaling relation*

$$2 - \alpha = d\nu \tag{19}$$

containing the space dimension d. Equations (15), (16), and (19) leave only *two independent static critical exponents* characterizing the transition.

For dynamic critical phenomena, one arrives at a *dynamic scaling hypothesis* (Hohenberg and Halperin, 1977), originally proposed in the context of the λ transition of helium-4, by generalizing Eq. (10) to

$$G(\mathbf{k},\omega) = \frac{1}{|\mathbf{k}|^{2-\eta}}\,\hat{g}_{\pm}(|\mathbf{k}|\xi, \omega/\omega_c(\mathbf{k})) \tag{20}$$

for the frequency-dependent correlation function. Scaling laws of the form in Eqs. (14), (9), and (20) can be derived by the renormalization-group theory (see Sec. 3.2.4).

2. MATHEMATICAL REPRESENTATIONS

2.1 Microscopic Hamiltonians

In view of the expected universality of critical phenomena, simplified models containing the essential physics, namely the symmetry properties of the order parameter and the nature of the interactions, have provided a useful means for theoretical studies. For example, the *Ising* Hamiltonian describes a scalar order parameter, $\phi = \langle \sigma_i \rangle$, where the spin variables $\sigma_i = \pm 1$ are defined on a d-dimensional lattice, interacting with each other via a pair interaction J_{ij}, and subject to an external field with local strength h_i,

$$H[\sigma_i] = -\frac{1}{2}\sum_{i,j} J_{ij}\sigma_i\sigma_j - \sum_i h_i\sigma_i. \tag{21}$$

Positive exchange interaction J amounts to a ferromagnetic coupling, tending to align the spins, while an antiferromagnetic $J < 0$ favors alternating spin orientation. Its range is often restricted to nearest-neighbor interaction, but could also be taken as long-range. In the simplest case, the nonzero J_{ij} are chosen as constant, but in order to describe disordered systems they may as well be drawn from a certain random distribution (*random-bond* Ising model). Similarly, for most applications the external field is assumed to be uniform, $h_i = h$, but may in certain circumstances also be considered a random variable (*random-field* Ising model). Once the Hamiltonian is specified, in principle all thermodynamic properties of the model can of course be derived from the partition sum (see STATISTICAL MECHANICS, CLASSICAL)

$$Z = e^{-F/k_BT} = \mathrm{Tr}(e^{-H/k_BT}) \tag{22}$$

$$= \sum_{\{\sigma_i = \pm 1\}} e^{-H[\sigma_i]/k_BT}, \tag{23}$$

and the definition of thermodynamic averages

$$\langle A \rangle = \frac{1}{Z}\mathrm{Tr}(e^{-H/k_BT}A). \tag{24}$$

The short-range Ising model without disorder can be shown to display a second-order finite-temperature phase transition for all dimensions $d \geq 2$, whereupon the discrete symmetry $\sigma_i \leftrightarrow -\sigma_i$ is broken (see CRITICAL PHENOMENA). The statistical mechanics of lattice gases as well as binary liquid mixtures may be mapped onto Ising-type models; this once more illustrates the intimate analogies of phase transitions in very different systems.

Similarly, a three-component vector order parameter is incorporated in the anisotropic *Heisenberg* model,

$$H = -\frac{1}{2}\sum_{i,j} [J_{ij}^{\perp}(S_i^x S_j^x + S_i^y S_j^y) + J_{ij}^{\parallel} S_i^z S_j^z] - \sum_i h_i S_i^z \qquad (25)$$

(we use the notation S_i^α, $\alpha = x, y, z$, for the three-component spin variables here; of course, this may be readily generalized to an n-component order parameter), where the symmetry-breaking field h_i is taken along the z direction. For nearest-neighbor interactions, in the cases $J^{\parallel} > J^{\perp} > 0$ and $J^{\perp} > J^{\parallel} > 0$ the Hamiltonian [Eq. (25)] describes a uniaxial ferromagnet or planar ferromagnet, respectively, while in the special situation $J_{ij}^{\parallel} = J_{ij}^{\perp}$ Eq. (25) yields the isotropic Heisenberg model, and for $J_{ij}^{\parallel} = 0$ the xy model, the latter being appropriate for the description of superfluid helium-4, for example (see Fisher, 1967; Ma, 1976a). As a consequence of the continuous rotational symmetry broken in the ordered phase, the Heisenberg and xy models may have long-range order only for $d > 2$ dimensions. The two-dimensional xy model displays another very interesting scenario, namely the Berezinskii–Kosterlitz–Thouless transition (Nelson, 1983): There appears a phase, although without long-range order, in which the correlation function decays as a power law. The system then disorders at higher temperatures via the creation and unbinding of pairs of topological defects (vortex-antivortex pairs of spin excitations). The relatively simple models introduced above have become of paradigmatic importance in the statistical mechanics of phase transitions. One should keep in mind, however, that in more complicated physical situations more elaborate models may be required.

2.2 Ginzburg–Landau Functional

Near a continuous phase transition, predominantly long-wavelength properties will be of significance, because of the divergence of the correlation length according to Eq. (8). Therefore, a continuum model for just the long-wavelength degrees of freedom should be sufficient and appropriate, at least for the description of the universal features. We remark that this concept of an *effective (field) theory* is of course defined on a certain energy scale, which in this context is set by the transition temperature. On different scales, the corresponding effective models may differ considerably, and one may in fact imagine them to be generated by a sequence of symmetry-breaking phase transitions occurring at successively lower energies.

Such an effective model for the long-wavelength degrees of freedom may either be derived from a microscopic Hamiltonian, such as Eq. (21) or (25), by mapping the partition function on a continuum problem and performing a gradient expansion; or merely be written down by carefully exploiting symmetry arguments. Let us denote the n-component vector order parameter by $\boldsymbol{\phi}$. For the case of a second-order phase transition breaking an O(n) symmetry, the effective free energy, also called Hamiltonian in the context of critical phenomena, which retains only the lowest orders in the gradients and nonlinear terms, is the *Ginzburg–Landau free energy functional* (in d dimensions)

$$\mathcal{F}[\phi] = \int d^d x \left[\frac{r}{2}\boldsymbol{\phi}^2 + \frac{u}{4}(\boldsymbol{\phi}^2)^2 + \frac{1}{2}(\nabla\boldsymbol{\phi})^2 - \mathbf{h}\cdot\boldsymbol{\phi} \right], \qquad (26)$$

where $r = a(T - T_c)$, and a, u are positive coefficients, while $\mathbf{h}$ is the (n-component) external field. The coefficient of the gradient term in Eq. (26) was assumed to be positive, assuring that spatially uniform configurations be energetically preferred to inhomogeneous ones, and has then been absorbed in a redefinition of the field variable $\boldsymbol{\phi}$. For $n = 1$ the Hamiltonian [Eq. (26)] has the discrete symmetry of the Ising model [Eq. (21)] (i.e., for vanishing h), with a scalar order parameter, while for $n = 2$ and $n = 3$ the continuous symmetries of the xy model and the isotropic Heisenberg model are recovered.

Again, the thermodynamics can be retrieved from the partition function, which mathematically assumes the form of a functional integral of the probability distribution

$\mathcal{P} \propto \exp(-\mathcal{F}/k_BT)$ over the vector field $\boldsymbol{\phi}(x)$:

$$Z = Z_0(T)\int \mathcal{D}[\boldsymbol{\phi}(x)]e^{-\mathcal{F}[\boldsymbol{\phi}]/k_BT}. \qquad (27)$$

Here the term Z_0 contains those contributions that are not explicitly stated in the Ginzburg–Landau functional [Eq. (26)] and that should be insignificant near the transition. Figure 5 depicts the probability distribution $\mathcal{P}$ in the case of a uniform one-component order parameter ϕ, containing the first two terms of the integrand in Eq. (26), for $r > 0$, and $r < 0$, respectively (the phase transition occurs at $r = 0$). We note that a very convenient way to calculate correlation functions uses derivatives with respect to the components of $\mathbf{h}$, e.g.,

$$G_{\alpha\beta}(x - x') = \frac{(k_BT)^2\partial^2 \ln Z[\mathbf{h}]}{\partial h_\alpha(x)\partial h_\beta(x')}. \qquad (28)$$

2.3 Landau–Ginzburg Approximation

2.3.1 Mean-Field Theory Evaluating the functional integral [Eq. (27)] is a highly nontrivial task, and in general one is forced to resort to some approximation. Because of the exponential in the integrand, one might expect the probability distribution to be sharply peaked, and the thermodynamics of the system thus to be dominated by the most probable configuration, which is given by the solution to the stationarity equation

$$\begin{aligned} 0 &= \frac{\delta\mathcal{F}}{\delta\boldsymbol{\phi}(x)} \\ &= [r + u\boldsymbol{\phi}(x)^2 - \nabla^2]\boldsymbol{\phi}(x) - \mathbf{h}(x). \end{aligned} \qquad (29)$$

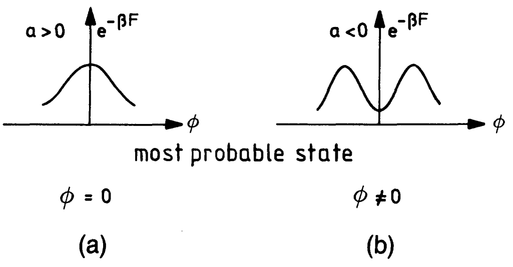

FIG. 5. Probability distribution $\mathcal{P} \propto \exp(-\mathcal{F}/k_BT)$ for the Landau part of the free energy $\mathcal{F}$, Eq. (26), as function of a single-component order parameter ϕ, for (a) $T > T_c$, and (b) $T < T_c$.

In order to determine the homogeneous order parameter [$\nabla\boldsymbol{\phi}(x) = 0$] as a function of T, one must evaluate the Landau–Ginzburg equation [Eq. (29)] for $\mathbf{h} = h\mathbf{e}_n \to 0$ (note the order of limits here: *first* take the thermodynamic limit, and only *then* let the symmetry-breaking field vanish; with the reverse procedure there would be no nonzero order parameter for symmetry reasons, because one would have to average over the degenerate ground states). This yields

$$\boldsymbol{\phi} = \begin{cases} 0, & T \geq T_c, \\ \pm\sqrt{|r|/u}\mathbf{e}_n, & T < T_c; \end{cases} \qquad (30)$$

and inserting Eq. (30) into Eq. (26) one arrives at the following approximate result for the singular part of the free energy F_s:

$$F_s[\boldsymbol{\phi}] = \begin{cases} 0, & T \geq T_c, \\ -r^2L^d/4u, & T < T_c \end{cases} \qquad (31)$$

(here L^d is the volume of a cube in d-dimensional space). By comparison with Eqs. (1) and (4), one thus immediately finds the critical exponents $\beta = \frac{1}{2}$, and $\alpha = 0$; more precisely, the specific heat displays a discontinuity at the transition temperature T_c, the height of which is

$$\Delta C_{h=0} = T_c a^2 L^d/2u. \qquad (32)$$

Similarly, for finite external field Eq. (29) leads to the equation of state in terms of the order-parameter component ϕ_n parallel to the symmetry-breaking field $\mathbf{h} = h\mathbf{e}_n$,

$$h = (r + u\phi_n^2)\phi_n, \qquad (33)$$

from which the exponent for the critical isotherm is readily obtained to be $\delta = 3$. Finally, differentiating Eq. (33) with respect to h yields the isothermal susceptibility

$$\chi = \begin{cases} 1/r = C_+(T - T_c)^{-1}, & T > T_c, \\ 1/2|r| = C_-(T_c - T)^{-1}, & T < T_c, \end{cases} \qquad (34)$$

and hence the critical exponent $\gamma = 1$ (on both sides of the transition), as well as the also universal amplitude ratio $C_+/C_- = 2$. The above results for the critical indices coincide with those of the mean-field approximation for the Ising and Heisenberg models, and with the exponents found for the van der Waals gas near its critical point. (In the mean-field approximation for the Ising model [Eq. (21)], for instance, the exchange field $\Sigma_j J_{ij}\sigma_j$ acting on spin σ_i is replaced by its average $\Sigma_j J_{ij}\langle\sigma_j\rangle$.)

We note that if u in Eq. (26) became negative, which may happen as some external parameter, e.g., the pressure, is varied, additional terms would have to be included in the Ginzburg–Landau functional for stability reasons. In the case of an underlying O(n) symmetry, the leading such nonlinearity would be $\propto (\phi^2)^3$, and the ensuing phase transition of first order. Its transition temperature $T_1 \neq T_c$ is to be defined by the condition that the free energies of the distinct coexisting phases be equal. In the special case that u vanishes, T_c becomes a tricritical point, displaying most interesting and complex scaling behavior.

2.3.2 Gaussian Fluctuations In keeping the most probable state only, fluctuations have been neglected entirely so far. However, the divergence of the susceptibility, Eq. (34), implies that fluctuations must indeed become very strong near the critical point. The next step is therefore to check whether the above results are altered by including fluctuations to lowest order. Thus, we introduce the deviations $\psi(x)$ from the most probable state $\phi(x)$, given by the solution to Eq. (29), by writing the order-parameter field as $\phi(x) + \psi(x)$, and expand the Ginzburg–Landau functional [Eq. (26)] with respect to $\psi(x)$, keeping terms up to second order only. This is most conveniently done in Fourier space, where we define the Fourier transform of $\psi(x)$ as

$$\psi(x) = L^{-d/2} \sum_{k\in \mathrm{B}} \psi_k e^{ikx}; \tag{35}$$

here B denotes the Brillouin zone for the allowed values of the k vectors. The partition function [Eq. (27)] then becomes

$$Z = Z_0(T) \int \prod_k d\psi_k e^{-\mathscr{F}_G[\psi]/k_\mathrm{B}T}. \tag{36}$$

Beginning with the situation above T_c, for $h = 0$, the Fourier expansion renders the Ginzburg–Landau functional diagonal, $\mathscr{F}_\mathrm{G} = \Sigma_k(r + k^2)\psi_k \cdot \psi_{-k}/2$. The functional integrals in the partition function thus reduce to simple Gaussian integrals, yielding for the free energy in *Gaussian approximation*

$$F_s(T,h = 0) = -k_\mathrm{B}T \frac{n}{2} \sum_k \ln \frac{2\pi k_\mathrm{B}T}{r + k^2}, \tag{37}$$

and by transforming the discrete sum over the Brillouin zone into an integral, the most singular part of the specific heat follows as

$$C_s = k_\mathrm{B}L^d \frac{n}{2} (Ta)^2 \int \frac{d^dk}{(2\pi)^d} \frac{1}{(r + k^2)^2}. \tag{38}$$

The result of evaluating the integral is

$$C_s = \begin{cases} A_+(T - T_c)^{-(4-d)/2}, & d < 4, \\ \propto \ln(T - T_c), & d = 4, \\ B - A(T - T_c)^{(d-4)/2}, & d > 4; \end{cases} \tag{39}$$

hence while for $d > 4$ the specific heat shows a (nonanalytical) cusp at T_c, it diverges for $d \leq 4$, with the exponent $\alpha = (4 - d)/2$; here an exponent "0" is to be understood as a logarithmic singularity. Neglecting deviations from the most probable state therefore turns out to be entirely unjustifiable in the latter case, where the thermodynamics is obviously dominated by the order-parameter fluctuations.

Similarly, in the ordered phase one finds

$$C_s = TL^d a^2/2u + A_-(T_c - T)^{-(4-d)/2} \tag{40}$$

for $d < 4$; the critical exponent α is therefore the same above and below the transition. The universal (i.e., depending only on d and n) amplitude ratio for the specific heat is $A_+/A_- = n/2^{d/2}$, where the factor n stems from the fact that the $n - 1$ transverse fluctuations (with respect to the direction of the spontaneous order parameter) do not contribute to the specific heat in the ordered phase.

With the help of the result in Eq. (40), the *Ginzburg–Levanyuk criterion* (see Als-Nielsen and Birgeneau, 1977) may be formulated, stating that fluctuations are negligible as long as the first term ΔC dominates over the second contribution; introducing $\xi_0 = (aT_c)^{-1/2}$ this means that the Landau–Ginzburg approximation gives essentially correct answers, provided

$$|\tau|^{(4-d)/2} \gg \frac{\mathcal{N}}{(\xi_0 L)^d} \Delta C, \tag{41}$$

where $\mathcal{N}$ is a numerical factor. Therefore, for $d > d_c = 4$ fluctuations are not very important [$\alpha_{fl} < 0$, Eq. (39)], and mean-field types of approach yield reliable results. Below this *upper critical dimension*, however, such approximations will break down in the vicinity of T_c. Depending on the value of ξ_0, the nonclassical scaling behavior (with exponents different from the mean-field indices) will be important only very near to the critical point, or already noticeable even far away from it.

For example, for magnets typically $\xi_0 \approx 1$ Å, and fluctuations become important for $|\tau| < \tau_{\mathrm{GL}} \approx 0.01$. For the normal–superfluid transition of helium-4, $\xi_0 \approx 4$ Å, and $\tau_{\mathrm{GL}} \approx 0.3$, which renders this system a prominent candidate for the study of critical phenomena (also, by varying the pressure one can explore a line of critical points and thus examine universality issues in detail). On the other hand, for conventional (low-T_c) superconductors ξ_0 is of the order 1000 Å, and $\tau_{\mathrm{GL}} \approx 10^{-10}$ to 10^{-14}, which means that the Ginzburg–Landau theory is an excellent approximation there. This is in remarkable contrast with the high-T_c materials, where $\xi_0 \approx 1$ Å, and fluctuations play a dominant role; in fact, they account for an enormously rich phase diagram of the cuprate-based superconductors (see Blatter *et al.*, 1994).

For $|\tau| < \tau_{\mathrm{GL}}$, it does not at all suffice to add to the results of the Ginzburg–Landau approximation the Gaussian corrections, since in this temperature range higher-order nonlinear contributions will be even more infrared divergent and eventually exceed those from the harmonic term. This constitutes of course a serious breakdown of the standard perturbational procedure, and signals that an entirely new theoretical approach is required in the case $|\tau| < \tau_{\mathrm{GL}}$.

For finite external field, the partition function [Eq. (36)] becomes above T_c

$$Z[\mathbf{h}] = \exp\left[\frac{1}{2k_{\mathrm{B}}T}\sum_k \frac{\mathbf{h}_k \cdot \mathbf{h}_{-k}}{r + k^2}\right], \tag{42}$$

and the correlation function can be obtained by differentiating this generating functional [see Eq. (28)]. Above T_c, the result in k space is

$$\langle \psi_k^\alpha \psi_{-k'}^\beta \rangle = \frac{k_{\mathrm{B}}T}{r + k^2}\,\delta_{kk'}\delta^{\alpha\beta}; \tag{43}$$

consequently, for $r = 0$ one finds in real space

$$G(x) \propto 1/|x|^{d-2}, \tag{44}$$

and thus the critical exponent defined in Eq. (7) is $\eta = 0$ in the Landau–Ginzburg approximation. Also, the inverse of r defines the square of a characteristic length, which we identify with the correlation length, $\xi_+ = r^{-1/2}$, and hence $\nu = \frac{1}{2}$. In three dimensions, the Fourier transform of Eq. (43) is the *Ornstein–Zernicke correlation function*

$$G(x) = \frac{k_{\mathrm{B}}T}{4\pi|x|}\,e^{-|x|/\xi_+}. \tag{45}$$

In the ordered phase, one has to distinguish between the longitudinal and transverse correlation functions, with respect to the spontaneous order parameter, which are still diagonal in the indices α, β, and for the O(n) symmetric model [Eq. (26)] in Gaussian approximation read

$$G_\parallel(k) = k_{\mathrm{B}}T/(\xi_-^{-2} + k^2) \tag{46}$$

and

$$G_\perp(k) = k_{\mathrm{B}}T/k^2, \tag{47}$$

respectively. Hence, on this level $G_\parallel(k)$ is of the form in Eq. (43), with a different correlation length $\xi_- = (2|r|)^{-1/2}$, however. Note that the amplitude ratio for the correlation lengths above and below the transition is universal again, with the mean-field value $\sqrt{2}$. Remarkably, the transverse correlation function diverges for $k \to 0$, which means that the range for the transverse correlations is infinite in the entire low-temperature phase. This can be shown to be a rigorous consequence of the breaking of the continuous rotational symmetry. For $n \geq 2$ and $d \leq 4$, the large transverse fluctuations [Eq. (47)] via nonlinear effects imply a longitudinal correlation function surpassing the result obtained within the harmonic approximation [Eq. (46)], which for $k \to 0$ has to be replaced by

$$G_\parallel(k) \propto 1/k^{4-d}. \tag{48}$$

Remarkably, Eq. (48) is a universal power law characterizing not a phase transition singularity, but an *entire ordered phase.* Yet the longitudinal correlation length ξ_- still retains some physical meaning; namely, it provides the scale on which the crossover from the critical behavior [Eq. (7)] to the asymptotic form [Eq. (48)] occurs.

In the Ising case ($n = 1$), Eq. (46) is qualitatively correct outside the critical region, and ξ_- sets the characteristic length scale in the ordered phase. For instance, a domain-wall configuration $\phi_K(x)$ connecting the two degenerate ground states $\phi_\pm = \pm\sqrt{|r|/u}$, and centered at x_0, extends over the range ξ_-,

$$\phi_K(x) = \phi_\pm \tanh\frac{x - x_0}{2\xi_-}, \tag{49}$$

as can be seen by solving the Landau–Ginzburg differential equation [Eq. (29)] for $h = 0$, allowing for a spatially varying order parameter with the appropriate boundary conditions.

3. RENORMALIZATION GROUP

3.1 Introductory Remarks

The term "renormalization" of a theory stands for a certain reparametrization, with the goal that the resulting renormalized theory be more tractable than the original one. Historically, renormalization was invented by Stückelberg and Feynman, in order to cure quantum field theories (e.g., quantum electrodynamics) from divergences (see UNIFIED FIELD THEORIES). Instead of the bare parameters (masses and coupling constants), the Lagrangian was expressed in terms of physical masses and coupling coefficients, such that ultraviolet-divergent (UV) virtual processes were systematically absorbed in the relationship between the bare and physical quantities, thus rendering the renormalized theory finite. The renormalization procedure is not unique; the renormalized quantities may for instance depend on a cutoff length scale up to which certain virtual processes are taken into account. The *renormalization-group* (RG) theory studies the dependence on this specific length scale, also called *flow parameter*. The name renormalization group derives from the fact that two successive RG transformations lead to a third such transformation.

In the context of critical phenomena, where one needs to explain the long-distance (or, in Fourier space, small–wave-number) regime, it is natural to implement the renormalization scheme by performing some kind of elimination of the short-wavelength fluctuations. Such a partial evaluation of the partition function will be much easier to achieve than a calculation of the complete partition sum, and also permits the systematic implementation of approximate methods. As a result of the elimination step, the remaining degrees of freedom will experience modified *effective* interactions.

Quite generally, various benefits can be expected from such a RG procedure:

1. The new coupling coefficients might be smaller. By repeating the renormalization process, one may thus arrive at an effectively free theory with no interactions.
2. The successively iterated coupling coefficients, also called the *parameter flow*, may have a finite *fixed point*, at which the system does not change any more under subsequent RG transformations. Since the elimination of some degrees of freedom is accompanied by a change of the underlying lattice spacing, or length scale, one may anticipate that the fixed points are under certain circumstances related to critical points. Furthermore, one may hope that the properties of the flow near these fixed points will yield information about the universal physical quantities in the vicinity of the critical point.

Below, we shall find scenario **1** in the case of the one-dimensional Ising model and **2** for the Ising model in two dimensions, as well as for the Ginzburg–Landau–Wilson effective field theory (ϕ^4 model).

3.2 Real-Space Renormalization Group

The idea of any RG approach in statistical mechanics is to exploit the scale invariance near a critical point in parameter space. In real-space RG transformations, which refers to procedures working in direct space (as opposed to Fourier space), one eliminates specific degrees of freedom that are defined on a lattice, thus performing a partial partition sum. Then the lattice constant of the ensuing system is readjusted, and also the internal variables are renormalized, in order to achieve a new Hamiltonian whose form resembles the original one. By comparison, effective couplings are defined, which thus become scale dependent. The fundamental paradigm is that certain fixed points in parameter space exist, at which these running couplings remain invariant. At these fixed points, the theory is manifestly scale invariant, and the critical exponents can be obtained by studying the linearized flow equations. As this concept of the RG may seem rather abstract at first sight, the method is explained by applying a simplified version to the ferromagnetic Ising model [Eq. (21)] in $d = 1$ and $d = 2$ dimensions (Niemeijer and van Leeuwen, 1976). Then a more general discussion, including an explanation of the emergence of scaling laws, is given. A continuous field-theoretical formulation for the RG in momentum space is presented in Sec. 3.3.

3.2.1 1D Ising Model For a one-dimensional Ising chain with constant ferromagnetic nearest-neighbor exchange coupling $J_{ij} = J > 0$ in zero external field, the Hamiltonian [Eq. (21)] becomes $H = -J \sum_i \sigma_i\sigma_{i+1}$, and introducing the abbreviation $K = J/k_BT$ the partition function [Eq. (23)] reads (for N spins, and periodic boundary conditions $\sigma_{N+1} = \sigma_1$)

$$Z_N = \sum_{\{\sigma_i=\pm 1\}} \exp\left[K \sum_i \sigma_i\sigma_{i+1}\right]. \tag{50}$$

A partial evaluation of Eq. (50) may be performed by summing over every other spin in the chain, marked by an "x" in Fig. 6. The sum over the possible orientations of spin i, for instance, yields

$$\sum_{\sigma_i=\pm 1} e^{K\sigma_i(\sigma_{i-1}+\sigma_{i+1})} = \exp[2g' + K'\sigma_{i-1}\sigma_{i+1}], \tag{51}$$

for the result can only depend on whether the adjacent spins σ_{i-1} and σ_{i+1} are oriented parallel or antiparallel to each other. By comparing the results for these two configurations, $\sigma_{i-1}\sigma_{i+1} = \pm 1$, one readily obtains the two recursion relations

$$K' = \tfrac{1}{2} \ln \cosh 2K, \tag{52}$$

$$g' = \tfrac{1}{2}(\ln 2 + K'). \tag{53}$$

Thus, via decimation of half of the spins in the chain one arrives at another Ising Hamiltonian, whose nearest-neighbor coupling is K'; in addition, a spin-independent contribution g' to the free energy is generated. If this transformation is repeated, the *exact* recursion relations [Eqs. (52) and (53)] quite generally describe how the effective couplings $K^{(k)}$ and $g^{(k)}$ in the kth step result from the corresponding values in the $(k-1)$th elimination step. In Fig. 7, the ensuing flow for the coupling K, starting with some initial value K_0, is depicted for several steps of the procedure. Clearly, the fixed-point equation $K^* = (\frac{1}{2}) \ln \cosh 2K^*$ has two solutions: $K^* = 0$, which (for the original fixed J) corresponds to infinite temperature, or vanishing effective interaction; and $K^* = \infty$, the $T = 0$ fixed point. On starting at some initial value $K_0 > 0$, the parameter flow always drives the system into the $K^* = 0$ fixed point [by expanding Eq. (52) around $K^* = 0$, this fixed point is seen to be stable]. Physically, this means that there can be no ordered state at any finite temperature $T > 0$, because asymptotically the ratio of exchange coupling and tem-

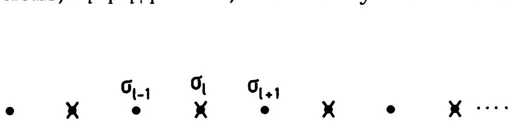

FIG. 6. Decimation transformation for the one-dimensional Ising chain with nearest-neighbor interaction.

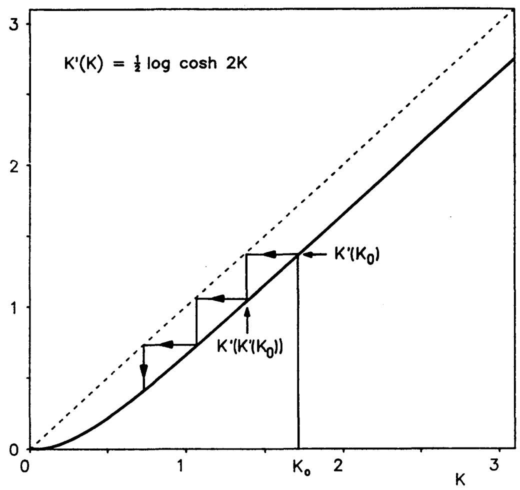

FIG. 7. Recursion relation for the nearest-neighbor coupling of the Ising chain (full; the dashed line marks the line $K' = K$). The iteration steps are indicated by the arrows.

perature vanishes, and the system becomes completely disordered.

At $T = 0$, however, the situation is rather special. Expanding Eq. (52) near $1/K^* = 0$ yields $1/K' = 1/K + \ln b/(2K^2)$, where $b = 2$ is just the factor rescaling all lengths. It now turns out to be useful to introduce $\delta = \ln b$, such that after l steps $b^l = e^{\delta l}$, and then take the limit $\delta \to 0$; thereby the discrete RG steps are mapped onto a continuous flow with the flow parameter l. The resulting differential flow equation for the now scale-dependent coupling $K(l)$ reads to lowest order

$$\frac{dK^{-1}(l)}{dl} = \tfrac{1}{2}[K^{-1}(l)]^2, \tag{54}$$

which is readily integrated to $K(1) - K(l) = l/2$. From this, the temperature dependence of the correlation length ξ can be determined by applying the ("matching") condition that $K(b = \xi)$ be a constant of order 1. This gives

$$\xi \propto \exp(2J/k_BT), \tag{55}$$

i.e., the correlation length diverges exponentially at the *marginal* critical point $T = 0$, a result that may also be readily obtained by more elementary methods.

Using the above recursion relations the partition function may be evaluated:

$$\begin{aligned} Z_N &= e^{Ng(K')}Z_{N/2}(K') = \cdots \\ &= \exp\left[N\sum_{k=1}^{n}\frac{g(K^{(k)})}{2^{k-1}} + \ln Z_{N/2^n}(K^{(n)})\right]. \end{aligned} \tag{56}$$

The factor 2 in Eq. (56) can be interpreted as stemming from a readjustment of the overall scale, as the number of degrees of freedom is being diminished by the elimination procedure. The reduced free energy (in units of k_BT) thus becomes $f = -(1/N)\ln Z_N(K)$. As is apparent from Fig. 7, $K^{(k)}$ rapidly becomes very small, and perturbative methods may be employed. Assuming $K^{(n)} \approx 0$, one arrives at the approximate result

$$f^{(n)}(K) = -\sum_{k=1}^{n}\frac{g(K^{(k)})}{2^{k-1}} - \frac{1}{2^n}\ln 2, \tag{57}$$

for in a noninteracting spin-1/2 system the free energy per spin is $-\ln 2$. Figure 8 shows the rapid approach toward the exact result, $f(K) = -\ln(2\cosh K)$, as the number of elimination steps is increased.

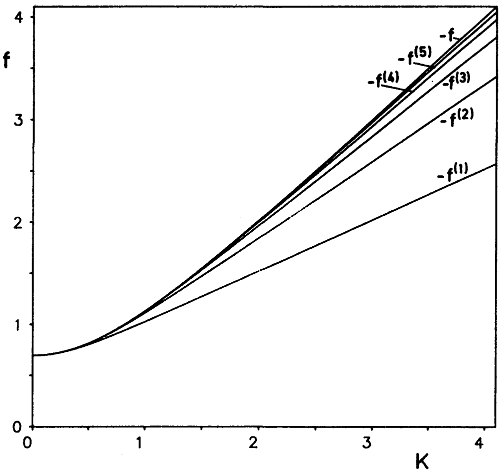

FIG. 8. Reduced free energy f for the nearest-neighbor Ising chain. The $f^{(k)}$ denote the approximation to the exact result f as obtained in the kth step of the RG procedure.

3.2.2 2D Ising Model More interesting is the case of the two-dimensional Ising model, which is known to have a phase transition at a finite temperature $T_c > 0$ (see Critical Phenomena). Here a quadratic lattice with nearest-neighbor ferromagnetic interactions will be considered (Fig. 9). In order to find the recursion relations in this case, one may perform the partial partition sum over those spins

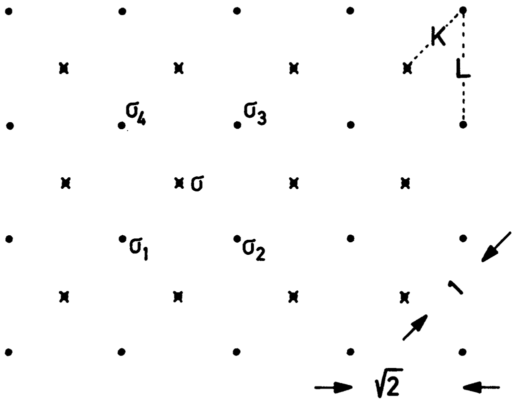

FIG. 9. Ising model on a quadratic lattice. Even if originally there were only nearest-neighbor interactions K present, by application of the decimation procedure next-nearest-neighbor couplings L are generated.

marked with an "x" in Fig. 9, which leads to a new square lattice with a lattice constant larger by a factor of $\sqrt{2}$ than that of the original one. A typical sum is

$$\sum_{\sigma=\pm 1} e^{K\sigma(\sigma_1+\sigma_2+\sigma_3+\sigma_4)}$$
$$= \exp[A' + K'(\sigma_1\sigma_2 + \sigma_2\sigma_3 + \sigma_3\sigma_4 + \sigma_4\sigma_1)] \times \exp[L'(\sigma_1\sigma_3 + \sigma_2\sigma_4) + M'\sigma_1\sigma_2\sigma_3\sigma_4]; \tag{58}$$

thus some new interaction, namely a next-nearest-neighbor coupling L' and a four-spin interaction M', are *generated* by the transformation. In the vicinity of the actual critical value $K_c = J/\kappa_B T_c = 0.4406$, one finds $M' \ll L' \leq K'$. Therefore, M' shall henceforth be neglected here (a more thorough perturbational analysis is given in Niemeijer and van Leeuwen, 1976.) The terms A', K', and L' can readily be expressed by K. If these relations are expanded to second order in K, and if one realizes that a next-nearest-neighbor interaction L in the original Hamiltonian appears as a contribution to the nearest-neighbor interaction in the primed Hamiltonian, one obtains

$$K' = 2K^2 + L, \tag{59}$$

$$L' = K^2. \tag{60}$$

A simple physical picture behind these approximate recursion relations is that they just represent the numbers of paths between the remaining spins, weighted by the product of the bonds involved.

It should be clear, however, that with each step of the elimination new couplings appear, as opposed to the one-dimensional case. Of course, restricting the flow to the subspace (K,L) will not produce quantitatively satisfactory results, but still the structure and typical features of such recursion relations are preserved.

The fixed points of Eqs. (59) and (60) are

1. $K^* = L^* = 0$,
2. $K^* = L^* = \infty$, and
3. $K_c^* = \frac{1}{3}$, $L_c^* = \frac{1}{9}$ (Fig. 10).

As in the 1D Ising model, fixed points **1** and **2** refer to infinite temperature (disordered phase) and $T = 0$, respectively. Yet now the latter describes an entire (ordered) phase. Furthermore, there is an additional nontrivial finite fixed point, which governs the second-order transition separating these two phases. For at each step in the procedure, the effective lengths are reduced by a factor $b = \sqrt{2}$, which applies to the correlation length also, and therefore at a fixed point either $\xi = 0$ (which is true for the $T = 0$ and $T = \infty$ fixed points), or $\xi = \infty$ (for finite values of K^* and L^*), which implies scale invariance. Therefore, the fixed point (K_c^*, L_c^*) with diverging correlation length describes the critical state. Even more, actually all points lying on a trajectory leading into the fixed point represent critical behavior, because on these paths the correlation length is infinite as well.

In order to determine the critical behavior of the model, the recursion relations [Eqs. (59) and (60)] are linearized near the point (K_c^*, L_c^*) in parameter space; with $\delta K_l = K_l - K_c^*$ and $\delta L_l = L_l - L_c^*$ in the lth step of the

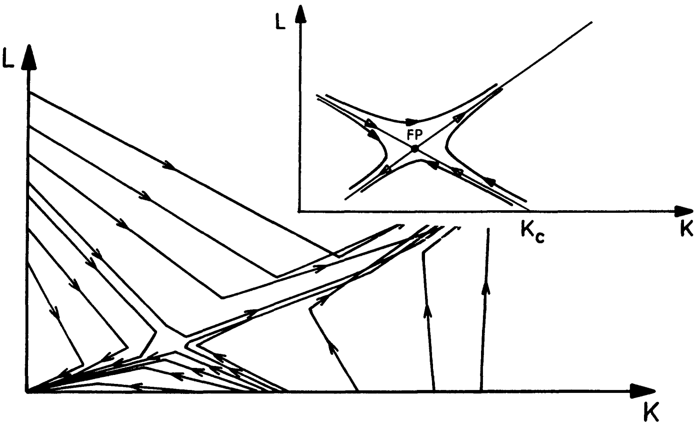

FIG. 10. Flow diagram for the two-dimensional Ising model on a square lattice near its critical point. (Only the results of every other recursion step are shown.) The inset shows the behavior in the vicinity of the critical fixed point, which is described by Eq. (63).

procedure, one finds

$$\begin{pmatrix} \delta K_l \\ \delta L_l \end{pmatrix} = \begin{pmatrix} \frac{4}{3} & 1 \\ \frac{2}{3} & 0 \end{pmatrix} \begin{pmatrix} \delta K_{l-1} \\ \delta L_{l-1} \end{pmatrix}. \tag{61}$$

The eigenvalues of the transformation matrix are $\lambda_{1,2} = (2 \pm \sqrt{10})/3$, and the corresponding eigenvectors $\mathbf{e}_{1,2} = (3, \pm\sqrt{10} - 2)$. Thus, if the original couplings are expanded in the basis of eigenvectors,

$$\begin{pmatrix} K_0 \\ L_0 \end{pmatrix} = \begin{pmatrix} K_c^* \\ L_c^* \end{pmatrix} + c_1\mathbf{e}_1 + c_2\mathbf{e}_2, \tag{62}$$

after l steps one arrives at

$$\begin{pmatrix} K_l \\ L_l \end{pmatrix} = \begin{pmatrix} K_c^* \\ L_c^* \end{pmatrix} + \lambda_1^l c_1\mathbf{e}_1 + \lambda_2^l c_2\mathbf{e}_2. \tag{63}$$

As is depicted in the flow diagram (Fig. 10), if $c_l \neq 0$, the flow will in general run away from the critical fixed point (K_c^*, L_c^*), which is thus unstable toward the *relevant perturbation* $c_1\mathbf{e}_1$, which is characterized by $|\lambda_1| > 1$. On the other hand, if $c_1 = 0$, the flow will always tend toward this fixed point, because $|\lambda_2| < 1$ ($\mathbf{e}_2$ is called the *irrelevant* direction; had we included more coupling parameters initially, additional irrelevant directions would have emerged). The original nearest-neighbor model had $L_0 = 0$. Inserting this in Eq. (62) for $c_1 = 0$, one finds the critical value of K (within the linear approximation), for which the decimation transformation will lead into the critical fixed point, to be

$$K_c = \tfrac{1}{3}\left(1 + \frac{1}{\sqrt{10} + 2}\right) \approx 0.3979, \tag{64}$$

which should be compared to the mean-field and exact values, $K_c = 0.25$ and $K_c = 0.4406$, respectively. Note that $K - K_c = -J(T - T_c)/k_B T T_c$, and hence $c_1 \neq 0$ whenever $T \neq T_c$. In this case, the flow will tend toward either the zero-temperature (for $T < T_c$) or the disordered fixed point (for $T > T_c$).

After a sufficient number of steps λ_2^l will be minute, and

$$(K - K_c)_l = b^{y_1 l}(K - K_c), \tag{65}$$

where $b = \sqrt{2}$, and $y_1 = 2 \ln\lambda_1/\ln 2 \approx 1.566$. As also $\xi_l = b^{-l}\xi$, and the definition of the critical exponent ν for the correlation length translates to $\xi \propto |K - K_c|^{-\nu}$, one finds

$$\nu = 1/y_1 \approx 0.638, \tag{66}$$

which is already larger than the mean-field result $\nu = \frac{1}{2}$, but still far off the exact value $\nu = 1$.

Similarly, an external field h may be included in the scheme. The approximate recursion relation for h turns out to be

$$h' = (1 + K)h, \tag{67}$$

with the fixed point $h^* = 0$, and the eigenvalue for the linearized recursion relation is $\lambda_h = 1 + K_c^* = \frac{4}{3}$. Hence the external field constitutes a second relevant variable besides (essentially) $T - T_c$. Notice that the flows for K and h decouple. The two relevant fields τ and h precisely correspond to the two independent critical exponents of the model.

In addition, the universal properties of the phases, as the stiffness exponent θ in Eq. (13), can be determined in a similar way. For the stiffness, the most convenient way is to study the change in free energy of a finite system as the boundary conditions are changed, e.g., from periodic to antiperiodic (see Fisher, 1993). For an Ising system of linear dimension $L = b$ in d dimensions, the domain wall energy at $T = 0$ turns out to be

$$\Sigma \approx 2Jb^{d-1}, \tag{68}$$

and hence $\theta = d - 1$. Thus, a rescaling of the length by b is equivalent to a recursion relation for the temperature

$$T' = b^{-\theta}T \tag{69}$$

for the temperature, which shows that the stiffness exponent may be identified with the negative eigenvalue $\lambda_T = -\theta$ at the zero-temperature fixed point ($T^* = 0$). Equation (68) demonstrates that the ordered phase is stable for $d \geq 2$ in the Ising model. For Heisenberg models with continuous rotational symmetry, on the other hand, one finds $\theta = d - 2$, and no long-range order is possible in two dimensions. Note that mean-field theory fails to predict such a *lower critical dimension*, at and below which fluctuations destroy the formation of spatially homogeneous long-range order.

3.2.3 General Real-Space RG Transformations A general real-space RG transformation maps a certain spin system $\{\sigma\}$, defined on a lattice, and with Hamiltonian $H\{\sigma\}$, onto a new spin system $\{\sigma'\}$ with new Hamiltonian $H'\{\sigma'\}$ and by a factor of $N'/N = b^{-d}$ fewer degrees of freedom. It may be represented by a transformation $\tau\{\sigma',\sigma\}$, such that ($k_B T$ has been set equal to unity here)

$$e^{-F-H'\{\sigma'\}} = \sum_{\{\sigma\}} \tau\{\sigma',\sigma\} e^{-H\{\sigma\}}, \tag{70}$$

with the conditions

$$\sum_{\{\sigma'\}} H'\{\sigma'\} = 0 \tag{71}$$

and

$$\sum_{\{\sigma'\}} \tau\{\sigma',\sigma\} = 1, \tag{72}$$

which guarantee that $e^{-F}\,\mathrm{Tr}_{\{\sigma'\}} e^{-H'\{\sigma'\}} = \mathrm{Tr}_{\{\sigma\}} e^{-H\{\sigma\}}$.

Important examples for such transformations are decimation transformations, and linear as well as nonlinear block-spin transformations. Several types of approximations, like the cumulant expansion and cluster and finite-lattice approximations, have been applied to various kinds of lattices (quadratic, triangular, etc.), where a large number of interaction coefficients have been included. In two dimensions, critical exponents and thermodynamic properties as a whole have thereby been obtained to an impressive degree of accuracy (Niemeijer and van Leeuwen, 1976). A combination of numerical Monte-Carlo methods and real-space RG transformations leads to the *Monte-Carlo renormalization group* (Swendsen, 1984). Apart from that, however, the more versatile momentum-space methods (see Sec. 3.3 below) have been far more useful in higher dimensions ($d > 2$).

3.2.4 Emergence of Scaling Laws While the decimation procedure employing only a few parameters does not provide quantitatively satisfactory results, and also is inappropriate for the study of correlation functions, it still elucidates the general structure of RG transformations R, whereupon the original Hamiltonian H is mapped onto a new one, $H' = R(H)$ (this includes the rescaling of lengths in the problem, or for the degrees of freedom: $N' = Nb^{-d}$ in d dimensions). Near the fixed-point Hamiltonian $H^* = R(H^*)$, one may expand $R(H^* + \delta H) \approx H^* + L\delta H$, which yields the linearized recursion relation $\delta H' = L\delta H$. The eigenoperators δH_1, $\delta H_2 \ldots$ for this linear transformation are then determined by the eigenvalue equations

$$L\delta H_i = \lambda_i \delta H_i. \tag{73}$$

A given Hamiltonian H that does not differ too much from the fixed-point Hamiltonian may be expanded according to

$$H = H^* + \tau\delta H_\tau + h\delta H_h + \sum_{j\geq 3} c_j \delta H_j, \tag{74}$$

where δH_τ and δH_h denote the two relevant perturbations, $|\lambda_\tau| = b^{y_\tau} > 1$, $|\lambda_h| = b^{y_h} > 1$, connected with the temperature variable $T - T_c$ and the external field h, while $|\lambda_j| < 1$ (and hence $y_j < 0$) for $j \geq 3$ (in the Ising case, $\delta H_h = \Sigma_i \sigma_i$). The coefficients τ, h, and c_j are called *scaling fields*.

After l steps, the free energy per spin, $f(\{c_j\}) = F_N(\{c_j\})/N$, transforms according to

$$f(\tau,h,c_3,\ldots) = b^{-dl} f(\tau b^{y_\tau l}, h b^{y_h l}, c_3 b^{y_3 l},\ldots) \tag{75}$$

in the linear approximation. (Here we have omitted an additive term, which does not affect the following derivation of the scaling law, but would of course be important for the evaluation of the total free energy.)

The scale parameter l may now be chosen conveniently, for example $|\tau| b^{y_\tau l} = 1$, which sets the first argument of f equal to ± 1; this yields

$$f(\tau,h,\ldots) = |\tau|^{d/y_\tau} \hat{f}_\pm (h|\tau|^{-y_h/y_\tau}, c_3|\tau|^{|y_3|/y_\tau},\ldots), \tag{76}$$

where $\hat{f}_\pm(x,y,\ldots) = f(\pm 1,x,y,\ldots)$. Close to T_c, the dependence on the irrelevant fields $c_3, \ldots$ can be neglected, and Eq. (76) then precisely assumes the scaling form [Eq. (14)], with the exponents

$$\beta\delta = y_h/y_\tau \tag{77}$$

and

$$2 - \alpha = d/y_\tau. \tag{78}$$

Thus, the scaling law [Eq. (14)] has been derived within the RG theory for fixed points with precisely one relevant field, aside from the external magnetic field and the irrelevant operators. Furthermore, the dependence of the irrelevant fields $c_3, \ldots$ yields *corrections to scaling*, which may have to be taken into account in situations not yet close enough to T_c to be in the fully asymptotic regime.

In order to relate y_τ to the exponent ν, one has to recall that l iterations reduce the correlation length to $\xi' = b^{-l}\xi$, which implies $(\tau b^{y_\tau l})^{-\nu} = b^{-l}\tau^{-\nu}$, and thus

$$\nu = 1/y_\tau \tag{79}$$

[see Eq. (66) for the 2D Ising model]. Thus, with the basic assumption that there exists a fixed-point Hamiltonian with two relevant operators, the scaling form of the free energy could be derived, and moreover, a prescription for the calculation of the critical exponents is provided. A similar procedure may be followed for the correlation function [Eq. (9)]. At this point, the renormalization of the spin variables, $\sigma' = b^\zeta \sigma$, becomes important; it turns out that the choice

$$\zeta = (d - 2 + \eta)/2 \tag{80}$$

ensures the validity of Eq. (7) at the critical point.

We add some remarks on the generic structure of the flow diagram in the neighborhood of a critical fixed point (Fig. 11). In the multidimensional space of coupling coefficients, there will be one specific direction that leads away from the fixed point (the relevant direction). The other eigenvectors of the linearized RG transformation span the *critical hypersurface*. Further away from the fixed point, the hypersurface is no longer a plane but acquires some curvature. From any point on the critical hypersurface, the trajectories lead into the critical fixed point. If the starting point is close to but not at the critical hypersurface, the corresponding trajectory will first run parallel to the hypersurface until the relevant part becomes magnified sufficiently, so that finally the trajectory leaves the vicinity of the critical hypersurface, and turns off to either the low- or high-temperature fixed point. For a particular physical system (a ferromagnet, a binary mixture, etc.), the parameters will depend on the temperature (the long-dashed curve in Fig. 11). The temperature for which this curve intersects the critical hypersurface constitutes its transition temperature T_c.

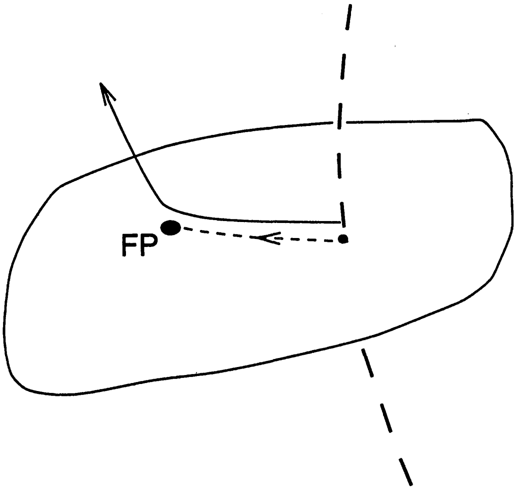

FIG. 11. Critical hypersurface. A trajectory in the critical hypersurface is shown dashed, and a trajectory starting close to the critical hypersurface is displayed as a full curve. The coupling coefficient of a particular physical system as a function of a control parameter is indicated by the long-dashed line.

From the above discussion, the universality property becomes obvious, too. All systems belonging to a particular part of parameter space, namely the region of attraction of a specific fixed point, are governed by the same scaling behavior and are described by identical power laws in the vicinity of the critical hypersurface of the fixed point.

3.3 Momentum-Shell Renormalization Group

3.3.1 Wilson's RG Scheme The RG method shall now be applied to the continuum model [Eq. (26)], called *Landau–Ginzburg–Wilson functional* in this context. A very intuitive approach was proposed by Wilson (Wilson and Kogut, 1974; Ma, 1976a). Basically, in momentum space the trace over the large-k degrees of freedom is performed, and thus recursion relations for the Ginzburg–Landau coefficients are obtained. Because the short-wavelength fluctuations are not expected to contribute essentially, the Brillouin zone may be approximated simply by a d-dimensional sphere with radius (cutoff)

Λ. The momentum-shell RG transformation then consists of the following steps:

1. Performing the trace over all Fourier components ϕ_k with $\Lambda/b < |k| < \lambda$ (Fig. 12) eliminates these short-wavelength modes.
2. By means of a scale transformation

$$k' = bk, \tag{81}$$

$$\phi' = b^{\zeta}\phi, \tag{82}$$

and therefore

$$\phi'_{k'} = b^{\zeta-d}\phi_k, \tag{83}$$

the ensuing effective Hamiltonian is brought to a form resembling the original model, by which then effective scale-dependent coupling parameters are defined.

By successive application of this RG transformation (which constitutes a semigroup, as there is no inverse element), the supposedly universal features of the long-wavelength regime are disclosed. The fixed points of the transformation will, as above, correspond to the distinct thermodynamic phases and the phase transitions between them. The eigenvalues of the linearized RG flow equations near the critical fixed point finally yield the critical exponents [see Eqs. (79), (77), and (78)].

Although a perturbational approach (with respect to u) is not at all justifiable in the critical region, it appears entirely sound in the region far from the critical point, where the fluctuations are negligible. The important observation now is that the RG flow connects these very different regimes, and thus results of the perturbation expansion obtained in the noncritical region can be transported to the vicinity of T_c, keeping track of the nonanalytic singularities on the way in a consistent, controlled, and reliable manner. Perturbative methods may also be employed in the elimination of the short-wavelength degrees of freedom (step **1**).

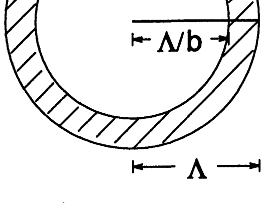

FIG. 12. Momentum-space RG: The partial trace is performed over Fourier components ϕ_k with momenta in the shell $\Lambda/b < |k| < \Lambda$.

3.3.2 Gaussian Model This concept shall now first be applied to the Gaussian model, where $u = 0$ (see Sec. 2.3.2),

$$\mathcal{F}_0[\phi_k] = \int_{|k|<\Lambda} \frac{r + k^2}{2} |\phi_k|^2 \tag{84}$$

[$\int_k = \int d^dk/(2\pi)^d$]. As Eq. (84) is diagonal in the Fourier modes, elimination of the large-k components simply produces constants; the form of the effective Hamiltonian is then unaltered, provided

$$\zeta = (d - 2)/2, \quad \text{i.e., } \eta = 0, \tag{85}$$

$$r' = b^2 r. \tag{86}$$

The fixed points of Eq. (86) are $r^* = \pm\infty$ corresponding to the high- and low-temperature phases, respectively, and the critical fixed point $r^* = 0$. The eigenvalue in the relevant temperature direction at this critical fixed point is obviously $y_\tau = 2$, and therefore the exponent $\nu = 1/2$ is recovered, as in mean-field theory.

3.3.3 Perturbation Theory and ϵ Expansion The nonlinear "interaction" term

$$\mathcal{F}_{\text{int}}[\phi_k] = \frac{u}{4} \int_{|k_i|<\Lambda} \phi_{k_1}\phi_{k_2}\phi_{k_3}\phi_{-k_1-k_2-k_3} \tag{87}$$

can now be treated perturbationally by expanding the exponential in Eq. (27) with respect to u. Separating the field variables into their parts in the outer and inner momentum shells, respectively, $\phi_k = \phi_{k_<} + \phi_{k_>}$, with $|k_<| < \Lambda/b$ and $\Lambda/b < |k_>| < \Lambda$, to first order in u one arrives at terms of the following (symbolically written) forms (henceforth, k_BT shall be set equal to 1):

1. $u \int \phi^4_< e^{-\mathcal{F}_0}$ just needs to be reexponentiated, for these degrees of freedom are not eliminated;

2. any terms with odd numbers of $\phi_<$ or $\phi_>$ like $u\int \phi_<^3\phi_> e^{-\mathcal{F}_0}$ vanish;
3. $u\int \phi_>^4 e^{-\mathcal{F}_0}$ yields a constant, contributing to the free energy; and finally
4. $u\int \phi_<^2\phi_>^2 e^{-\mathcal{F}_0}$, for which the Gaussian integral over the $\phi_>$ may be performed by using Eq. (43) for the *propagator* $\langle \phi_{k_>}^\alpha \phi_{-k_>'}^\beta\rangle_0$, an average calculated with the statistical weight $e^{-\mathcal{F}_0}$.

Quite generally, *Wick's theorem* states that expressions of the form $\langle \Pi_i^m \phi_{k_{i>}}\rangle_0$ factorize into a sum of products of all possible pairs $\langle \phi_{k_>}\phi_{-k_>}\rangle_0$, if m is even, and vanish otherwise. Especially for treating higher orders in perturbation theory, *Feynman diagrams*, with lines symbolizing the propagators, and *interaction vertices* standing for the nonlinear coupling u, provide a very helpful representation for the large number of contributions to be summed in the perturbation series.

With these means, the two-point function $\langle \phi_{k_<}\phi_{-k_<}\rangle$ and the similarly defined four-point function can be evaluated. Using Eq. (80), the following recursions for r and u are then obtained to first nontrivial order ("*1-loop*", a notation stemming from the graphical representation):

$$r' = b^2[r + (n+2)A(r)u], \tag{88}$$

$$u' = b^{4-d}u[1 - (n+8)C(r)u], \tag{89}$$

where A and C denote the integrals

$$\begin{aligned} A(r) &= K_d \int_{\Lambda/b}^{\Lambda} (k^{d-1}/r + k^2)dk \\ &= K_d[\Lambda^{d-2}(1 - b^{2-d})/(d-2) \\ &\quad - r\Lambda^{d-4}(1 - b^{4-d})/(d-4)] + O(r^2), \end{aligned}$$

$$\begin{aligned} C(r) &= K_d \int_{\Lambda/b}^{\Lambda} [k^{d-1}/(r + k^2)^2]dk \\ &= K_d\Lambda^{d-4}(1 - b^{4-d})/(d-4) + O(r), \end{aligned}$$

with $K_d = 1/2^{d-1}\pi^{d/2}\Gamma(d/2)$, and the factors containing the number of components n of the order-parameter field originate from the combinatorics of counting the equivalent ways for "contracting" the fields $\phi_{k_>}$, i.e., performing the integrals over the large momenta. Note that again Eq. (85) is valid here.

By linearizing Eqs. (88) and (89) at the Gaussian fixed point $r^* = 0$, $u^* = 0$, one immediately finds the eigenvalues $y_r = 2$ and $y_u = 4 - d$. Thus for $d > d_c = 4$, the nonlinearity $\propto u$ turns out to be irrelevant, and the mean-field exponents are valid, as has already been anticipated in Sec. 2.3.2. However, for $d < 4$ the fluctuations become relevant, and any initial $u \neq 0$ grows under renormalization. In order to obtain the scaling behavior in this case, we thus have to search for a nontrivial, finite fixed point. This is most readily done by introducing the differential flow again, via $b^l = e^{\delta l}$, and $\delta \to 0$, whereby the number of RG steps effectively becomes a continuous variable, and studying the ensuing differential recursion relations

$$\begin{aligned} \frac{dr(l)}{dl} &= 2r(l) + (n+2)u(l)K_d\Lambda^{d-2} \\ &\quad - (n+2)r(l)u(l)K_d\Lambda^{d-4}, \end{aligned} \tag{90}$$

$$\frac{du(l)}{dl} = (4-d)u(l) - (n+8)u(l)^2K_d\Lambda^{d-4}. \tag{91}$$

Namely, a fixed point is defined by the condition that $dr/dl = 0 = du/dl$. In Fig. 13, the flow of $u(l)$ according to Eq. (91) is depicted; for any initial value $u_0 \neq 0$ one finds that asymptotically, i.e., for $l \to \infty$, the nontrivial fixed point

$$u_c^* K_d = \frac{\epsilon}{n+8}\Lambda^\epsilon, \quad \epsilon = 4 - d, \tag{92}$$

is approached, which therefore describes scale-invariant behavior and should govern the universal critical properties of the model. Here, too, the RG procedure generates new interactions—for instance, terms $\propto \phi^6$ and $\nabla^2\phi^4$, etc., which in successive steps couple back into the recursion relations for r and u. However, it turns out that up to order ϵ^3 these terms may be disregarded.

The original assumption that u be small, justifying a perturbation expansion, now means that the effective expansion parameter here is the deviation from the upper critical dimension ϵ. Inserting this in Eq. (90) and collecting the terms of $O(\epsilon)$, one finds

$$r_c^* = -\frac{n+2}{2}u_c^* K_d\Lambda^{d-2} = -\frac{(n+2)\epsilon}{2(n+8)}\Lambda^2; \tag{93}$$

the physical interpretation for this result is

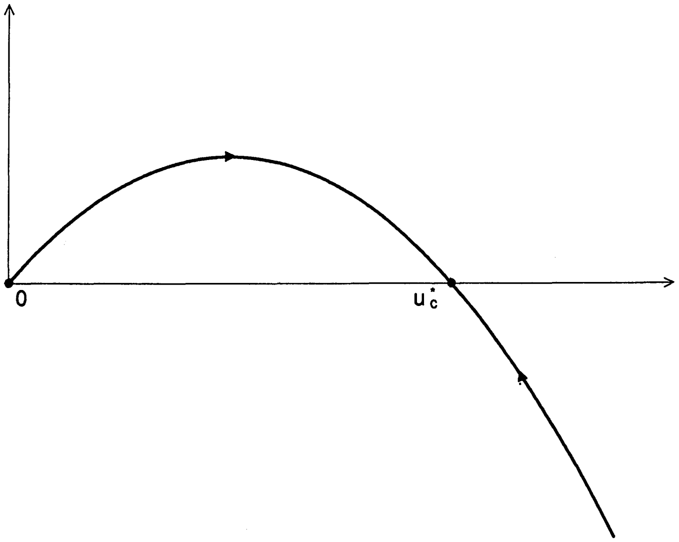

FIG. 13. Flow of the effective coupling $u(l)$, as determined from the right-hand side of Eq. (91). Both for initial values $u_0 > u_c^*$ and $0 < u_0 < u_c^*$, one has $u(l) \to u_c^*$ for $l \to \infty$.

that the fluctuations lead to a downward shift of the transition temperature. Finally, with $\tau = r - r_c^*$, the differential flow equation

$$\frac{d\tau(l)}{dl} = \tau(l)[2 - (n + 2)uK_d\Lambda^{d-4}] \qquad (94)$$

yields the eigenvalue $y_\tau = 2 - (n + 2)\epsilon/(n + 8)$ near the critical fixed point [Eq. (92)]. To one-loop order, $O(\epsilon)$, one therefore finds the critical exponent

$$\nu = \tfrac{1}{2} + \frac{n + 2}{4(n + 8)}\epsilon + O(\epsilon^2). \qquad (95)$$

Using $\eta = O(\epsilon^2)$ and the scaling relations (15), (16), and (19), one arrives at the following results [note the remarkable difference from the result of Eq. (39), obtained within the Gaussian approximation]:

$$\alpha = \frac{4 - n}{2(n + 8)}\epsilon + O(\epsilon^2), \qquad (96)$$

$$\beta = \tfrac{1}{2} - \frac{3}{2(n + 8)}\epsilon + O(\epsilon^2), \qquad (97)$$

$$\gamma = 1 + \frac{n + 2}{2(n + 8)}\epsilon + O(\epsilon^2), \qquad (98)$$

$$\delta = 3 + \epsilon + O(\epsilon^2) \qquad (99)$$

to first order in the expansion parameter $\epsilon = 4 - d$. The first nontrivial contribution to the exponent η turns out to appear at two-loop order,

$$\eta = \frac{n + 2}{2(n + 8)^2}\epsilon^2 + O(\epsilon^3). \qquad (100)$$

The universality of these results becomes manifest by the fact that they depend solely on the space dimension d and the number of order-parameter components n, and not on the original "microscopic" Ginzburg–Landau parameters. (In passing, we note that for long-range power-law interactions, $\propto |x|^{-(d+\sigma)}$, the critical exponents acquire an additional dependence on the parameter σ.) At the upper critical dimension, $d_c = 4$, the solution of Eq. (91) becomes an inverse power law instead of an exponential, which leads to logarithmic corrections to the mean-field exponents.

Differential recursion relations of the form of Eqs. (90) and (91) also constitute the basis for the treatment of more subtle issues, like the calculation of the scaling functions, or even *crossover phenomena*, within the RG approach. For instance, an anisotropic perturbation in the n-component Heisenberg model favoring m directions leads to a crossover from the O(n) Heisenberg fixed point to an m-component fixed point (see Amit, 1984, Chap. 5-3). The instability of the former is described by a crossover exponent. For a small anisotropic perturbation, the RG flow trajectory still comes very close to this unstable fixed point, which implies that further away from T_c the system behaves like an n-component system, before it is finally dominated by the anisotropic critical behavior. The crossover from one RG fixed point to another may be illustrated (and measured) by introducing *effective exponents*, defined as logarithmic derivatives of appropriate physical quantities. Other important perturbations that have been treated in the framework of RG theory are so-called cubic terms reflecting the underlying crystal structure, and contributing a fourth power of the Cartesian components of ϕ, as well as the dipolar interaction that alters the harmonic part of the theory.

For systems characterized by certain spatial anisotropies, the upper critical dimension may be shifted from $d_c = 4$ to lower values as a result of restricted space for fluctuations. For example, for uniaxial dipolar ferromagnets $d_c = 3$, as well as for tricritical points, where $u = 0$ and a sixth-order term in ϕ is required. In the case of elastic structural phase transitions, for instance, one finds $d_c = \frac{5}{2}$ or $d_c = 3$, for a one- or two-dimensional soft sector, respectively (Schwabl, 1985).

3.3.4 More Sophisticated Field-Theoretical Methods Once one has to go beyond the first order in the perturbation expansion, Wilson's k-shell renormalization scheme, despite its very intuitively appealing features, is not the best choice for practical calculations. The technical reason is that the integrals in Fourier space involve nested momenta, and become rather tedious with a finite cutoff Λ. Thus, it appears more convenient to use a field-theoretical renormalization scheme, where $\Lambda \to \infty$ (Amit, 1984). Yet this leads to additional ultraviolet (UV) divergences in the integrals for $d \geq d_c$. Observing that at the critical dimension d_c both the ultraviolet and infrared (IR) singularities appear combined in logarithmic form [$\propto \ln(\Lambda^2/r)$], the idea is to treat the UV divergences with the methods originally developed in quantum field theory, and through this diversion arrive at the correct scaling equations for the opposite, IR limit.

Formally, this is done by taking advantage of the fact that the original unrenormalized theory does not depend on an arbitrarily chosen renormalization point; as a consequence one is led to the *Callan–Symanzik* or *RG equation*. This is a partial differential equation, which, when solved via the method of characteristics, leads to a set of ordinary differential equations that resemble the differential flow equations in Wilson's scheme. This procedure may be pursued provided the theory is renormalizable, which for the ϕ^4 theory is the case for $d \leq d_c$. However, this also means that irrelevant operators cannot, at least without considerable precautions, be included in the scheme. The field-theoretical treatments are therefore confined to the critical manifold in parameter space; yet, for the universal properties of the system under consideration, they yield fully equivalent results as compared with the momentum-shell approach.

ϵ expansions have been carried out up to seventh order; the resulting series is, however, only asymptotically convergent (quite obviously, the convergence radius of the perturbation series in u must be zero, as $u < 0$ corresponds to an unstable theory). Yet, by a combination of these fairly high-order results with the divergent asymptotic behavior and Borel-type resummation techniques, the critical exponents can be obtained with impressive accuracy; see Table 1 (Le Guillou and Zinn-Justin, 1985).

Near the lower critical dimension of the O(n) ($n \geq 2$) symmetric Heisenberg model, $d = 2$ (for the Ising case, $n = 1$, the lower critical dimension is $d = 1$; see Sec. 3.2.1), the ϵ expansion does not provide very accurate results, as might be expected. Near two dimensions, the investigation of the O(n)-symmetric nonlinear σ model by means of a $2 + \epsilon$ expansion, with a nontrivial fixed point of order ϵ corresponding to T_c, has proven to be more valuable (see Amit, 1984).

Besides the ϵ expansion, an expansion in terms of powers of $1/n$ is possible, where the limit $n \to \infty$ corresponds to the exactly solvable spherical model (Ma, 1976b). While this approach may help to clarify certain general issues, it is usually less accurate numerically, though, for the small values of n that are of practical interest.

Table 1. Best estimates for the static critical exponents γ, ν, β, and δ for the O(n)-symmetric ϕ^4 model in $d = 2$ and $d = 3$ dimensions, as obtained from large-order ϵ expansion in combination with Borel resummation techniques (from Le Guillou and Zinn-Justin, 1985). For comparison, the exact Onsager results for the 2D Ising model are also listed. The limit $n = 0$ describes the statistical mechanics of polymers.

		γ	ν	β	η
$d = 2$	$n = 0$	1.39 ± 0.04	0.76 ± 0.03	0.065 ± 0.015	0.21 ± 0.05

4. SCALING LAWS IN STATISTICAL PHYSICS

4.1 Phase Transitions and Properties of Phases

Phenomenological Ginzburg–Landau expansions, scaling approaches, and the language and methods of RG methods have become fundamental tools in the study of phase transitions and of other universal properties of condensed-matter phases, in a large variety of systems. A list (incomplete) includes structural phase transitions of various kinds, namely distortive, ferroelectric, order-disorder, and elastic transitions (see PHASE TRANSITIONS, STRUCTURAL; COLLECTIVE PHENOMENA IN SOLIDS), liquid crystals (see LIQUID CRYSTALS, STRUCTURE OF), magnetic systems (see MAGNETIC ORDERING IN SOLIDS), magnetic impurities in a lattice (*Kondo problems*; see Wilson, 1975), superfluidity (see SUPERFLUIDITY: LIQUID HELIUM SYSTEMS), and superconductivity (see SUPERCONDUCTIVITY, LOW-TEMPERATURE); here specifically the numerous phases of type-II superconductors subject to an external magnetic field have aroused considerable interest lately (see SUPERCONDUCTIVITY, HIGH-TEMPERATURE, and Blatter *et al.*, 1994). Complex scaling and crossover behavior may ensue when either anisotropies or additional long-range interactions are included.

Finite-size scaling studies how the asymptotic power laws of the thermodynamic limit are approached as the system size grows, and is thus an important tool for numerical studies of continuous phase transitions (Privman, 1990). Furthermore, the fact that all real systems are finite leads to additional interesting phenomena. At surfaces, new critical exponents may come into play (Diehl, 1986). Also, interfacial structures may change drastically as external parameters are varied; an important example is the wetting transition of liquid drops on a substrate (Dietrich, 1988).

Scaling and RG concepts have also been applied to the theory of symmetry breaking in the fundamental field theories of matter (see UNIFIED FIELD THEORIES), which also have important implications for cosmology (see GALAXIES AND COSMOLOGY). (We note that in elementary-particle physics a Compton wavelength $\lambda_c = \hbar c/m$ may be assigned to a particle of rest mass m. For large momenta $\hbar k \gg mc$, the theory becomes scale invariant, and the propagator behaves as $k^{-2+\eta}$. The correlation length ξ thus corresponds to the Compton wavelength or inverse mass.)

4.2 Disordered Systems

In many physical systems, disorder plays an important role. The basic question therefore is, under what circumstances can quenched randomness affect the nature of a phase transition and its properties. Let the disorder induce a relevant perturbation $g(x)$ in the effective Hamiltonian, e.g., changing the harmonic part of the Landau–Ginzburg–Wilson functional (*random* T_c), the scaling dimension of which is $[g] \propto L^{\Delta-d}$, with $\Delta \leq d$. The *Harris criterion* then states that the character of the pure transition may be considerably affected by the disorder, provided $\Delta < d/2$ (Itzykson and Drouffe, 1989). If defects of this kind are correlated only over short distances, this criterion says that the critical behavior is changed if the specific-heat exponent of the pure system is positive ($\alpha > 0$).

On the other hand, in the case of *random fields*, both the upper and lower critical dimensions can be changed as compared with the pure case. The *Imry–Ma argument* (see Nattermann and Villain, 1988) compares the interfacial energy $\propto L^\theta$ [Eq. (13)] with the gain in bulk free energy $\propto L^{d/2}$ by splitting into domains of size L (the mean square order-parameter fluctuations due to the random field add up to a contribution $\propto L^d$ for each domain). Thus, for $\theta \leq d/2$, the system will always break into domains and no long-range order can emerge. For Ising systems ($\theta = d - 1$), this will be true for $d \leq 2$, while in the case of continuous symmetry ($\theta = d - 2$) the lower critical dimension becomes $d = 4$.

An example for such disorder-dominated systems is *spin glasses*, e.g., an Ising spin glass with bond disorder, where the couplings J_{ij} in Eq. (21) are drawn from some stochastic distribution. Similarly, disorder can be introduced in Heisenberg models [Eq. (25)]. Because spin glasses are model systems for phase transitions in highly disordered materials, a considerable amount of effort has been devoted to the examination of such spin glasses (Binder and Young, 1986). In addition to the thermal average, all physical quantities have to be averaged over all possible configurations of the quenched disorder. A frequently used method in analytical calculations is the *replica trick*, which replaces the computation of the mean free energy by the average of the nth power of the partition function, and then entails taking both the derivative with respect to n and the limit $n \to 0$:

$$\bar{F} = -\lim_{n\to 0} \frac{\partial}{\partial n} \overline{Z^n}. \qquad (101)$$

Extensions of these studies have led to the investigation of manifolds in random media, a direct application of which may be found in biological membranes, or flux lines in high-T_c superconductors, and the design of neural networks (see NEURAL NETWORKS).

Disorder may also play a prominent role in the quantum regime ($T \to 0$). While near a phase transition with finite T_c quantum fluctuations are of minor importance (although quantum effects may provide the fundamental mechanism for the transition itself, as in magnets, superfluids, and superconductors), at $T = 0$ the interplay between disorder and quantum mechanics can lead to very interesting novel phases with unusual phase transitions. Examples of such quantum critical phenomena (see Continentino, 1994) are electron localization (see ELECTRON STATES, LOCALIZED), metal-insulator transitions (see METAL-INSULATOR TRANSITIONS; Belitz and Kirkpatrick, 1994), helium-4 on disordered substrates (disordered bosons), and quantum antiferromagnets, which are of relevance in the microscopic theory of high-temperature superconducting materials and as one phase of solid helium-3. For a Fermi system, the interesting singularities and the universal behavior are expected in the vicinity of the Fermi surface, instead of the point $k = 0$ in Fourier space, and therefore the RG approach has to be modified accordingly (Shankar, 1994).

The mathematical theory of percolation also has immediate applications for the structure of certain disordered systems, and their transport properties (see FRACTAL GEOMETRY; Bunde and Havlin, 1991). The percolation threshold may be understood as a critical point, and the scaling behavior in its vicinity can be obtained by mapping onto the so-called Potts model (Wu, 1982), and with the help of certain continuum models of the same universality class.

4.3 Polymers, Membranes

An important ingredient to the physics of macromolecules like polymers is the interplay and competition of energetic and entropic optimization. De Gennes has demonstrated that the partition function of a polymer, or the statistics of a self-avoiding random walk, can be mapped to the $n \to 0$ limit of the n-component Heisenberg model (see Table 1). As a consequence, scaling and RG approaches to the static and dynamic properties of polymers have been successfully employed (see POLYMERS, STRUCTURE OF; De Gennes, 1979; Freed, 1987). The inverse separation from the critical point $|\tau|^{-1}$ formally corresponds to the degree of polymerization (chain length) N of a long flexible polymer, and, e.g., in a dilute solution in a good solvent the average end-to-end distance of the polymer scales as $R_e \propto N^\nu$, where $\nu \approx 0.588$ (in three dimensions) is the $n = 0$ result for the correlation length exponent of the O(n) model. Naturally, similar attempts have been used for biological systems like muscular fibers and membranes (see STATISTICAL PHYSICS OF MEMBRANES AND LAMELLAR SYSTEMS).

4.4 Critical Dynamics and Nonequilibrium Phenomena

In Sec. 1.4, the extension of the above scaling concepts to dynamical phenomena was mentioned. The order-parameter dynamics displays critical slowing down near a second-order phase transition, described by the critical exponent z [Eq. (11)]. One very powerful and common mathematical description of critical dynamics rests on *Langevin-type equations of motion* (see STOCHASTIC PROCESSES) for the order-parameter fluctuations and the conserved quantities, which constitute the *slow modes* of the system (Hohenberg and Halperin, 1977; Enz, 1979). For, as a consequence of the continuity equation related to a conservation law, the corresponding density shows diffusive behavior (inverse relaxation time $t_0^{-1} \propto k^2$). In a phase with broken continuous symmetry, in addition the fluctuations transverse to the order parameter have to be included, for their static susceptibility is also singular for $k \to 0$ [Eq. (47)], and thus the corresponding mode has frequency $\propto \chi^{-1/2}$, and damping coefficient $\propto \chi^{-1}$. Collecting all these slow modes in a multicomponent field $\Phi(x,t)$, the equations of motion assume the general form

$$\frac{\partial \Phi^\alpha(x,t)}{\partial t} = K[\Phi] - \Gamma^\alpha \frac{\delta \mathcal{F}[\Phi]}{\delta \Phi^\alpha(x,t)} + \zeta^\alpha(x,t). \tag{102}$$

Here, $K[\Phi]$ comprises the reversible forces, as obtained from the microscopic equations of motion. The second term provides a damping term, which after some small perturbation drives the system back into the equilibrium state, where $\delta\mathcal{F}/\delta\Phi = 0$; the damping coefficients Γ^α are constants for the order-parameter fluctuations, if the latter is not conserved, and take the form $\lambda\nabla^2$ for each conserved quantity. Finally, all "fast" modes have been subsumed in the stochastic forces $\zeta^\alpha(x,t)$, whose mean is taken to be zero, $\langle\zeta^\alpha(x,t)\rangle = 0$, and whose second moments are, for simplicity, assumed to be drawn from a Gaussian distribution with a variance corresponding to "white noise":

$$\langle\zeta^\alpha(x,t)\zeta^\beta(x',t')\rangle = 2k_B T\Gamma^\alpha\delta^{\alpha\beta}\delta(x - x')\delta(t - t'). \tag{103}$$

The *fluctuation-dissipation theorem (Einstein relation)* [Eq. (103)] assures that for $t \to \infty$ the probability distribution is given by the equilibrium expression $\exp(-\mathcal{F}/k_B T)$.

The set of Eqs. (102) with (103) can then be very elegantly mapped onto a dynamic functional, and the ensuing field theory can be treated with precisely those perturbation expansions and RG methods explained above for the statics. In some cases, the underlying symmetries and/or conservation laws lead to so-called *Ward identities*, which yield a connection between the dynamic exponent z and already known static indices, prominently η. For example, for a model merely consisting of a conserved order-parameter field (model B according to the classification of Hohenberg and Halperin, 1977), the result is $z = 4 - \eta$; for the isotropic ferromagnet (model J) one finds $z = (d + 2 - \eta)/2$, and for planar ferromagnets as well as isotropic antiferromagnets (models E and G, respectively), $z = d/2$. In Table 2, a list of dynamical systems, with the corresponding values of z, and the physical quantities for which the critical slowing down can be observed in experiment, is presented. Note that although the range of the dynamical critical exponent is limited to $\frac{3}{2} \le z \le 4$ in three dimensions, the ensuing behavior of the transport coefficients can yet be as different as the diverging magnetization diffusion $D_M \propto |\tau|^{-1/3}$ for an isotropic antiferromagnet, and the vanishing order-parameter relaxation rate $\Gamma \propto |\tau|$ in the same system, or the vanishing magnetization diffusion constant $D_M \propto |\tau|^{1/3}$ for an isotropic Heisenberg ferromagnet.

An alternative route to finding these exponents, and probably superior for the issue of precisely calculating the scaling functions, is the *mode-coupling* approach, which at least in some cases may be represented as a self-consistent one-loop theory for the generalized (i.e., wave-number– and frequency-dependent) transport coefficients (Frey and Schwabl, 1995).

Another physical situation, where equations of motion of the type in Eq. (102) and a RG approach have been used, is the problem of quenching a system from above T_c into the low-temperature phase, and observing

Table 2. Dynamic critical exponents z in d dimensions, for various dynamical systems, along with a list of the physical quantities, and their temperature dependence in the vicinity of T_c, for which the ensuing critical slowing down may be observed experimentally (classification according to Hohenberg and Halperin, 1977). The approximate numerical results are for the three-dimensional case, using $\nu \approx \frac{2}{3}$, $\eta \approx 0$, and $\alpha \approx 0$.

System	Model	Dynamic exponent	Physical quantity
Anisotropic magnet	A	$z = 2 + c\eta,\ c = O(1)$	Relaxation rate $\Gamma \propto \lvert\tau\rvert^{z\nu} \approx \lvert\tau\rvert^{4/3}$
Uniaxial ferromagnet	B	$z = 4 - \eta$	Magnetization diffusion $D_M \propto \lvert\tau\rvert^{(z-2)\nu} \approx \lvert\tau\rvert^{4/3}$
Structural phase transitions	C	$z = 2 + \alpha/\nu$	Relaxation rate $\Gamma \propto \lvert\tau\rvert^{z\nu} \approx \lvert\tau\rvert^{4/3}$
Planar ferromagnet	E	$z = d/2$	Magnetization diffusion $D_M \propto \lvert\tau\rvert^{z\nu} \approx \lvert\tau\rvert$
Superfluid helium-4	F	$z = \frac{1}{2}(d + \tilde{\alpha}),\ \tilde{\alpha} = \max(\alpha,0)$	Thermal conductivity $\lambda_T \propto \lvert\tau\rvert^{(z-2)\nu} \approx \lvert\tau\rvert^{-1/3}$ (+ logarithmic corrections)
Isotropic antiferromagnet	G	$z = d/2$	Order-parameter relaxation $\Gamma_N \propto \lvert\tau\rvert^{z\nu} \approx \lvert\tau\rvert$ Magnetization diffusion $D_M \propto \lvert\tau\rvert^{(z-2)\nu} \approx \lvert\tau\rvert^{-1/3}$
Isotropic Heisenberg ferromagnet	J	$z = \frac{1}{2}(d + 2 - \eta)$	Magnetization diffusion $D_M \propto \lvert\tau\rvert^{(z-2)\nu} \approx \lvert\tau\rvert^{1/3}$

how the ordered domains grow with time (Bray, 1993).

Upon relaxing the condition of Eq. (103), the same methods may also be applied to phase transitions in nonequilibrium systems. A prototypical example might be the Burgers–Kardar–Parisi–Zhang equation, which is supposed to describe the kinetic roughening of growing surfaces (Family and Vicsek, 1991), but is also intimately connected to the problem of directed lines in random environment, and to the hydrodynamics of randomly stirred fluids. Related issues are the depinning transitions of lines and interfaces, and the dynamics of charge-density waves. The behavior of interfaces in disordered systems in general poses a number of most interesting issues and requires certain new conceptual approaches (see Forgacs *et al.*, 1991).

The properties of systems very far from equilibrium, well within the scope of scaling approaches and RG methods, turn out to be remarkably rich. On the one hand, there is the vast field of nonequilibrium pattern formation (Cross and Hohenberg, 1994). On the other hand, self-similar and self-affine structures emerge in many dynamical processes (see FRACTAL GEOMETRY), which are hence good candidates for the application of the above methods. The ubiquity of fractals and $1/f$ noise has led to the paradigm of *self-organized criticality (SOC)* (reviewed in Bak and Creutz, 1994). SOC refers to the tendency of large dissipative systems to drive themselves into a self-similar critical state without the special adjustment of parameters. SOC has been suggested for avalanches in sand piles, earthquake statistics, evolution, spreading of diseases, forest fires, and many others (Bak and Creutz, 1994). In the so-called forest-fire model, one finds SOC if a certain double separation of time scales holds (which represents still a large region in parameter space), while in other regions of the parameter space spiral structures emerge (Drossel and Schwabl, 1994).

At any rate, scaling ideas and the language of the renormalization group, including such concepts as effective Hamiltonians, relevant and irrelevant perturbations, fixed points, diverging correlation lengths, self-similarity and power laws, and universal long-wavelength and low-frequency behavior of collective modes, as well its powerful mathematical tools, have provided considerable new insight into the physics of many important research areas, and it seems likely that more interesting applications will be discovered in the future.

GLOSSARY

Asymptotic Regime: Region near the critical point where the relevant perturbations dominate, leading to pure power laws.

Corrections to Scaling: Contributions of irrelevant operators to thermodynamic quantities.

Correlation Length: Length scale for the spatial decay of correlations, usually a function of the external control parameters (temperature, magnetic field, etc.).

Critical Exponents: Exponents describing the power laws at continuous phase transitions.

Critical Slowing Down: Decrease of the order-parameter decay or oscillation rate ω_c, characterized by the dynamic exponent z; cf. Eq. (11).

Critical Surface: Hypersurface in parameter space with the property that all RG trajectories starting on it lead into the critical fixed point.

Crossover: Change in scaling behavior from power laws characterized by a certain unstable fixed point to different power laws governed by the asymptotically stable fixed point.

Effective Theory: Mathematical model describing the long-wavelength and low-frequency behavior of a physical system, at a certain energy scale.

Fixed Point: Point in the space of coupling coefficients that remains invariant under the RG transformation.

Lower Critical Dimension: Borderline dimension below which a certain model or physical system does not have a phase transition leading to long-range order.

Order Parameter: Certain macroscopic quantity that may be used to characterize different phases.

Relevant and Irrelevant Perturbations: Eigenoperators of the linearized RG transformation that grow and decrease, respectively, under successive RG steps.

Renormalization-Group (RG) Transformation: Operation by which a Hamiltonian is transformed into a new one, with a reduced number of degrees of freedom, accompanied by a subsequent scale transformation.

Scaling Law: Mathematical expression of the fact that at a critical point the free energy and correlation functions are scale invariant, i.e., are generalized homogeneous functions.

Scaling Relations: Equations that relate certain critical indices, thus reducing the number of independent exponents.

Universality: The fact that critical properties depend only on global properties such as the dimension and the symmetry and number of components of the order parameter.

Upper Critical Dimension: Borderline dimension above which the critical exponents of a certain model or physical system are correctly given by their mean-field values. Below the upper critical dimension, fluctuations are relevant and affect the scaling behavior.

INTRODUCTION

When crystalline materials are subjected to changes of temperature *T*, pressure *P*, magnetic field *H*, etc., they will change their atomic arrangements. If such changes involve topological modifications of the crystal structure and/or changes of symmetry, the various structures represent phases with structural phase transitions (SPTs) between them.

A typical example for a phase transition between a hexagonal structure (at high temperatures) and a trigonal structure (at low temperatures) is shown for quartz (SiO_2) (Fig. 1). Small rotations of SiO_4 tetrahedra destroy the hexagonal symmetry and lead to a denser arrangement of tetrahedra at low temperatures. The amplitudes of the various polyhedra tilts increase with decreasing temperature, whereas no such tilts exist at temperatures above the transition point. This transition mechanism, with gradual and mostly very subtle atomic shifts, is termed "displacive." (A more precise definition of the term "displacive" is based on the appearance of soft phonons as fundamental excitation of such systems; a simple static picture is given later.)

Symmetry breaking can occur via many other mechanisms. A common mechanism involves the ordering of different sorts of atoms on various positions in a crystal structure. This process is often seen in alloys, which may form a random distribution of metal atoms such as Cu and Au at high temperatures but an ordered structure at low temperatures. Another example, more similar to that of quartz, is the feldspar structure. Feldspars are most common materials: ca. 60% of the outer crust of the planet Earth is made from feldspars and related materials. In Fig. 2, the framework of feldspar at high and low temperatures is depicted. In each case, the structure is made up from oxygen tetrahedra with a metal position inside. This metal atom can be Al or Si. At high temperatures, Al and Si are disordered; at low temperatures, they are ordered whereby the order starts at a well-defined transition temperature. The degree of order increases when cooled further. Note that the AlO_4 and SiO_4 tetrahedra have different sizes so that the ordering of Al and Si is accompanied by local strain in the structure, which accommodates for the appropriate atomic ordering. SPTs in which the essential mechanism is related to changes of atomic order are usually called "order-disorder" (or simply od).

Many other transition mechanisms exist, and it is not just temperature that acts as the relevant variable to generate SPTs but also pressure, variations of the chemical composition, etc. Furthermore, all these mecha-

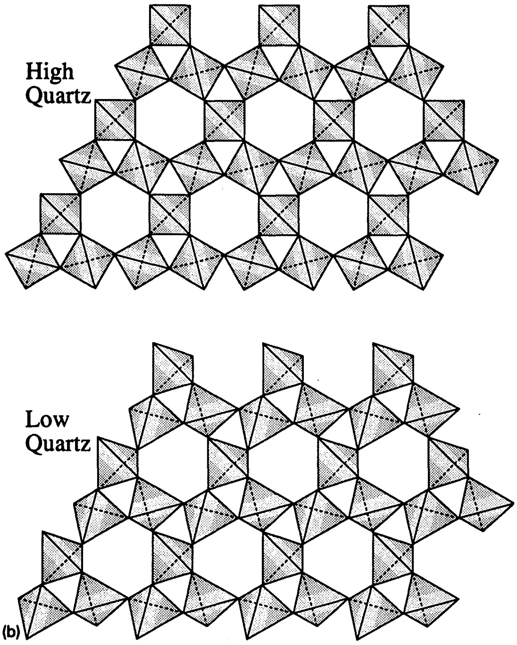

FIG. 1. Crystal structures of quartz at temperatures above and below the transition temperature. Rather rigid SiO_4 tetrahedra build up a framework that reduces its specific volume at low temperature via tilts of the tetrahedra. Courtesy A. Putnis, Cambridge.

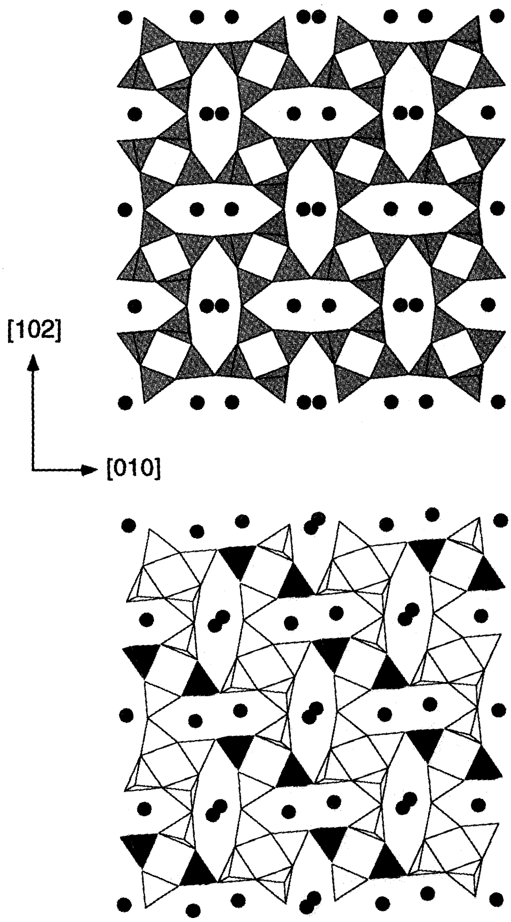

FIG. 2. Structural changes in alkali feldspars (Na,K)-$AlSi_3O_8$: the high-symmetry form is monoclinic with random distribution of Al and Si on tetrahedral sites. The alkali atom reflects the overall monoclinic symmetry (top). The triclinic, low-symmetry form shows Al ordered on the black tetrahedra whereas Si is inside the unshaded tetrahedra. The monoclinic symmetry is broken during the STP. The locations of alkali atoms are indicated by the circles. Courtesy D. Palmer, Cambridge.

nisms can interplay, so that materials often show several SPTs, each of which influences all others. It is an essential first step for research on SPTs to disentangle the various contributions (Landau and Lifshitz, 1980; Bruce and Cowley, 1981; Khatchaturyan, 1983; Levanyuk and Sigov, 1988; Salje, 1993b).

1. ENTROPIC EFFECTS FOR TEMPERATURE-DRIVEN SPTs

A SPT occurs when the enthalpic energy H is compensated by entropy S so that the Gibbs free energy $G = H - TS$ changes sign. A simple atomistic picture illustrates this mechanism (Salje *et al.*, 1991). Let us first consider local potentials that are anharmonic so that the midpoint of the potential is not necessarily at an energy minimum (Fig. 3). The second energy contribution is the coupling between the relevant atomic positions. In SPT, this communication is mainly achieved by elastic deformation of the structure (structural stress) or via electric dipolar forces. In both cases, the effective interaction decays as $1/R^3$ with increasing distance R. This long-ranging effective interaction together with its strong directional dependencies (in contrast to nearest-neighbor Ising models) allows us to summarize the effect of all interactions on each atom as a field ("mean field theory," MFT), and we may depict the interatomic coupling as a simple spring (Fig. 3). The effective Hamiltonian of this model is then the sum over the kinetic energy, the local potentials, and the coupling energy:

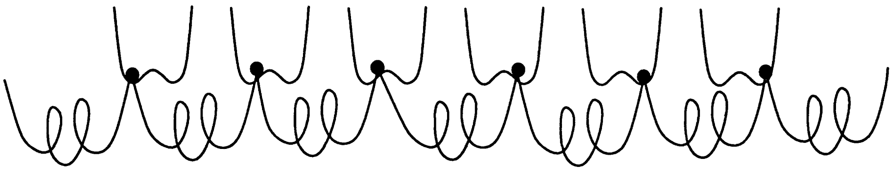

FIG. 3. Simple model representing a physical system with nonharmonic local potentials and harmonic intersite interactions.

$$H = \sum_l \left(\frac{1}{2M}P_l^2 + \frac{1}{2}M\Omega_{ol}^2 Q_l^2 + \frac{1}{2}uQ_l^4 + \cdots\right) - \frac{1}{2}\sum_{l\neq l'} v_{ll'}Q_lQ_{l'}. \tag{1}$$

Here M is the effective atomic mass, P is the momentum, Ω_{ol} is the local frequency for small oscillations around the local energy minimum at site l if it were purely parabolic in the absence of interatomic interactions, u gives the strength of the anharmonicity, and $v_{ll'}$ are the coupling constants that form the amplitudes Q_l on site l and $Q_{l'}$ on site l'. We can now define an order parameter Q as the time- and space-averaged value of the position coordinates Q_l on all sites l. This average value is denoted by angular brackets $Q = \langle Q_l \rangle$. If the average position is situated in the middle of the potential, we find $Q = 0$. If the average position is shifted to the right or the left, we find $Q > 0$ or $Q < 0$. One sees already in this simple model that $Q = 0$ represents a high-symmetry phase, whereas $Q > 0$ and $Q < 0$ represent a low-symmetry phase. If the low-symmetry phase contains macroscopic areas with $Q > 0$ and others with $Q < 0$, these areas are called "domains" with "domain walls" between them. The order parameter is a one-dimensional parameter in this simple model; higher dimensional order parameters are needed in 3D structures with high crystallographic symmetries. If the site ordering is not uniform, the order parameter is defined as the relevant Fourier component of $\langle Q_l \rangle$:

$$\langle Q_l \rangle = Q = Q_0 \exp(-i\mathbf{q}\cdot\mathbf{r}).$$

Thermal fluctuations occur around the order parameter, with

$$\sigma = \langle (Q_l - Q)^2 \rangle,$$

which depend on temperature via the dissipation-fluctuation theorem as

$$\sigma = \frac{\hbar}{2M\Omega}\coth\frac{\hbar\Omega}{2k_\mathrm{B}T}. \tag{2}$$

The Gibbs free energy G can then be calculated in MFT at the wave vector q at which long-range order with the order parameter (OP) $Q = \langle Q_l \rangle$ occurs. The SPT occurs when G changes sign with $Q = 0$ in the high-symmetry phase and a gradual increase of $Q \neq 0$ in the low-symmetry phase.

Approximate solutions exist for three regimes, which are characterized by a parameter $\Delta = v/M\Omega_0^2 - 1$ that vanishes when the intersite coupling compensates the parabolic part of the on-site potential. We furthermore define two temperatures. Firstly, T_c defines the temperature below which the high-symmetry phase becomes unstable. Secondly, thermal fluctuations saturate at temperatures below $\theta_s = \hbar\Omega_0/2k_\mathrm{B}$, whereas at $T \gg \theta_s$ fluctuations increase linearly with temperature [Eq. (2)].

The three solutions mostly used for the analysis of experimental observations are the following.

1.1 Displacive Phase Transitions

These have $0 \leqslant \Delta \ll 1$, and

$$G = \tfrac{1}{2}A\theta_s\left[\coth\frac{\theta_s}{T} - \coth\frac{\theta_s}{T_c}\right]Q^2 + \tfrac{1}{4}BQ^4 + \tfrac{1}{6}CQ^6, \tag{3}$$

which becomes for $\theta_s \ll T$ the standard Landau potential

$$G = \tfrac{1}{2}A(T - T_c)Q^2 + \tfrac{1}{4}BQ^4 + \tfrac{1}{6}CQ^4. \tag{4}$$

Here Q follows from the minimum condition

$\partial G/\partial Q = 0$ (see below). Note that the standard Landau potential is a high-temperature approximation and does not hold at temperatures at which the quantum-mechanical treatment of phonons becomes relevant.

1.2 "Almost" Displacive Transitions

These also have $\Delta \leqslant 1$, and

$$\sigma = \sigma_c\left(\frac{\eta\Omega_0}{\Omega}\right)\coth\left(\frac{\eta\Omega}{\Omega_0}\right), \tag{5}$$

$$\Omega^2 = \Omega_0^2[1 + \Delta(3 - 2\sigma/\sigma_c)], \tag{6}$$

where

$$\eta = \hbar/2M\Omega_0\sigma_c, \quad \sigma_c = (v - M\Omega^2)/3u,$$
$$Q^2 = 3(\sigma_c - \sigma). \tag{7)–(9}$$

These "self-consistency equations" have to be solved numerically in order to obtain the value of Q for each temperature T. The resulting curves of Q vs T show smaller values of Q at low temperatures compared with the equivalent solution [Eq. (3)].

1.3 The Order-Disorder Limit

The order-disorder (od) limit is reasonably well described by the Bragg–Williams equation

$$Q = \tanh(QT_c/T), \quad \Delta \gg 1. \tag{10}$$

In Fig. 4, a sequence of measured OPs are compared with theoretical predictions for $\Delta < 1$. In all cases, Landau theory is a good approximation for $T \gg \theta_s$, and we list the analytical expressions for the temperature dependence of the OP for the Landau potential [Eq. (4)]:

1. a "second-order" transition:

$$Q = \left(\frac{T_c - T}{T_c}\right)^{1/2} \tag{11}$$

for $T < T_c$, $C = 0$, $B > 0$;

2. a "tricritical" transition:

$$Q = \left(\frac{T_c - T}{T_c}\right)^{1/4} \tag{12}$$

for $T < T_c$, $C > 0$, $B = 0$;

3. a "first-order" transition

$$Q^2 = -\frac{1}{2C}[B - \sqrt{B^2 - 4AC(T - T_c)}]$$

for

$$T < T_{\text{trans}} = T_c + B^2/4AC, \tag{13}$$

$$B < 0, C > 0.$$

Other Landau potentials including odd-order terms (when compatible with the symmetry of the crystal) or higher-order terms lead to similar expressions for $Q(T)$.

Experimental observations often follow the predicted T dependence of Q very well—in particular for displacive phase transitions (Fig. 4). In fact, the applicability of the generalized Landau expression in Eq. (3) is much wider than originally anticipated and includes thermal regimes with OPs close to unity (Salje, 1993b; Salje *et al.*, 1991). Furthermore, structural phase transitions for which the order parameter disappears continuously on heating through the transition point (cases **1** and **2**) do not necessarily show criticalities as in case of phase transitions with short-range interactions such as described in the nearest-neighbor Ising model. In most cases, critical fluctuations are suppressed by the long-ranging and strongly anisotropic elastic interactions in the crystal structure (Cowley, 1976; Folk *et al.*, 1979; Marais *et al.*, 1991).

2. THE ORDER PARAMETER

The order parameter, OP, was so far introduced as a measure for the deviation of the structural state in the low-symmetry phase ($Q \neq 0$) from that of the high-symmetry phase ($Q = 0$). Its meaning stems from thermodynamic requirements, and it is not always obvious how the order parameter is related to structural quantities that maintain the general structural topology of the high-symmetry phase. One finds that all symmetry elements of the low-symmetry structure are already present in the high-symmetry phase. Some symmetry elements of the high symmetry, on the other hand, disappear during the phase transition, i.e., specific symmetry elements are "broken." This requires that an

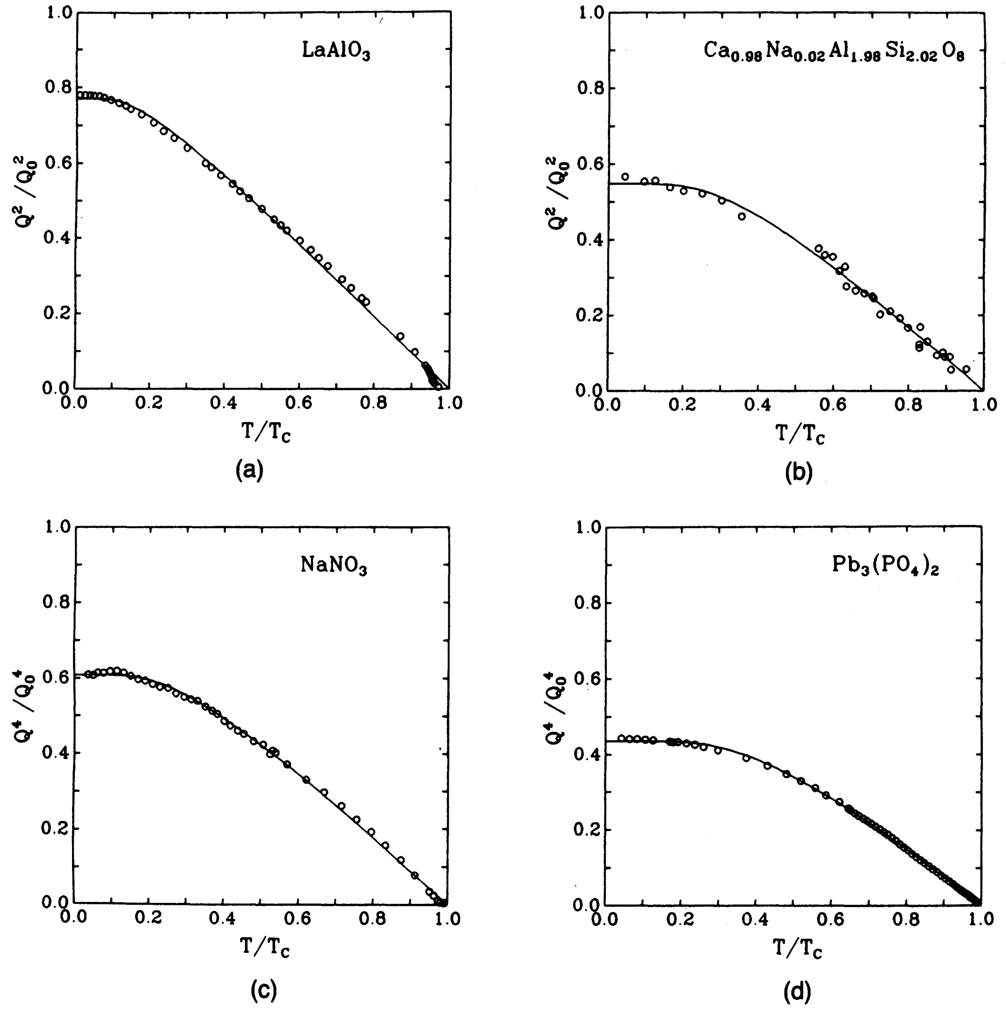

FIG. 4. Temperature evolution of the OP for four typical SPTs. In each case, the curves of a self-consistent solution [Eqs. (5)–(9)] are shown. The relevant parameters are, for (a) $LaAlO_3$, $T_c = 800$ k, $\theta_s = 95$ k, $\Delta = 0.116$; for (b) $Ca_{0.98}Na_{0.02}Al_{1.98}Si_{2.02}O_8$ (anorthite), $T_c = 513$ k, $\theta_s = 226$ k, $\Delta = 0.082$; for (c) $NaNO_3$, $T_c = 552$ k, $\theta_s = 165$ k, $\Delta = 0.174$; and for (d) $Pb_3(PO_4)_2$, $T_c = 455$ k, $\theta_s = 259$ k, $\Delta = 0.087$. In all cases $\Delta \ll 1$, so that the data points follow approximately the predictions of classic Landau theory.

additional parameter exists that specifies the thermodynamic state of the low-symmetry structure (which is already completely defined in the high-symmetry structure).

Let us illustrate this requirement using the example of quartz in Fig. 1. In the high-symmetry form, the space- and time-averaged orientation of the tetrahedra is fully determined by the symmetry of the crystal structure. In the low-symmetry structure, this is not the case because the symmetry is reduced so that small rotations of the tetrahedra are compatible with the symmetry constraints. In order to characterize the low-symmetry structure, we need to specify "how much" the tetrahedra rotated and "in which direction."

In a similar manner, the high-symmetry phase of the feldspar structure requires that Al and Si are randomly distributed over the relevant tetrahedra positions. In the low-symmetry structure, this distribution is no longer random with some structural sites being occupied preferentially by Al rather than Si. Again, one needs to quantify to what degree this site ordering has taken place.

As the basic process of breaking a symmetry constraint is always the same, it makes sense to introduce a thermodynamic quantity that describes the structural state of the low-symmetry phase in a universal manner. This thermodynamic parameter is called the order parameter Q. In order to connect Q with the thermodynamic properties of the material, we simply note that the Gibbs free energy G has to depend on $T, P, \ldots$ *and* Q in $G(T,P, \ldots, Q)$. With $Q = 0$ in the high-symmetry phase, we can then define $\Delta G = G - G(Q = 0)$ as the excess Gibbs free energy. Similarly, it is customary to define all other physical quantities as excess values with respect to the state defined by $Q = 0$. Once the dependence of ΔG on Q is either determined experimentally or anticipated by phenomenological models (such as in Sec. 1), the dependence of Q on $T, P \ldots$ simply follows from the equilibrium condition that G must have a minimum at the equilibrium value of Q, i.e., $dG/dQ = 0$, $d^2G/dQ^2 > 0$. All other physical parameters are then determined via their relationship with Q.

It is essential for the definition of an order parameter that a close structural relationship exists between the two phases. This allows us to describe a "difference structure" as the true crystal structure minus the high-symmetry structure as reference structure, i.e., we calculate the difference of atomic densities $\rho(\mathbf{r}) = \rho_{Q\neq 0}(\mathbf{r}) - \rho_{Q=0}(\mathbf{r})$. The pattern of this difference structure describes then directly the atomic displacements, changes in site occupancies, etc. The OP is then the amplitude of this reference structure and tells us "how much happens," whereas the pattern itself describes "what happens." The OP is usually normalized to unity for the maximum change and is zero when no change occurs, i.e., in the high-symmetry phase.

The required close structural relationship may not exist, however. If one crystal structure transforms into another without any topological relationship between them, the transition is called "reconstructive" and no order parameter besides a trivial normalized volume ratio of the two phases can be defined. If the two structures transform into each other with a well-defined three-dimensional topological relationship, the transition is called "topotactic." For two-dimensional relationships, the structural transition is called "epitactic." Several materials show layer-type structures. If the relative stacking of the layers changes during a phase transition, the transition is called "polytypic." The various structures that can be related by such polytypic phase transitions (hypothetical or real) are usually called "polytypes"; they are distinguished by the different stacking of identical (or almost so) slabs as the basic structural unit. The order parameter Q describes in this case the amount of material in a given stacking sequence.

Group-theoretical methods have been used to derive the symmetry properties of Q. The OP is a scalar quantity for phase transitions between structures with triclinic, monoclinic, or orthorhombic symmetry. For transitions from phases with higher symmetry, the order parameter can have up to three components $Q = \{Q_i, i \leq 3\}$ representing degeneracies of the symmetry constraints. Further degeneracies stem from the fact that the order parameter is a complex quantity $Q = Q_0 e^{-i\mathbf{q}\cdot\mathbf{r}}$, if the structural change is not uniform. In this case, the translational symmetry is broken with the excess wave vector $\mathbf{q}$ ($\mathbf{q} = 0$ if the translational symmetry is maintained). Degeneracies can occur if the relevant wave vector $\mathbf{q}$ describes several symmetry-equivalent transition mechanisms.

Similar symmetry constraints also exist for the terms in a polynomial expression of the excess Gibbs free energy. As this energy is invariant under all symmetry operations, only those terms Q^n or $Q_i^n Q_j^m$ are symmetry allowed that are invariant under all symmetry operations. The various possible combinations are listed in a great number of publications.

Let us consider a typical geometrical example. A structural unit such as an octahedron is embedded in a cubic crystal structure (Fig. 5). Now let us consider a movement of the structural unit such as a rotation, an elongation, etc. The movement is topologically identical if we interchange the three cubic axes, so that the crystal axes cannot depend on the choice of the Gibbs free energy. The OP must be threefold degenerate, therefore. The symmetry-allowed form of the Gibbs free energy includes then three components Q_1, Q_2, and Q_3 with

$$\begin{aligned} G = G_0 &+ \tfrac{1}{2}A'(Q_1^2 + Q_2^2 + Q_3^2) \\ &+ \tfrac{1}{4}B(Q_1^4 + Q_2^4 + Q_3^4) \\ &+ \tfrac{1}{4}B'(Q_1^2Q_2^2 + Q_2^2Q_3^2 + Q_1^2Q_3^2) + \cdots . \end{aligned} \tag{14}$$

For $B' = 0$, there is no correlation between

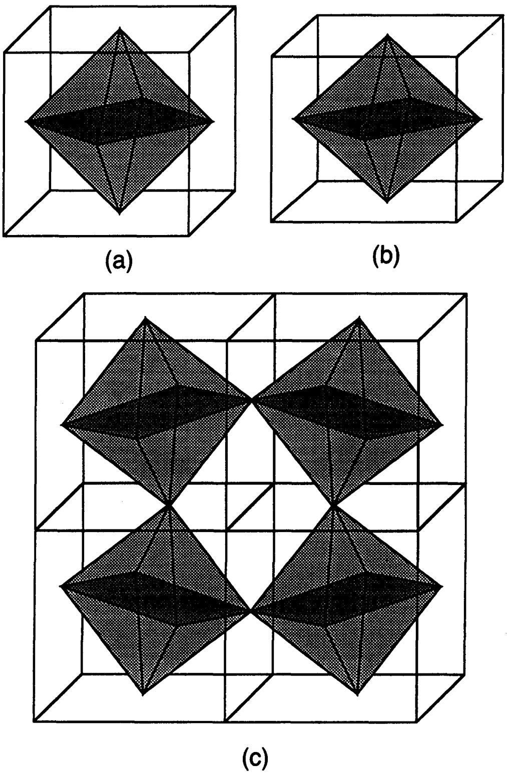

FIG. 5. Phase transitions generated by the distortion of (a) an octahedron in a cube-shaped cage. Two basic deformations can occur depending on the energy contribution of B'; (b) an elongation or shrinking along one of the cube axes (with three degenerate orientations) or along the cube diagonal (with four degenerate orientations). (c) If the translational symmetry is broken via rotation of the octahedra but not the cubes, tetragonal and trigonal structures are commonly formed.

Q_1, Q_2, and Q_3 with each component Q_i generating a phase transition. The term $Q_i^2Q_k^2$ couples the three components of the order parameter. With the condition $\delta G = 0$, $\delta^2 G > 0$ leads to only two types of solutions ($B' \neq 0$) (Slonczewski and Thomas, 1970):

$$\text{(a)}\ Q = (\pm Q,0,0), (0,\pm Q,0), (0,0,\pm Q), \tag{15}$$

$$\text{(b)}\ Q = \frac{1}{\sqrt{3}}(\pm Q,\pm Q,\pm Q). \tag{16}$$

The solution (a) represents a tetragonal phase with the fourfold axis along the cubic a, b, or c axis. The solution (b) describes a trigonal phase with the triad along the cubic [1 1 1], [$\bar{1}$ 1 1], [1 $\bar{1}$ 1], or [1 1 $\bar{1}$] axis. Such phase transitions between cubic and tetragonal or trigonal symmetries are often encountered, in particular in perovskite type crystal structures.

If the wave vector **q** of the order parameter Q is zero, the translational symmetry of both phases is equal. Such phase transitions are sometimes called "ferrodistortive." If **q** leads to a doubling of the translational unit, the transition is "antiferrodistortive." All simple multiplications of the size of the translational unit lead to a "commensurate" phase because the translational periodicity of the low-symmetry phase is commensurate with that of the high-symmetry phase. If this is not the case, the low-symmetry phase is called "incommensurate" (IC). Most IC phases exist only for small temperature intervals although notable exceptions occur (e.g., Na_2CO_3).

3. FERROELASTICITY AND FERROELECTRICITY

Atomic ordering may involve the reshuffling of atoms of different size or with different polyhedral environments. In such cases, the interchange of atoms will lead to a local distortion of the crystal structure. Local distortions lead to stresses that penetrate far into the structure and influence other atomic-ordering processes even when they happen at large distances from the original event. It is this long-ranging character of the elastic interactions that makes them so important. Experimental work has shown that in many SPTs a strong coupling between the OP and elastic degrees of freedom is observed (Salje, 1993b; Cowley, 1976; Folk *et al.*, 1979; Marais, 1991). As a consequence, the shape of the structural unit changes by typically 1%–6% with a smaller change of the specific volume. Even larger changes are seen in some metallic alloys. The excess deformation is called the "spontaneous strain." The generation of the spontaneous strain contributes significant elastic energy to the excess Gibbs free energy and leads to temperature dependences of elastic constants. In many crystals, a SPT was first discovered by the experimental observation of such anomalous thermal expansions using x-ray or neutron-diffraction methods. Materials with elastic anomalies are called coelastic. A specific case exists if the

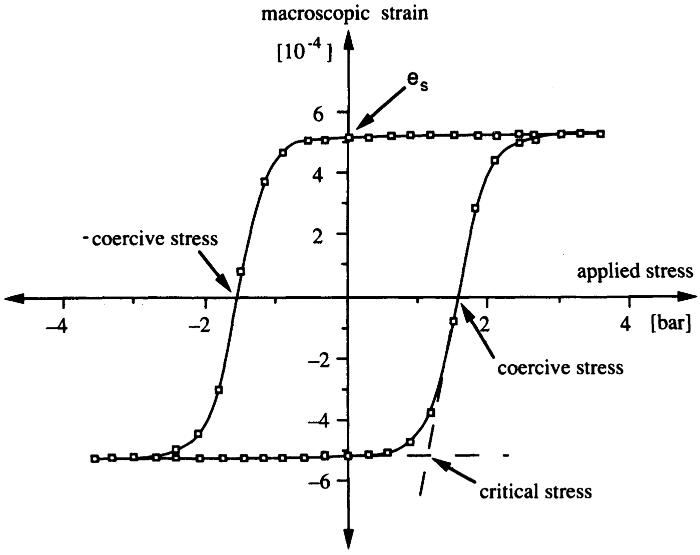

FIG. 6. Ferroelastic hysteresis for $Pb_3(PO_4)_2$.

spontaneous strain can be switched between symmetry-equivalent orientations (ferroelasticity). In Fig. 6, a ferroelastic hysteresis related to $Pb_3(PO_4)_3$ is shown for a macroscopic sample (Salje, 1993b). Mechanical shear stress of a monoclinic sample allows switching of the monoclinic axis by 120°, so that the macroscopic shape of the crystal changes accordingly. This switch is fully reversible.

Similar hysteresis phenomena exist for ferroelectric materials in which the reorientation of the order parameter involves the change of the spontaneous polarization (Lines and Glass, 1977). In Fig. 7, the spontaneous polarization in $BaTiO_3$ is shown as the dipole moment of the positively charged Ti and the negatively charged O with less contribution from Ba. The centers of gravity of the posi-

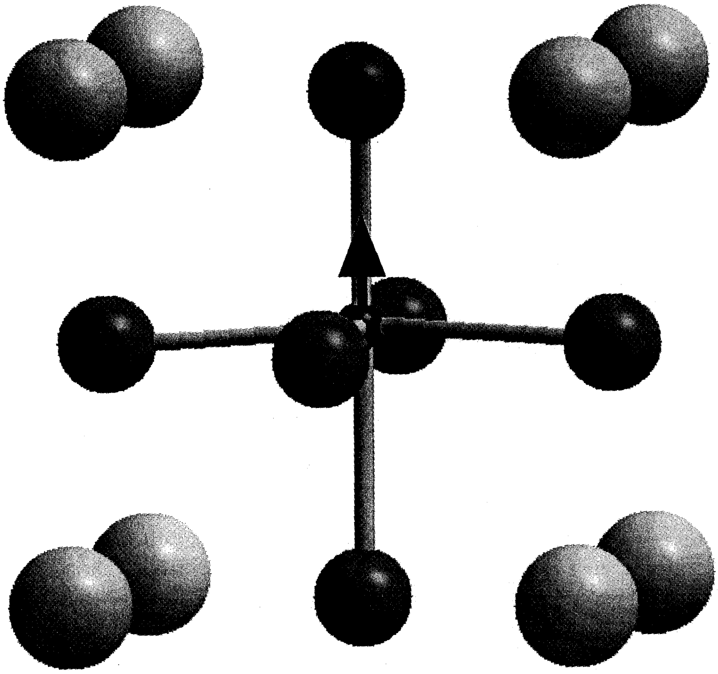

FIG. 7. Crystal structure of ferroelectric, tetragonal $BaTiO_3$. During the SPT from the paraelectric cubic phase, the black Ti cations are slightly shifted with respect to the darker gray oxygen anions. The charge separation generates a spontaneous dipole moment.

tive and negative changes are not identical, so that an electrical dipole moment builds up in the low-symmetry phase (i.e., the spontaneous polarization). Ferroelasticity and ferroelectricity sometimes occur simultaneously with comparable contributions of the electrical and mechanical energy to the excess Gibbs free energy (e.g., in KH_2PO_4).

4. COUPLING BETWEEN ORDER PARAMETERS

Several SPTs may occur in the same material if temperature or pressure is varied over large intervals. For example, almost all incommensurate transitions lead to a second, commensurate (lock-in) transition. Other examples include cascades of three or more transitions each of which breaks a different symmetry element of the same high-symmetry phase. If such elements are restored in a subsequent transition, the SPT is called "reentrant."

Even when the T and P conditions for the various SPTs are very different, the OPs may still interact. The total excess Gibbs free energy is then the sum of the individual contributions and the interaction energy G_{coupling}:

$$G = G_1 + G_2 + G_{\text{coupling}}.$$

Three types of coupling occur commonly whereby the dependence of the coupling energy on the OPs is different (Salje, 1993b):

1. If the coupled order parameters have the same symmetry (but, say, different transition points), $G_{\text{coupling}} = \lambda Q_1 Q_2$ is the coupling energy in lowest order of the OPs. The term λ is a measure for the coupling strength.
2. The coupling energy $\lambda Q_1^2 Q_2^2$ may occur under all symmetry conditions and is often considered as the "standard" coupling term.
3. Specific systems show $G_{\text{coupling}} = \lambda Q_1 Q_2^2$ or $\lambda Q_1^2 Q_2$, whereby this product of OPs must be invariant under the relevant symmetry operations.

The stability of phases has now to depend on both order parameters, which are commonly displayed in the order-parameter vector diagram (Fig. 8). Such diagrams contain all combinations of order parameters that represent thermodynamic equilibrium under the various T and P conditions. The origin is always $Q_1 = Q_2 = 0$, i.e., the high-symmetry phase. When T and P are changed, the structural states run along the trajectories in the diagram. Structural states outside the trajectories represent no minima of the Gibbs free energy and are, thus, not equilibrium states.

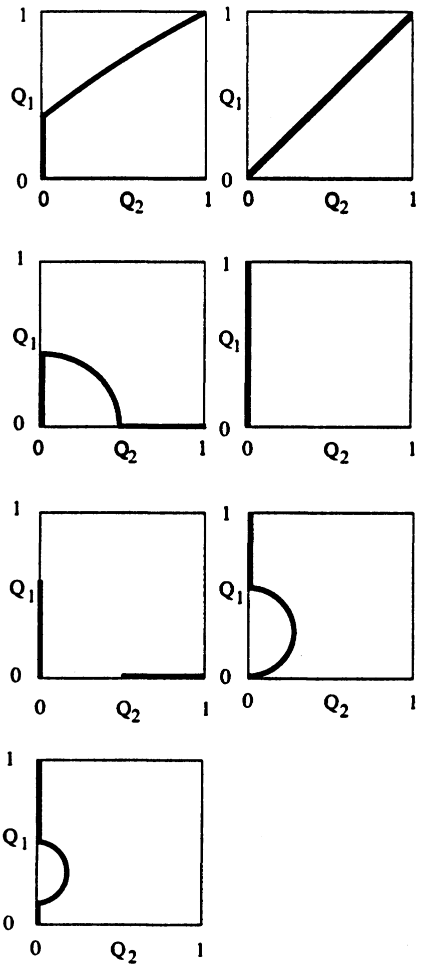

FIG. 8. The typical order parameter vector diagrams for two OPs coupled biquadratically ($\propto \lambda Q_1^2 Q_2^2$). An equilibrium structural state is always characterized by two OPs, which define a point in the diagram. All equilibrium points together form lines of equilibrium states. Changing T, P, etc. moves the equilibrium point along such equilibrium lines as shown in the figures. The high-symmetry phase is represented by the origin ($Q_1 = Q_2 = 0$). Additional phase transitions occur when one of the OPs vanishes [e.g., between the states ($Q_1 = 0$, $Q_2 \neq 0$) and ($Q_1 \neq 0$, $Q_2 \neq 0$)].

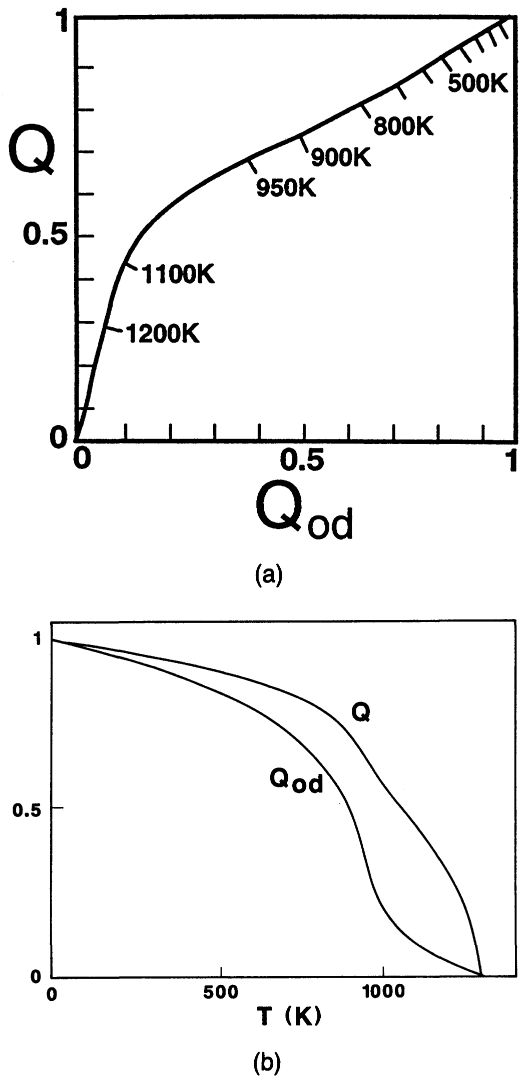
Bilinear coupling **1** leads to bending of the equilibrium line, which is the locus of all stable configurations. Topological changes occur for nonlinear coupling with the creation of additional phase transitions that stem from the competition between the OPs and are *not* due to an independent, third, transition mechanism. All quantitative analyses of SPTs with several OPs have to account for these coupling effects, which greatly modify the T and P dependences of the OPs. A typical example of the experimentally observed T dependence of two coupled OPs is shown in Fig. 9.

5. INFLUENCE OF DEFECTS

SPTs are influenced by structural defects. Defects often couple with thermal fluctuations. Defects can generate anomalies such as excess heat capacities, softening of elastic constants, and parasitic short-range order in the high-symmetry phase. These anomalies tend to mimic closely the behavior of critical systems with short-range interactions (such as magnetic phase transitions). It makes sense, therefore, to describe these anomalies with the same effective exponents, α for the specific heat, β for the order parameter, and γ for the susceptibility. Note that the observed anomalies are not intrinsic to the SPT but they are generated by the lattice relaxations around the defects. Common exponents for α are $\frac{1}{2}$ for unpolarized defects and $\frac{3}{2}$ for polarized defects (in contrast to $\alpha = 0$ for the defect-free SPT in the MFT approximation and as observed in many ferroelastic crystals). Other values exist depending on the details of the relaxation (Levanyuk and Sigov, 1988).

At temperatures small compared with T_c, the OP increases (reduces) when the defects stabilize (destabilize) the low-symmetry phase. The extrapolated transition temperature is accordingly changed. These changes are linear for small defect concentrations ($\Delta G_{\text{defect}} \propto \zeta N Q^2$ changes T_c to $T_c + N\zeta$). For larger defect concentrations N, strongly nonlinear effects lead to a "plateau" of the extrapolated T_c vs N curves.

If the defects stabilize the low-symmetry phase, they may destroy the high-symmetry phase altogether. A typical example is that a point defect leads to a local lattice deformation that has a common component with the spontaneous strain. Both contributions generate the total spontaneous strain, which will not disappear (because of the defect contribution) at $T > T_c$ thereby preventing the high-symmetry phase from appearing under heating. A common example is that the defect acts as fields H_d conjugated to the OP with $\Delta G_{\text{defect}} \propto -\lambda H_d Q$. In this case, Q decreases near the defect-free transition point but then forms a tail at $T > T_c$ (Fig. 10). The structural phase with $Q = 0$ is no longer a minimum of



(a)

(b)

FIG. 9. Example for an experimentally determined order-parameter vector diagram of two coupled OPs (bilinear coupling $\propto \lambda Q_1 Q_2$) for Na feldspar in Fig. 2. Q_{od} represents the OP for the od process of ordering Si and Al on various lattice sites, Q represents an OP of a displacive SPT. (a) Vector diagram, (b) temperature evolution of both OPs [after Salje (1993b)].

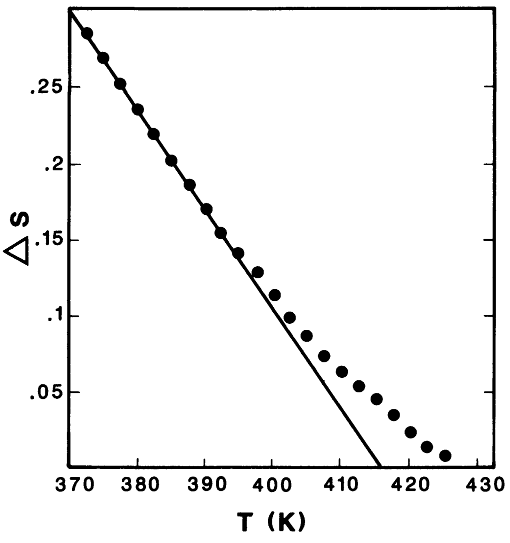


FIG. 10. Defect-related tail in displacive SPT in (Na,K) feldspar. The excess entropy ΔS is proportional to the square of the OP; the pure material has a SPT at 416 K. Defects generate a tail of the OP at higher temperatures.

the total Gibbs free energy (i.e., $\delta G = 0$ always leads to $Q \neq 0$). If the defect field is intrinsic to the crystal structure, this behavior is called a nonconvergent SPT, indicating that the high-symmetry form is asymptotically approached but never reached. Strictly speaking, a nonconvergent SPT is not a SPT because the actual transition does not take place, although the thermodynamic and structural features of nonconvergent behavior are appropriately described within the same theoretical framework as that of SPTs (including the intrinsic field term).

6. TWINS AND ANTIPHASE BOUNDARIES AS FINGERPRINTS OF SPTs; SURFACE RELAXATIONS

The generation of the OP may allow the crystal to become heterogeneous with different values of the OP in different domains. In ferrodistortive SPTs if two domains have OPs with opposite sign, the domains are called twins with a twin boundary between them. Such OPs usually carry large spontaneous strain e_{ik}. The locus of the boundary X_i is determined by the compatibility between the two twins S_1 and S_2, i.e.,

$$[e_{ik}(S_1) - e_{ik}(S_2)]X_iX_k = 0, \tag{17}$$

leading for traceless e_{ik} to two types of walls. These two types of walls would be strictly orthogonal in the metric of the high-symmetry phase. In the low-symmetry phase, the angle between the walls is $\pi/2 \pm \omega$ where the small angle ω is numerically identical to the relevant tensor component of the spontaneous strain ($\omega \lesssim 10^{-2}$). In many experimental observations, this angle ω is too small to be seen and it is customary to describe the wall pattern with the two types of wall as "right-angle domain walls." Walls that are fully localized by symmetry constraints (e.g., those along mirror planes of the high-symmetry phase) are called W walls. Those which have orientational degrees of freedom are called W' walls. W' walls occur, e.g., when the only symmetry constraint is that a twofold axis of the high-symmetry phase has to be contained in the wall. The wall can then rotate around the axis in order to minimize its energy. The rotation angle will then depend explicitly on the control parameter (e.g., T) (Salje, 1993b).

The internal structure of twin walls is usually derived from the Euler–Lagrange equation with $G = G(Q,T) + \frac{1}{2}g(\nabla Q)^2$:

$$\frac{dQ}{dt} \propto \frac{\partial G}{\partial Q} + g\frac{d^2Q}{dx^2}, \tag{18}$$

where x is the distance from the twin wall. The gradient energy describes the energy needed to modify the OP spatially. The solutions depend on the explicit form of $G(Q,T)$; in most cases, they are identical with or close to the solution for the simplest Landau potential with

$$Q = Q_0 \tanh(x/w), \tag{19}$$

where Q_0 is the equilibrium OP and w is the wall thickness. The term w increases close to the transition point as

$$w = \sqrt{\frac{2g}{A|T - T_c|}}, \tag{20}$$

where $\sqrt{2g/AT_c}$ is in the order of lattice repetition units.

The internal structure of twin walls is

modified when several order parameters couple (Houchmandzadeh *et al.*, 1991). Instead of having a rather smooth bend of the OP from one equilibrium value on one side of the wall to another equilibrium value on the other side of the wall, new structural states may occur inside the wall. These new states are described by the second order parameter. The true crystal structure inside the wall and close to the wall is then characterized by the space dependence of the two OPs. Within the spirit of order-parameter vector diagrams introduced in Fig. 8, we now depict solutions of the Euler–Lagrange equation for two OPs as a graph of one OP vs the second OP and obtain the "trajectory" of the domain wall in the order-parameter space. Two typical trajectories for walls with biquadratic coupling between two OPs are shown in Figs. 11(a) and 11(b). The first OP is Q_1 and shows a modified hyperbolic tangent profile. The second OP, Q_2, is zero in the uniform state [Fig. 12(a)] and is generated only inside the wall. In the spatial evolution of the order-parameter vector diagram [Fig. 12], the effective OP "rotates" in the wall, so that this wall is called chiral (similar to magnetic Bloch walls). Parts of walls with right-handed and left-handed chirality meet in lines of vanishing chirality. The second solution in Figs. 11(b) and 12(b) shows a right-handed chirality on one side of the wall and a left-handed chirality on the other side. Such walls are called bichiral.

Antiferrodistortive phase transitions can lead to the formation of antiphase boundaries (APBs) in which the translational symmetry is broken. In cases with weak strain coupling, APBs wiggle through the crystal without orientational preference. Increasing strain coupling leads to preferential orientations and lock-in phenomena along the optimum direction. The thickness of APBs is of the order of interatomic distances.

Structural relaxations close to surfaces and interfaces are enhanced by SPTs. In case of interfaces, such relaxations appear as ripples of the OP and decrease exponentially with distance from the interface. The characteristic length increases close to the transition point. Surfaces show additional relaxations in the high- and low-symmetry phases. Such relaxations act as precursor phenomena although the relaxational modes are not necessarily identical with the deformation pattern of the actual phase transitions. Theoretical work predicts a dominance of incommensurate relaxations and quasiperiodic pattern formation even when the phase transition is (anti)ferro-distortive.

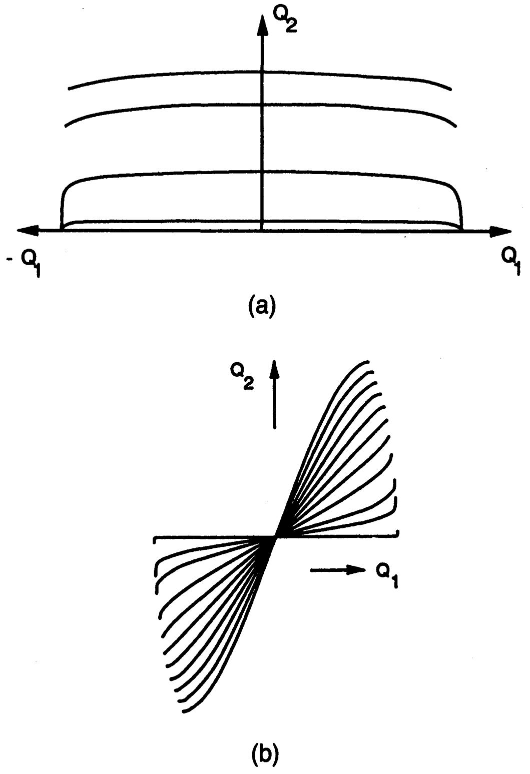

FIG. 11. Vector diagrams of biquadratically coupled OPs together with trajectories of the domain boundaries. Each line represents a trajectory with the stable OPs of the bulk at either end of the trajectory. In (a), only Q_1 changes sign in the boundary but not Q_2. Trajectories in (b) show Q_1 and Q_2 changing sign in the domain boundary.

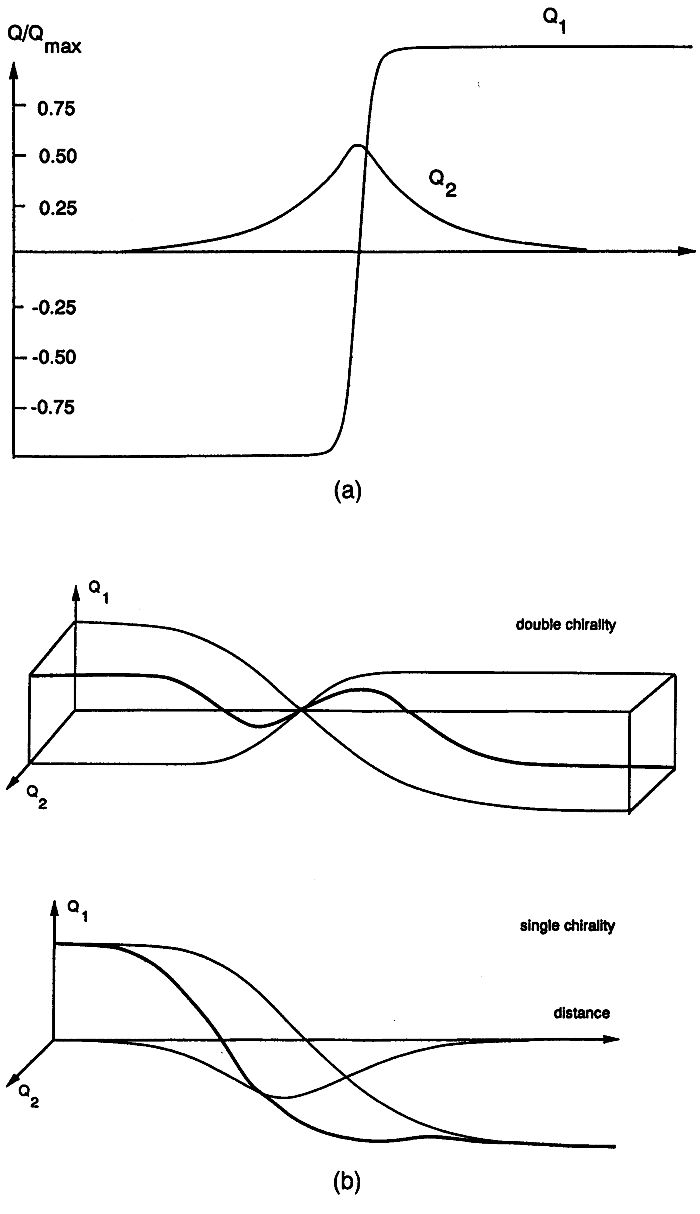
7. KINETICS OF SITE ORDERING

A system out of equilibrium (i.e., $\partial G/\partial Q \neq 0$) will tend to lower its energy via kinetic processes. In displacive SPTs, equilibrium is reached via phonon processes so that the time scale is fast. Much slower processes occur in od systems, which involve the activation of site exchanges that is necessary to interchange atomic sites. Two principal processes dominate od SPTs. Firstly, local site ordering lowers the energy so that local state parameters equivalent to OPs can be used to describe the kinetic rate equation. If only two



(a)

(b)

FIG. 12. Typical wall profiles for both types of trajectories shown in Fig. 11. (a) Q_1 changing sign but not Q_2 whereby the case $Q_2 = 0$ in the bulk is shown. Q_2 exists only in the wall indicating a SPT created in a domain boundary but not in the bulk. (b) The two types of wall profiles with both OPs changing sign (top) and only one changing sign (bottom). The latter is similar to a chiral Bloch wall in magnetism whereas the former self-compensates the chirality in opposite sign on either side of the wall. The abscissa is the distance from the center of the wall; typical wall thicknesses are measured in tens of ångstroms.

local states exist (e.g., like in spin systems), the rate is determined by the random choice of sites and subsequent state changes according to Boltzmann statistics [the so-called "Glauber" kinetics, often in the MF limit because of long-ranging correlations (Glauber, 1963)]. In more complex framework structures, many local exchange schemes exist and compete for the kinetic mechanism. Several structural states intermediate between the nonequilibrium starting configuration and the final (equilibrium) configurations have energy states between the initial and final states. These intermediate states can then serve as "stepping stones" for the system progressing kinetically toward equilibrium. If a sufficient number of such intermediate states exist, the kinetic rate law can be described in the continuum approximation (and in MFT due to long-ranging interactions) by the generalized time-dependent Ginzburg–Landau equation $dQ/dt \propto \partial G/\partial Q$, where G is the equilibrium Gibbs free energy.

The second process involves the transport of atoms (e.g., via interstitial sites). This part of the ordering requires chemical neutrality and is "conserved" so that each local change of state is compensated by an equivalent change in the opposite direction somewhere else in the structure. This process dominates exsolution kinetics and follows for two-state systems the so-called "Kawasaki" rate law, i.e., now pairs of sites are chosen for an exchange of state variables according to Boltzmann statistics (Kawasaki, 1966; Langer, 1971). This kinetic mechanism is in contrast to Glauber statistics where each site is chosen individually so that it is only in the Kawasaki case that the global order parameter remains unchanged. In SPTs, both processes may exist simultaneously and a general rate equation for continuous state parameters can be formulated (Salje, 1993a):

$$\frac{dQ}{dt} \propto \left(1 - \frac{\xi_c^2}{\xi^2}\frac{\sinh(\xi\nabla)}{\xi\nabla}\right)\frac{dG}{dQ}, \tag{21}$$

where ξ is the Kawasaki length and ξ_c scales the amount of conservation in the individual rate process: With $\xi_c = 0$ we recover the time-dependent Ginzburg–Landau equation, and $\xi_c = 1$ defines in lowest order the so called "Cahn–Hilliard rate equation" (Langer, 1971; Amengual *et al.*, 1993; Salje, 1993a).

These rate laws have been used successfully to describe the kinetics of atomic ordering in framework structures and exsolution processes in alloys and other materials. The dependences of G and the kinetic operator $L = 1 - (\xi_c^2/\xi^2)\sinh(\xi\nabla)/\xi\nabla$ on the gradient operator ∇ lead to heterogeneous patterns for the OP. The exact form of these patterns and their time dependence (e.g., coarsening of domain structures) is still a matter of debate. Experimental observations often show that exsolution patterns ($\xi_c = 1$) show stripe patterns of (approximately) parallel domains with strong variations of the OP at the boundary between two domains. The internal structure of the boundaries appears to be similar to twin boundaries in ferroelastic crystals. SPTs involving atomic ordering show characteristic sequences of mesoscopic domain structures. The early stages contain tweed patterns consisting of patches of ordered material with different OPs (e.g., opposite signs in different patches) and wall-like boundaries between them. In the course of kinetic ripening of such microstructures, the tweed transforms into stripe patterns with well-developed domain walls. These stripe patterns then coarsen via an increase of the domain width (Plate 1).

Kinetic development of such mesoscopic microstructures with characteristic lengths of some 100 Å has been simulated by computer experiments (Parlinski *et al.*, 1993; Semenovskaya and Khatchaturyan, 1992). In most cases, the effective interaction between the sites is assumed to be elastic; the entropic part is determined by pseudospin variables at the sites, which describe the occupancy by one or the other atomic species. The standard Hamiltonian of such a system is (Marais *et al.*, 1991)

$$H_{\text{eff}} = \tfrac{1}{2}\mathbf{uAu} - \tfrac{1}{2}\mathbf{uFs}, \tag{22}$$

where $\mathbf{u}$ is the displacement vector, $\mathbf{A}$ is the dynamical matrix, $\mathbf{s}$ is the pseudospin variable, and $\mathbf{F}$ describes the spin-lattice coupling. This Hamiltonian can be renormalized to spin coordinates at sites R and R':

$$H_{\text{eff}} = -\sum_{\mathbf{RR}'} J(\mathbf{R} - \mathbf{R}')S(\mathbf{R})S(\mathbf{R}'). \tag{23}$$

The spin-spin coupling is now long-ranging with a strong directional dependence and nonanalytical behavior in the long-wavelength limit:

$$J(R) \propto \frac{1}{R^3}\,[A_2Y_{2m}(\theta,\varphi) + A_4Y_{4m}(\theta,\varphi)] + \frac{Z}{N} \tag{24}$$

with the constant term Z/N where N is the number of particles and Z is the Zehner–Eshelby constant describing the macroscopic relaxation of the sample. Using this Hamiltonian in computer simulation, the characteristic domain structures of tweed and stripes have been reproduced. Such mesoscopic structures are shown in Plate I for a simulation of 64×64×8 unit cells with thermodynamic conditions similar to those for the experimental results in Fig. 13.

8. CONCLUSION

Structural phase transitions are dominated by long-ranging interactions, which makes their description by mean field theories possible. Much work has been domi-

Putnis, Cambridge.

nated by the application of Landau theory, including the coupling between several order parameters and their saturation at low temperatures. Future work is likely to concentrate on the time dependence (kinetics) of structural phase transitions.

GLOSSARY

Excess Gibbs Free Energy *ΔG*: Difference between the Gibbs free energies of the low-symmetry phase $G(Q)$ and the high-symmetry phase $G(Q = 0)$, also called the excess Gibbs free energy of the SPT.

Order Parameter (*Q*): Variable that describes the structural state, with $Q = 0$ for the high-symmetry phase and $Q \neq 0$ for the low-symmetry phase.

Phase Transition Temperature: (T_c for continuous phase transitions, T_{trans} for stepwise transition.) Temperature at which the Gibbs free energy of the high-symmetry form is identical to that of the low-symmetry form.

Saturation Temperature (θ_s): Temperature below which the temperature dependence of the order parameter diminishes rapidly.

Spontaneous Strain (e_{ik}): Strain of the crystal generated by the phase transition. The spontaneous strain is measured as change of lattice parameters with respect to the high-symmetry phase.

INTRODUCTION

Philosophy of physics, as currently understood, studies the conceptual foundations and philosophical implications of physics, and examines the interdependence between observation and theory as well as the structure and interrelation of physical theories. It also deals with issues traditionally classified as "metaphysical," such as the nature of space, time, matter, and energy. Last, but not least, it discusses the question of whether physical theories lead to, or are compatible with, a coherent and intellectually satisfying picture of the world.

Philosophy of physics differs from physics with respect to both the objectives aimed at and the techniques or tools employed. The objective of physics is the construction of a physical theory of nature by discovering new data, embedding them in a consistent scheme, and testing the consequences of the theory by experimental methods. The objective of the philosophy of physics is the study of the nature of a physical theory by examining its evidential and inferential foundations, its logical consistency, and its metaphysical assumptions and implications. The work of the philosopher of physics is therefore usually, in contrast to that of the physicist, *ex post facto*. The tools of the physicist are the laboratory and the computer, the tool of the philosopher of physics is the method of conceptual analysis.

This contradistinction does not, however, imply that a great physicist could not be also a philosopher of physics—a combination that, as we shall see, has been rather the rule than the exception, especially at periods of revolutionary innovations.

The historical development of physics can be divided into three major periods:

1. preclassical physics, which began in the sixth century B.C. with the natural philosophy of the school of Miletus (Thales and his disciples) and lasted until the scientific revolution of the 17th century;
2. classical or Newtonian physics, which came to an end at about 1900; and
3. modern physics, which began with the advent of the special theory of relativity and of quantum mechanics.

Because of the perpetual interaction between physics and its philosophy, it will prove useful to adhere to this historical division also in our discussion of the philosophy of physics.

1. THE PHILOSOPHY OF PRECLASSICAL PHYSICS

1.1 The Early Development of the Philosophy of Physics

The first to use the expression "philosophy of physics" as a *terminus technicus* was Aristotle. He used this term, in his treatise *Metaphysics* (Book 6, Chap. 1, 1026 a 18)*, in order to distinguish its subject matter from those of other branches of philosophy and science. In fact, at his time philosophy consisted already of several subdivisions, ranging from metaphysics to ethics and aesthetics. But prior to his time, when philosophy was born, when Thales and his school, the φυσικοι in Aristotle's terminology, emancipated themselves from mythological beliefs, rational reflexion was almost exclusively a philosophy of nature or φυσις, the Greek term for nature. These "physikoi" tried to explain the multifarious phenomena of nature by conceiving them merely as modifications of one and the same substratum or as manifestations of a single all-embracing principle. Their quest for a universally valid explanatory principle has ever since become one of the guidelines of physical research. The search for a unified theory of physics in our days is but a modern version of this quest.

In the fifth century B.C., the Pythagoreans claimed to have found this principle in the relation between numbers or in the structure of geometrical patterns. On the other hand, Empedocles, convinced that qualitative differences cannot be accounted for by only one principle, posited four principles, which he identified with the four elements earth, water, air, and fire; in addition, he introduced the two principles of Love and Strife, anticipating thereby the dynamics of attractive and repulsive forces in physics. Atomism, inaugurated by Leucippus and Democritus, conceived the universe to consist only of atoms and the void; devoid of qualitative properties except impermeability, atoms may differ in size, shape, arrangement, and position, and are in perpetual motion through the void. Although rejected by Aristotle and anathematized in the Middle Ages, atomism exerted a profound influence on the development of physics. True, the "atom" of Democritus is not that of Boyle, Dalton, or Rutherford, or the atom as conceived in the modern theory of elementary particles. But some of the fundamental tenets of ancient atomism persisted almost unchanged throughout the ages. Leucippus' dictum "Nothing comes into being at random, but everything comes from reason and by necessity" was the earliest enunciation of the principles of causality and determinism that dominated classical physics. Democritus' statement "Things appear to be colored, sweet or bitter, but in reality there are only atoms and the void" anticipated the distinction between primary and secondary qualities; the former, like solidity, extension, or motion, are properties inherent in bodies and inseparable from them, while the latter, like color, sound, or taste, are "nothing in the objects themselves" (Locke, 1690), but merely sensations in our consciousness. This distinction led Galileo, Descartes, Hobbes, and Locke to confine the task of physics to the study of only quantitative relations. It also raised, however, the philosophical question of whether macroscopic entities, like tables or trees, have an existence on their own, not only as aggregates of atoms—that is, the problem of whether the composite is more than the sum of its components and has a reality of its own.

An answer to this problem was given by Plato, who declared that the objects perceived by our senses are but imperfect copies or crude imitations of their ideas or "forms," which exist in a supersensible world beyond space and time and which are accessible to us only by pure thought. Influenced by Pythagoras, Plato contended that true knowledge of physical objects can be obtained only by mathematical studies of the ideas or forms of the objects. Consistent with his philosophy, Plato proposed in his influential dialogue *Timaeus* a purely geometrical theory of the structure of atoms as regular polyhedra.

Aristotle rejected the Platonic transcendentality of forms and argued that the form or idea of an object inheres in its substance: Every object is a union of matter and form; matter endows it with its individuality, form makes it a member of a class of similar objects. On this metaphysical assumption, he based his inductive-deductive method, according to which physical research has to progress from sense experience and to derive by induction generalizations that serve as premises for the deduction and explanation of observed phenomena. To avoid an infinite regress of explanations, self-evident premises have to be posited without demonstration. In accordance with the rule that "demonstrations must be based on premises prior to and better known than the conclusions," as stated in his *Posterior Analytics* (Book 1, Chap. 3, 72 b 25), Aristotle laid the foundations of the axiomatic approach to the formulation of physical theories and developed a rather elaborate proof-theory, stating, e.g., that "that proof is the better which proceeds from the fewer postulates" (*ibid.*, Book 1, Chap. 25, 86 a 33). His invention of the axiomatic method had an incisive influence not only on mathematics, where it was first applied to geometry by Euclid in his *Elements*, but also on the development of physics. Archimedes, for example, adopted the axiomatic method in his presentation of the science of statics when he began his treatise *On the Equilibrium of Planes* with the postulate that "equal weights balance at equal distances," implying thereby that a symmetrically loaded lever is in equilibrium.

---

*All references to works of Aristotle use what is known as the Bekker pagination (Bekker, 1831–1870).

Already Aristotle himself axiomatized, though not yet in a syntactical formalism, his theory of enforced motion by postulating that "any object that is in motion must be moved by some agent" (256 a 3) and that the mover must be in direct contact with the moved. This statement requires some explanation. In his treatise *Τα Φυσικα* (the Greek for "nature," from which the discipline of "physics" derived its name), Aristotle defined "physics" as the science of things that move or change, and he distinguished enforced from natural motion. The motion of a vehicle, when drawn by a horse, or of a stone, when thrown by a hand, is an enforced motion, while the motion of an apple falling off a tree is a natural one. The Aristotelian theory of natural motion is intimately related to the doctrine of the natural places of the elements, which doctrine in turn is the basis of Aristotle's cosmological world picture. For he accepted the traditional theory of the four elements earth, water, air, and fire, the natural places of which determine the sublunary spheres with Earth at the center; the celestial spheres that enclose the finite universe consist of a fifth element, the incorruptible ether. Now, the natural motion of an object in the sublunary world is but the quest of the element of which it consists to return by the shortest way to its natural place; and the natural motion of celestial matter is the eternal and self-contained circular motion. This ontological and nomological differentiation between a physics of the heavens and a physics of the Earth complied later very well with the teachings of medieval theology and contributed, therefore, to the survival of Aristotelian physics throughout the Middle Ages.

1.2 Philosophy and Experimentation in Preclassical Physics

Ancient and medieval physicists based their science upon observation and speculation and not, as a rule, on experimentation. Sociologists explain this fact by pointing out that in those times the institution of slavery provided cheap labor and thus retarded the development of energy-saving technologies and hence also the construction of scientific instruments. Another no less important reason was undoubtedly the thesis of the ancient philosophy of physics that nature is endowed with a life of its own (hylozoism) and that things can behave naturally only within their natural habitat. An experiment, in contrast to passive observation, was regarded as an interference with the course of nature or even as an act of violence. In fact, simple devices, such as the lever, the wheel and axle, or the pulley, were not called "physical" instruments but rather "mechanical" contrivances, for the Greek term μεχανη, the root of the words "machine" and "mechanics," meant "trick" or "deceit"; by using these appliances, one supposedly bilked or cheated nature to behave contrary to itself. "When we have to produce an effect contrary to nature . . .," says the pseudo-Aristotelian treatise *Mechanical Problems*, "we call it mechanical" (*Mechanica*, 847 a 10). In short, since the performance of an experiment imposes artificial conditions, "contrary to nature," an experiment, it was argued, could never increase our knowledge about nature. This idea, though slightly modified, reappeared in modern physics, where according to certain interpretations of quantum mechanics the Heisenberg indeterminacies result from disturbances caused by the measuring process.

As a result of the invention of mechanical devices that, like the waterwheel, were widely applied to spare human effort, these arguments began to lose much of their cogency already in the early Middle Ages. During the Renaissance, the development of mechanical craftmanship in architecture, engineering, and the fine arts led gradually to an appreciation of experimentation, as illustrated by Leonardo da Vinci's experiments with small-scale models to solve architectural problems. Finally, though not yet for the purpose of discovering new physical effects or laws, Galileo Galilei established the method of controlled experimentation in order to test mathematically derived conclusions. Since, as Galileo (1623) put it, "The book of nature is written in mathematical language" and since an experiment *qua* quantitative test is likewise described in mathematical terms, the experiment was no longer regarded as an extraneous interference with nature.

With his experimental study of free fall, Galileo refuted the teleological conception of "natural motion" and replaced it by the purely descriptive notion of a uniformly accelerated motion satisfying the famous formula $s = \frac{1}{2}gt^2$, the earliest physical equation to contain "time" as the independent variable. Galileo also introduced the use of thought experiments, as, e.g., in his refutation of Aristotle's thesis that heavy bodies fall faster than light ones, by simply conceiving a heavy body as a combination of light components and showing that the Aristotelian thesis thus leads to a self-contradiction.

2. THE PHILOSOPHY OF CLASSICAL PHYSICS

2.1 Philosophical Problems of Classical Mechanics

The most devastating attack against Aristotelian physics was, of course, the announcement of the principle of inertia, the very antithesis of Aristotle's first axiom of motion. Historians differ on who was the first to announce the law of inertia, whether it was Galileo who applied it only to horizontal motions along the surface of the Earth, whether it was the Dutch physicist Isaac Beeckman who derived it from the properties of space, or whether it was Descartes who deduced it from the conservation of linear momentum (Jammer, 1990). In his *Philosophiae Naturalis Principia Mathematica*, which has been called "the most important work ever published in the physical sciences" (S. W. Hawking), Isaac Newton (1687) formulated the principle of inertia as the first law of motion as follows: "Every body continues in its state of rest, or of uniform motion in a right line, unless it is compelled to change that state by forces impressed upon it." Although Newton's first law has ever since been regarded as a cornerstone of classical physics, its philosophical status is still a matter of dispute. Opinions differ on whether it should be regarded as the result of experimental experience (Frank, 1946), whether it is an idealized construct, inaccessible to empirical realization, and hence merely a convention (Poincaré, 1902), or whether it should serve as a definition of the absence of forces or as a statement of the existence of inertial systems. As the Preface of the second edition of the *Principia* clearly indicates, for Newton the first law was firmly rooted in experience. True, Newton regarded physics, as the title of his work clearly shows, as a part of philosophy; but his philosophy was not a kind of speculative metaphysics but rather "experimental philosophy" in the sense of Francis Bacon's *philosophia experimentalis* (Bacon, 1620). Newtonians were convinced that the laws of motion express undeniable truths. In fact, according to Leonhard Euler (1750), these laws could even be used to reverse the traditional relation between physics and philosophy, for "knowledge of the truths of mechanics can serve as a guide in the thorny researches of philosophy . . . and it would be justified to reject all the reasons and all the ideas of metaphysics, however well founded they otherwise be, if they lead to conclusions contrary to these truths of mechanics." This statement proclaimed not only the independence of physics but even its epistemological priority over philosophy and was a protest against the traditional view that had been dominating physical thought in the past. Let us not forget in this context that philosophical, teleological, and theological thought had played an important role in the development of physics. Descartes, for example, derived the conservation laws of mass and of linear momentum from the immutability of God; for Newton, absolute space was an attribute of divine omnipresence; Maupertuis interpreted the principle of least action, from which can be derived the Lagrangian and Hamiltonian equations, the most frequently used equations in theoretical physics, as a teleological maxim, according to which nature strives to attain a maximum of parsimony. It took quite some time until it was understood that these extremum principles are merely integral formulations of differential equations and as such not more indicative of purposiveness in nature than any other law of physics.

In the 19th century, physics and philosophy were regarded as two independent and autonomous disciplines. Their alienation led, at the close of that century, to the program of a systematic elimination of all metaphysical ingredients from physics. The way to this positivistic enterprise had been prepared already by the sensationalistic school founded by George Berkeley, a contemporary of Newton. It claimed that physical objects in their *knowable* aspects are reducible to sensible properties (*"esse est percipi"*). But it did not completely exempt itself from metaphysics since the physical object continued to lurk behind the scenes as the source of its sensible appearances. The radical step of identifying the physical object with its sensible appearances was made by Ernst Mach. His positivistic replacement of metaphysical notions by logical constructions and operational definitions was instrumental for the rise of modern physics, as we shall see in Sec. 4.

2.2 The Philosophy of Space and Time in Classical Physics

Most of the philosophical problems of classical physics are conceptually related to Newton's laws of motion. It will have been noted, for example, that the first law, as stated by Newton, does not specify the reference system relative to which the state of rest or uniform motion is to be determined. The question of the identification and ontological status of this reference system became one of the major problems in the philosophy of space and time. Newton thought to have solved this problem with his theory of absolute space, absolute time, and absolute motion, the existence of which he claimed to have proved experimentally. A water-filled bucket, suspended by a twisted rope, was allowed to rotate with the unwinding of the rope; analyzing the different phases of this bucket experiment, Newton argued that the deformation of the rotating water surface could not be due to the motion of the water relative to the bucket but was rather the result of a centrifugal force and hence, according to the second law of motion, of an acceleration, which, since not relative to the bucket, must be relative to something else that he identified with absolute space.

Newton also maintained the absoluteness of time. Herein he followed his teacher Isaac Barrow (1670) who in his *Lectiones Geometricae* had already rejected the Aristotelian-scholastic conception of time as "the number (or measure) of motion" and argued that since God's creation of the world is itself a process that takes place in time, time must have existed prior to the act of creation. Influenced by Barrow and the Cambridge Platonists, like Henry More, whose notions of space and time were theologically biased, Newton declared in the famous Scholium of the second edition of the *Principia* that God, being eternal and infinite, and existing always and everywhere, "constitutes duration and space." In addition to these arguments, Newton also resorted—a point rarely mentioned—to purely epistemological considerations in support of his theory of absolute space and absolute time. Thus he wrote, for example, anticipating somewhat Immanuel Kant's critical approach in the "Transcendental Aesthetic" of the *Critique of Pure Reason* (Kant, 1781), "One can imagine that there is nothing in space, yet we cannot think that space does not exist, just as we cannot think that there is no duration, even though it would be possible to suppose that nothing whatever endures" (Hall and Hall, 1962).

Newton's theory of space and time was strongly opposed by G.W. Leibniz's relational theory according to which space and time are merely systems of relations between things or events. In a posthumously published essay, Leibniz (1715) presented a deductive construction of relational time and space that became the prototype of modern causal theories of space-time. Leibniz defined the temporal relations of simultaneity and priority in terms of causal relations and space as the order of simultaneous things or events. In a famous epistolary debate with Newton, who was represented by Samuel Clarke, Leibniz argued that absolute space offers no sufficient reason why physical objects have the particular position or orientation they happen to have and are not "placed the quite contrary way, for instance by changing East into West" (Clarke, 1717). Neither succeeded in convincing the other. Leibniz failed to counter Newton's dynamical arguments, while Newton, aware of the fact that mechanics obeys Galilean relativity so that only accelerations but not velocities can be absolute, failed to identify the privileged reference frame. He could only conjecture that "in the remote regions of the fixed stars, or perhaps beyond them, there may be some body absolute at rest," an idea taken up later by Carl Neumann (1869) in his theory of the "Alpha-Body" (Jammer, 1954).

Because of the spectacular success of Newtonian mechanics in its applications to terrestrial and astronomical problems, the absolutist theory dominated classical physics until the end of the 19th century. In the course of that century, the ancient idea of the ether, which had played an important role in the natural philosophy of Descartes, Huygens, Hooke, Euler, and others, gained renewed prominence as an explanatory principle for electrical, magnetical, and optical phenomena. With the general acceptance of Augustin Fresnel's theory of the ether as an all-pervasive stationary substratum, in which light propagates and through which the Earth is moving, the ether became the representative of the ultimate system of reference and assumed the role of absolute space. On this assumption, the time required for a light wave to pass between two points on the surface of the Earth would have to depend on whether the light wave is moving in the direction of the Earth's motion or opposite to this motion.

As is well known, the meticulously performed ether-drift experiments, like the famous Michelson–Morley interferometer experiment, showed with their "null results" the untenability of these ideas and led, with the rise of the special theory of relativity, to the abolishment of the ether and with it, presumably, of absolute space. This does not mean, however, that a non-null result of these experiments would have left Newtonian space-time as the only surviving alternative or that the issue "absolute vs relational space" has been definitely settled thereby. In fact, quite a few modern philosophers of space and time abstain from taking sides or even declare that "relativity theory, in either its special or general form, is more inimical to a relational conception ... than is classical physics" (Earman 1989; Jammer, 1993).

2.2.1 The Dimensionality Problem of Space One of the first to realize that the three-dimensionality of space, which had been usually taken for granted, poses a physical problem was Immanuel Kant. In the very first of his published writings, he claimed that "the threefold dimension of space is due to the law according to which the forces in substances act upon another" and "that the strength of their action holds inversely as the square of the distance" (Kant, 1747). Kant's reasoning can be explained most briefly by using the notation of modern vector analysis as follows. If **P** denotes the force produced by a substance of amount M which is enclosed by a surface S of radius r, then by the divergence theorem of Gauss M is equal (up to certain constants) to $\mathbf{F} \cdot d\mathbf{S}$; hence, if **F** varies like r^{-2}, S must be two-dimensional and space consequently three-dimensional.

What Kant had in mind was of course Newton's inverse-square law of gravitation. The discoveries, after 1760, of Tobias Mayer and of Charles Augustin Coulomb that also magnetic and electric forces obey the same inverse-square law seemed to support the objection, raised by Kant's critics, that the inverse-square dependence is a consequence of the three-dimensionality of space rather than vice versa as Kant maintained. It is remarkable that recent results in the study of the dimensionality problem of physical space, which Kant inaugurated in 1747, agree on this issue more with Kant than with his opponents. In order to understand this issue, let us divide the problem into three questions:

1. What, precisely, is meant by saying that physical space has a certain number of dimensions?
2. How do we know that it really has, as generally claimed, three dimensions (or, equivalently, that space-time has four dimensions)?

3. Is there a *raison d'être*, an inherent reason, for this dimensionality?

The first question is a problem of mathematics and has been dealt with by Poincaré, Brouwer, Menger, Urysohn, and other mathematicians. The second question has been answered by physicists who, like Paul Ehrenfest (1917), showed that the stability of planetary orbits, the stability of atoms and molecules, the unique properties of wave operators and many other phenomena are manifestations of the three-dimensionality of space (perhaps only after compactification if the recent Kaluza–Klein–type theories are admitted). Concerning the third question, which from the philosophical point of view is perhaps the most interesting one, it is generally agreed that there is no fully satisfactory answer. There are, however, some indications that, as Hermann Weyl (1949) phrased it, the "physical laws may cease to be indifferent to the number of dimensions on some deeper level that has hardly been touched by the physics of today. There is thus good reason to hope that our problem will one day find a cogent solution along such lines."

For a number of reasons, a promising candidate along these lines is perhaps the electromagnetic field. Referring to the fact that the Dirac equation of quantum electrodynamics, the best-established theory of elementary particles, makes sense only in a (3 + 1)-dimensional space-time, already Cornelius Lanczos (1962) declared that "we can hardly doubt that electricity has something to do with the specifically four-dimensional nature of the universe." The Maxwell equations, which can be established without "any appeal whatsoever to the notion of metric or length" (Misner and Wheeler, 1957), relate the electric field vector **E**, which as a polar vector has in an n-dimensional space n components, with the magnetic field vector **B**, which as an axial vector, or more precisely an antisymmetric second-rank tensor, has $\frac{1}{2}n(n-1)$ components. The necessary equality of the number of their components holds in an n-dimensional space only if $n = 3$, that is, only in a coordinate system in which the number of the coordinate axes equals the number of planes spanned by the axes. Only in an $(n + 1)$-dimensional space-time can Maxwell's theory be constructed upon an invariant integral form of the action and be conformally invariant. Only there do there exist two fields related as "duals," as Weyl once pointed out. Only in a (3 + 1)-dimensional space-time do Maxwell's equations determine the Maxwell field with the same "strength" as the Einstein equations determine the metric of the gravitational field (Einstein, 1956) or as the Weyl linear first-order matrix differential equation of the free neutrino determines the neutrino field (Penney, 1965). Furthermore, the Maxwell equations are fully compatible with quantum mechanics; if one calculates, for instance, the angular momentum in a multipole light-wave field, a quantity that must be an integral number of h, Maxwell's equations neatly avoid the impasse by yielding only ratios in which Planck's quantum of action h has cancelled out (Biedenharn, 1969). Finally, all information about the physical world reaches us only via the electromagnetic field. If then, in view of this truly astonishing all-pervasive reign of Maxwell's equations, we concede that the electromagnetic field is the prior datum of experience, then clearly the *raison d'être* of the (3 + 1)-dimensionality of space-time is the existence of the electromagnetic field and "that which constitutes the spatial character of reality is then simply the four-dimensionality of the field" (Einstein, 1953). But then also Kant's derivation of the three-dimensionality of space from the laws "according to which the forces in substances act upon another" is not so erroneous as his critics contend.

In contrast to the dimensionality of space, the dimensionality of time has scarcely ever been the subject of philosophical inquiry. It has played some role in certain scholastic debates about the Aristotelian doctrine of the unity and uniqueness of time. For if time, as defined by Aristotle, is the measure of motion, the obvious multiplicity of motion, it was argued, should imply a multiplicity of times ("*tot tempora quot motus*"). It was in this context that, e.g., Roger Bacon in his *Liber Primus Communium Naturalis* emphasized in 1245 that time "has only one dimension like length." A noteworthy exception is also a passage in Kant's *Inaugural Dissertation* in which time is represented as a one-dimensional line, intersected by surfaces (today we would say "hypersurfaces") of simultaneity, anticipating modern graphical representations of space-time (Kant, 1770). The controversial speculations of accounting for precognition or extrasensory perception, such as J. W. Dunne's (1927) theory of multidimensional time or C. D. Broad's thesis of two-dimensional time, had little relevance to physics. A serious attempt at rigorously deriving the one-dimensionality of time was made only within the context of the theory of relativity (Dorling, 1970).

2.2.2 The Directionality Problem of Time Just as Newton's first law, the law of inertia, by not specifying the reference system relative to which it holds, gave rise to problems in the philosophy of space (as explained in Sec. 2.2), so did Newton's second law give rise to problems in the philosophy of time. The second law, expressed in Euler's formulation, states that "force equals mass times acceleration" or $F = md^2x/dt^2$ and, being a second-order differential equation, is invariant under the time-reversal transformation $t \rightarrow -t$. Hence, if $f(t)$ is a solution of the equation of motion, $f(-t)$ is a solution too, so that, if any process occurs in accordance with the laws of mechanics, so does the reverse process. The same invariance holds for the Lagrangian or Hamiltonian equations of motion, and for the Maxwell equations of the electromagnetic field, as well as for the Lorentz force formula. Moreover, it also holds for the fundamental equations of modern physics, such as Einstein's field equations of the gravitational field in general relativity, the Schrödinger equation in quantum mechanics, and even the equations of quantum electrodynamics (Watanabe, 1951). And yet, experience shows that the time-reversed versions of processes such as the fall of an apple from the tree or of the emission of an electromagnetic wave or the heat flowing from a hotter to a colder body never occur in nature. The most elementary example of irreversibility is the case of two particles in a Newtonian universe. If initially they are approaching each other, they will eventually be moving apart; but if they are initially moving apart, they will never be approaching each other.

Already Aristotle mentioned in his *Physics* instances of such an irreversibility, and referring to the so-called "destructive power of time," he pointed out that "we are wont to say that time crumbles things" (221 a 32); but he emphasized that "after all, it is not really time itself that destroys things in this way, but the changes that do destroy take place in time" (222 b 26). Two thousand years later, physicists reaffirmed that the apparent asymmetry does not result from the properties of time itself but is rather due to an asymmetry inherent in the physical processes. They thus faced the question of how it is possible that, for instance, the changes or motions of a macroscopic body are not time reversible, whereas the laws of motion pertaining to its constitutive parts are.

The earliest attempt to answer this question was made in the context of thermodynamics and the statistical theory of entropy. In 1854, Rudolf Clausius announced what became known as the second law of thermodynamics, namely that the entropy of an isolated system never decreases. Ludwig Boltzmann, who had studied Maxwell's probability distribution of the velocities of molecules, made use of them in the construction of his famous H function, whose negative value behaves like entropy. By showing in his H theorem that on the molecular level a nonequilibrium state evolves toward equilibrium with an increase of entropy corresponding to an increase of randomness, he thought to have solved the problem of how individual time-reversible motions can account for collective time-irreversible motions.

However, his proof of the monotonic increase in time of the negative value of the H function contained a probabilistic postulate, the assumption of the molecular chaos (*Stoßzahlansatz*) according to which the velocity of a molecule is uncorrelated with its position. This probabilistic component of the proof was not only the ultimate reason of Josef Loschmidt's "reversibility paradox" and Ernst Zermelo's "recurrence paradox," it also led Boltzmann to admit that the entropy law itself has only probabilistic validity, so that there might exist in the vast expanses of space regions in which the entropy decreases and time "runs backward."

Although the conception of time "running backward" has sometimes been used in physics, as, e.g., in Richard P. Feynman's interpretation of an antiparticle as a particle moving "backward in time" for a fraction of a microsecond, in order to explain pair production and pair annihilation, there is little agreement among physicists and philosophers on what precisely it means that the direction of time is reversed throughout cosmic expanses envisaged by Boltzmann. Could intelligent beings, if they existed in such regions, regard their own time as "forward" and merely claim that the entropy decreases, as the philosopher Hans Reichenbach (1956) suggested? If it is true, as Norbert Wiener (1958) and F. Russell Stannard (1966) contended, that any exchange of information or any physical interactions between regions of opposing time directions are impossible, such considerations would always be doomed to be mere speculations.

Boltzmann's search for a reduction of thermodynamics to Newtonian mechanics was motivated primarily by his desire to save the mechanistical world picture and the unity of physics. His awareness of having ultimately failed in accomplishing this task may well have been one of the causes of his suicide. It is therefore noteworthy that more recently the incompetence of classical mechanics to describe irreversible processes has been challenged and it has been pointed out that there exist irreversible processes that do not involve any increase of entropy (Popper, 1956). In fact, time-irreversible solutions of Newton's equations actually have been constructed, albeit only by resorting to forces the existence of which is not vouchsafed by classical mechanics or by any other well-established theory in physics. Nonentropic, boundary-dependent, so-called *de facto* (in contrast to nomologically) irreversible processes have become a widely discussed topic in the philosophy of time (Grünbaum, 1963).

It has also been pointed out that it is a widespread error to invoke the second law of thermodynamics as an objective criterion of the direction of the "flow" of time from the past to the future, or what Arthur Stanley Eddington (1929) called "the arrow of time," to express the one-way property of time that has no analog in space. Since the entropy law has no factual content in the absence of an independent definition of the direction of increasing time, such a criterion would only debase this law to a mere tautology.

Alternative criteria for the definition of the direction of time, the so-called "nonentropic time arrows," have been proposed. The most important of these are the "electromagnetic time arrow," based on the exclusive acceptance of the retarded solutions of the electromagnetic wave equation, the "microscopic time arrow," based on the fact that a rare mode of the neutral K-meson decay can be explained only as a violation of the time-reversal invariance, the "cosmological time arrow," which derives the unidirectionality of time as a result of the expansion of the universe, the "quantum-mechanical time arrow," expressing the preparation-registration asymmetry of quantum states (Bohm *et al.*, 1994), and the "quantum-gravitational arrow of time" (Wald, 1980).

It has, however, also been maintained that the idea of a "time arrow" has no objective reality in nature nor that it is even required in theory, for "throughout the sciences of physics and chemistry, symmetrical or two-way time everywhere suffices . . . we can no longer regard effect as subsequent to cause. If we think of the present as pushed into existence by the past, we must in precisely the same sense think of it as pulled into existence by the future" (Lewis, 1930). This theory of "symmetrical time" does not necessarily conceive of time as merely a psychological phenomenon, as has been done by numerous philosophers in the past; it only denies the existence of a preferential and structurally distinguished direction of time. It resembles, therefore, but is not identical with, the conception of spatialized time that characterizes the "block universe" interpretation of the space-time of relativity, which will be dealt with in the sequel.

3. ANTIMECHANISTIC THEORIES

3.1 Dynamism

The purely mechanistic world picture, most consistently proposed by Descartes according to whom only space (or extension, as he called it) and motion are the ultimate ingredients of physical reality, and subsequently modified in Boyle's kinetic theory of matter, suffered already a serious blow as soon as Newton ascribed to the notion of "force" physical reality. The "dynamization" of physics, which characterizes the renunciation of the mechanistic world picture in favor of a dynamical one, was a gradual and slow-paced process that began with Leibniz, who, in fact, introduced the term "dynamics" in his treatise *Specimen Dynamicum* (Leibniz, 1695). In opposition to Descartes, Leibniz declared that "agere est character substantiarum," "To act is the characteristic of substance; extension, on the other hand, is nothing but the continuation or diffusion of the substance already presupposed, which thrives, withstands and resists. . . ." This statement may well serve as the motto of "dynamism," the doctrine that "force" (in Greek δυναμις), which at that time denoted also what later was called "energy," has ontological supremacy in nature and is the ultimate element of physical reality. In contrast to the scholastic dictum "*operari sequitur esse*" ("action follows existence"), dynamism declares "*quod non agit, non existit*" ("what does not act, does not exist"). That in spite of such declarations Leibniz had to resort in his treatment of mechanical problems to the corpuscular theory of particle collisions had methodological reasons.

Physical arguments for the vindication of dynamism against the corpuscular-kinetic approach have been put forward especially by Roger Joseph Boscovich (1758) on the basis of the principle of continuity, which admits only continuous changes in nature in accordance with the proverbial "*natura non facit saltus.*" The ultimate particles of matter or atoms cannot be spatially extended, Boscovich argued, because this would imply a discontinuous change of density at their boundaries. Furthermore, in a collision of two particles their velocities would have to change abruptly when they rebound from each other. Hence, he concluded, atoms must be merely unextended or pointlike sources of force. To account for the impenetrability and gravitation of matter, he assumed that these forces are repulsive at small distances and become attractive in accordance with Newton's law of gravitation. Using modern terminology, one is tempted to say that the Boscovichian atom is a singularity of a field of forces.

Boscovich's ideas had a profound influence on many philosophers, amongst them Christian Wolff, Moses Mendelssohn, Immanuel Kant, Gustav Theodor Fechner, and Hermann Lotze, as well as on physicists like André Ampère, Augustin Cauchy, Siméon Poisson, and, most importantly, Michael Faraday. For Faraday, under the influence of Boscovich, was the first to propose experimental evidence for the physical reality of the notion of force. As a mathematical device that assigns to each point in a region of space some quantity, the value of which is a function of the coordinates of space and time, this notion had been used before by Lagrange, Laplace, and others. But if the criterion of the physical reality of a theoretical construct lies in the demonstration that this construct possesses detectable properties other than those for the sake of which it has been introduced, Faraday's famous experiments, described in his *Experimental Researches in Electricity and Magnetism* (1839), fully satisfy this criterion with respect to the notion of field. Although Faraday's philosophical interest focused primarily on the problem of whether electric and magnetic interactions propagate continuously through space or are actions at a distance, his work and its elaborations by James Clerk Maxwell and Heinrich Hertz led to a change in the conception of physical reality that Einstein (1934) called "the most profound and fruitful one that has come to physics since Newton." On another occasion, Einstein went even further when he wrote, "Under the influence of the ideas of Faraday and Maxwell the notion developed that the whole of physical reality could perhaps be represented as a field whose components depend on four space-time parameters. If the laws of this field are in general covariant, then the introduction of an independent (absolute) space is no longer necessary" (Einstein, 1953).

3.2 The Electromagnetic World Picture

Still after the introduction of the field conception the mechanistic world picture had a strong ally to keep it alive, the advantage of its psychological pictorability. The statement of William Thomson (Lord Kelvin) that we could really "understand a particular topic in physics" only "if we can make a mechanical model of it" characterizes this psychological need and explains why even a mathematically minded physicist, like Maxwell, described electromagnetic phenomena, and in particular the ether of optics, in terms of mechanical models. But Maxwell was fully aware that such pictorial representations should not be taken too seriously. "I wish merely to direct the mind of the reader to mechanical phenomena which will assist him in understanding the electrical ones. All such phrases in the present paper are to be considered as illustrative, not as explanatory," he wrote in his famous article "A Dynamical

Theory of the Electromagnetic Field" (Maxwell, 1865).

Only two years after his death, an electromagnetic field theory of dynamics made its debut with a study by Joseph John Thomson that envisaged the possibility of explaining mechanical inertia in terms of electromagnetism. A new research program intended to abolish the hegemony of mechanics by reducing it to electromagnetism rather than to reduce electromagnetism to mechanics. The central difficulty of explaining ordinary mass seemed to have been solved by showing that a moving charged particle has an effectively greater mass than its rest mass as a consequence of self-induction in accordance with Faraday's laws. Oliver Heaviside, George F. C. Searle, Wilhelm Wien, and most persistently Max Abraham, who declared in 1902 that "the mass of the electron is of purely electromagnetic nature," believed that ultimately all processes in nature would be reduced to convection currents and their radiations and that the "stuff" of the world would be stripped of its material substantiality. The metaphysical maxim underlying these ideas, namely that matter no longer does what it does because it is what it is, but is what it is because it does what it does, attracted much attention even on the part of more conservative physicists. Thus for example Boltzmann (1897), who had tried to reduce thermodynamics to mechanics, gave his blessings to this new program when he wrote, "... The advantage of deriving the whole science of mechanics from conceptions which anyhow are indispensable for the explanation of electromagnetism would be as important as if conversely electromagnetic phenomena were explained on the basis of mechanics. May the former succeed."

3.3 Energetism

In its attempt to renounce the supremacy of the mechanistic philosophy of nature, the electromagnetic doctrine had a serious competitor in the energetic monism or energetism, which claimed that the "stuff" of the physical universe is energy. Energetism referred to the empirical evidence that the various types of physical energy can be transformed one into another in accordance with the law of energy conservation. It interpreted these phenomena in terms of a single substratum that manifests itself as mechanical, thermal, chemical, electromagnetic, and possibly still other forms of energy. The metaphysical tenets of energetism can be traced back to the romantic *Naturphilosophie* of Friedrich W. J. Schelling, Lorenz Oken, and Wolfgang von Goethe, who criticized the mechanico-atomistic approach of Newtonian physics as incapable of giving a true account of nature, which they regarded as a vitalistic evolutionary system. Encouraged also by remarks made by Hans C. Oersted and Faraday, and searching for a scientific foundation of a nonmaterialistic world view, the energetists replaced the mechanistic-corpuscular conception of matter, motion, and the ether by the notion of energy.

One of the earliest energetists was the evolutionist Herbert Spencer, mostly known for his application of Darwinism to social developments. In his *First Principles,* using still "force" as synonymous with "energy," he wrote "We come down, then, finally to Force, as the ultimate of ultimates. Though Space, Time, Matter, and Motion, are apparently all necessary data of intelligence, yet a psychological analysis shows us that these are either built up of, or abstracted from, experience of Force," (Spencer, 1862). The most prominent advocate of energetism, however, was the chief founder of modern physical chemistry, Friedrich Wilhelm Ostwald. His energetism was based not only on his agreement with Ernst Mach that the atom is merely a convenient methodological device, but on much deeper metaphysical deliberations. What we sense, he claimed, is not the dubious and in itself entirely indefinite "matter" that classical physics thought to have brought within the compass of exact quantitative determination by its concept of inertial mass, it is rather a source of activities or energies that affect our senses. Ostwald claimed to have deduced Newton's second law of motion from the law of energy conservation, a deduction that would have decisively changed the course of modern physics. But as Boltzmann (1896) has shown, Ostwald's reasoning was mathematically flawed. Still, the idea of a "dissolution of matter into energy" became a topic of great interest. It was widely publicized, e.g., by Gustave Le Bon (1905) in a book published in the same year in which Einstein wrote his first paper on relativity and derived the mass-energy equivalence ($E = mc^2$) that prompted

Bertrand Russell (1948) to declare that "mass is only a form of energy . . . it is energy, not matter, that is fundamental in physics."

4. THE PHILOSOPHY OF MODERN PHYSICS

4.1 The Philosophical Background of Modern Physics

Twentieth-century physics extended the reach of scientific exploration to areas that previously had been inaccessible to research, such as high-speed phenomena or the structure of atoms. It soon became evident that, in order to cope with the newly discovered phenomena, not only the laws but even the conceptual foundations of traditional physics had to be subjected to a drastic revision. Questions concerning the precise meaning and the philosophical implications of the new conceptions confronted the physicist with the need of adopting a specific philosophical stance for his work. From the epistemological point of view, he could choose between *realism*, which maintains that the physical theory reflects, strictly or only structurally, the behavior of real objects, the existence of which was affirmed without doubt, and *positivism*, according to which the task of physics consists only in describing relations between measurable quantities or results of measurements, without specifying whether anything, yielding these results, does actually exist. From the metaphysical point of view, he has the option between *determinism*, according to which, like in classical physics, the final state of a system is unambiguously determined or predictable, provided the initial conditions and the laws are known, and *probabilism*, which admits chance as an unavoidable and inherent element at least in the realm of microscopic phenomena. Each of the four compatible combinations among these alternatives has a representative among the founders of modern physics.

4.2 Philosophical Problems of the Special Theory of Relativity

Special relativity was the first fully elaborated physical theory the conceptual foundations of which deviated fundamentally from those of classical physics. Traditionally, it is said to be based on two major principles; the principle of relativity, which for purely mechanico-kinematical processes had been announced already by Galileo (Galilean relativity), and the principle of the invariance of the velocity of light, which explained the null results of the well-known ether drift experiments, such as the Michelson–Morley experiment, performed at the end of the 19th century. Aware of the apparent contradiction between these two principles and puzzled by certain asymmetries in the explanations of electromagnetic phenomena, Einstein resolved these difficulties in 1905 by a drastic revision of the traditional conceptions of space and time. The critical step in these revisions was Einstein's operational definition of the simultaneity of spatially separated events. In fact, the only topic of the first section of his revolutionary paper "On the Electrodynamics of Moving Bodies" (Einstein, 1905) was precisely the concept of simultaneity from which, in the sequel of the paper, the relativistic effects, the relativity of simultaneity, the time dilatation, the length contraction, and even the Lorentz transformations are derived (in accordance with the two principles) as logical consequences. Taking into consideration that this procedure, as documentary evidence proves, was instrumental for the development also of quantum mechanics and modern physics as a whole, "It is hard to overestimate the impact of Einstein's definition of simultaneity" not only on the physics but also on the "philosophy of this century," as a contemporary philosopher of science expressed it (Nerlich, 1982).

Although the notion of simultaneity had been the subject of numerous discussions in the past (Jammer, 1986), Einstein realized that it had never been given a physically meaningful definition. For according to Einstein (1917a), "The concept does not exist for the physicist until he has the possibility of discovering whether or not the concept is applicable in a given case. We thus require a definition of simultaneity such that this definition supplies us with the method by means of which, in the present case, one can decide by experiment whether or not two events occur simultaneously." Einstein's approach, at that time, was obviously that of a staunch positivist, similar to that which had prompted Ernst Mach, 40 years earlier, to his well-known operational definition of the concept of mass (Jammer, 1961).

Einstein defined simultaneity in terms of clock synchronization as follows. Let e_A and e_B denote events that occur respectively at the points A and B of an inertial reference frame. A clock stationary at A, indicates "A time" and an identically constructed clock, stationary at B, indicates "B time." "Common time" can now be defined as follows. A light signal is emitted from A at "A time" t_A, is reflected from B at "B time" t_B, and returns to A at "A time" t'_A. If $t'_A - t_B = t_B - t_A$, then the two clocks are said to indicate "common time" and are called synchronized; and if they, thus synchronized, indicate the same time at the occurrences of e_A and e_B, these two events are by definition simultaneous.

Assuming that this procedure can be generalized for any number of points and that simultaneity is an equivalence relation, Einstein called the thus-generalized common time "the time of the reference system" or simply "coordinate time." In the sequel, he proved the relativity of simultaneity and of time by showing that two events simultaneous in one reference system are not so in another, and that the coordinate time of a given event differs in different reference systems.

Einstein's definition of simultaneity and the conclusions he drew from it gave rise to a number of logical, epistemological, and metaphysical problems. It was asked, for instance, whether Einstein's reasoning was not circular in view of the fact that his definition of time used the notion of an inertial system which, if defined as a system in which Newton's first law holds, obviously presupposes the notion of time. Another logical problem dealt with the question of whether the equivalence of simultaneity, rather than being postulated, can be obtained as a logical consequence of fundamental assumptions.

Interested in clarifying such problems and convinced that only an axiomatic formalism reveals the precise logical structure of a theory, Hans Reichenbach (1924) reformulated the theory of relativity as a rigorously deductive axiomatized system. Faced with the choice of what to posit as axioms and what as definitions, Reichenbach distinguished sharply between the empirical or factual components and the definitional or conventional components of the theory. Calling a definition, or more generally any theoretical construction, conventional if it can be replaced by an alternative that, though logically incompatible with the former, has the same observational consequences, he realized that Einstein's simultaneity definition is conventional. More precisely, he argued, the empirical facts of the theory of relativity allow replacing the Einsteinian condition $t_B = t_A + \frac{1}{2}(t'_A - t_A)$ by the more general alternative $t_B = t_A + \epsilon\,(t'_A - t_A)$, where (for causality reasons) $0 < \epsilon < 1$, without ever leading to conflict with experience.

The thesis of conventionality, namely that no facts of nature preclude the choice of an arbitrary value of ϵ between 0 and 1, gave rise to heated debates and is still today a controversial issue. The traditional method to establish simultaneity or, equivalently, to synchronize distant clocks, by sending a light signal—or any other signal for that matter—from one clock to the other and taking into account the time lapse due to the transmission velocity of the signal, was countered by Reichenbach by pointing out that "to determine the simultaneity of distant events we need to know a velocity, and to measure a velocity we require knowledge of the simultaneity of distant events. The occurrence of this circularity proves that simultaneity is not a matter of knowledge" but a matter of convention. In fact, if c denotes the two-way velocity of light that has been measured by Fizeau, Foucault, Michelson, and others with the help of light-reflecting mirrors, etc., that is, in the above-mentioned notation, twice the distance between A and B divided by $t'_A - t_A$, where only the clock in A has been used showing that c is convention free, then Reichenbach's alternative equation yields for the one-way velocity of light from A to B the value $c/2\epsilon$. Hence, knowledge of ϵ and knowledge of the one-way velocity imply each other as Reichenbach contended in his *The Philosophy of Space and Time* (Reichenbach, 1928), which has been called "the greatest work in the philosophy of physics in the 20th century" (Salmon, 1977).

The professional literature abounds in ingenious proposals for convention-free measurements of the one-way velocity of light and for other very sophisticated contrivances to disprove the conventionality thesis. A historical example is the "twin-rod experiment" of two rods of equal rest length, moving in opposite directions with equal speeds; the meetings of their extremities have been claimed to be simultaneous events. This argument, based on what is one of the most simple experiments conceivable, has misled, among others, even Wolfgang Pauli (1958), one of the shrewdest critics physics ever had, to declare that it "shows that the determination of the simultaneity of spatially separated events . . . can be carried out entirely with the help of measuring rods, without the use of clocks." The fallacy of this and other proposals to this effect follows also from the fact that John A. Winnie (1970) and others succeeded in foregoing deliberately any choice of ϵ and in deriving from premises not containing any hidden one-way velocity assumptions the equations of relativistic kinematics with ϵ as a free parameter, and yet in obtaining all experimentally testable or "factual" results of the theory. However, David Malament's (1977) challenge of Grünbaum's (1963) profound elaboration of the conventionality thesis within the context of the causal theory of time has been regarded by many, though not by all, experts in this field as a serious blow to the thesis.

The metaphysical import of this issue can be gauged by the following considerations. The concept of the "present" or "now," defined as the totality of simultaneous events, or more precisely according to Minkowski as the simultaneity hypersurface through the "here-now" of the observer, depends not only, as relativity implies, on the state of motion of the observer or on the inertial system in which he or she is at rest, but also on the arbitrary choice of ϵ. Moreover, if only the present is real and the past and future unreal, as, e.g., Arthur N. Prior (1970), one of the founders of modern tense logic, persuasively contended, then reality itself is not only relative but also a conventional conception, which sounds like a *contradictio in adjecto*.

The relativization of simultaneity and time was criticized by many philosophers, and most severely by Henri Bergson, on the following grounds. Relativization may be applicable, perhaps, to "spatialized time" as used by Minkowski in his geometrical representation of space-time, it was argued; but since real time, which exhibits itself in dynamical processes and in the unfolding of states of consciousness, loses its uniqueness if joined with, or substituted by, any spatial representation, the time of relativity is but a misleading fiction.

This dynamical point of view stands in sharp contrast to the static "block universe" conception of time, according to which "the objective world simply *is*, it does not *happen*. Only to the gaze of my consciousness, crawling upward along the lifeline of my body, does a section of this world come to life as a fleeting image in space that continuously changes in time" (Weyl, 1949). As has been objected, however, even were the block-universe conception successful in eliminating temporal succession in the physical world, it could not avoid acknowledging the progress of time at least in the movement of our consciousness to the future, and every attempt to exclude dynamical time introduces somewhere at least surreptitiously the dynamical reality of time.

Nevertheless, the idea of the static four-dimensional universe found support in certain chronogeometrical analogs to the scholastic logical arguments for predestination and fatalism, which can be traced back to Aristotle's treatment of determinism in his *De Interpretatione*. The logical problem was this: Since according to the law *tertium non datur* a proposition is either true or false, and is so at all times, one of two contradictory propositions, like "tomorrow there will be a sea-battle" and "tomorrow there will not be a sea-battle," must be true today; hence, future contingencies are determinate before they occur. The chronogeometrical analogs in question are Cornelius W. Rietdijk's (1966) "rigorous proof of determinism from the special theory of relativity" and Hilary Putnam's (1967) similar proof of his claim that future events are real already in the present. Both proofs are based on the fact that for any two events e_1 and e_2 in Minkowski space-time there always exists a third event e_3 in space-like separation from them and hence simultaneous with e_1 in one inertial frame and with e_2 in another. If in particular e_1 is my "here-now" and e_2 any event in my future, then e_3 is happening in my "now" and also in the "now" of e_2. But if what happens now is determinate and real, and if determinateness and reality are frame independent, then e_2 is just as determinate and real as e_1. It follows that the future is determinate and real already in the present and that the notions of an "open future" and "free will" are fictitious.

Both proofs have been rebutted by Howard Stein (1968) and Roberto Torretti (1983) on the grounds that both arguments resort surreptitiously to the prerelativistic temporal structure of using the tenseless present for the pronouncement of their ontological assertions.

The "twin-rod experiment," mentioned above, was originally designed by Einstein (1911) to decide between two interpretations of the relativistic length contraction, whether it was a purely metrological effect, resulting from the measurement procedure or the "perspective of observation," like the change of a rod when viewed from different angles, or whether it is an intrinsic phenomenon as real as "a change of the length of a rod, caused by the change of temperature" (Podlaha, 1975). That the ether-theoretic FitzGerald–Lorentz contraction, which had been proposed to account for the null result of the Michelson–Morley experiment, had to be regarded, within the context of the Lorentz theory of electrons, as a real phenomenon, has never been questioned since it was explained as a result of the variation of the intermolecular electromagnetic forces due to the motion through the ether. Nevertheless, it became the paradigm of an *ad hoc* hypothesis in the sense of not being testable by experiments that differ in principle from the Michelson–Morley experiment (Grünbaum, 1963). It thus initiated numerous discussions on the logical and epistemological status of *ad hoc* hypotheses in physics and science in general. The Lorentz–Larmor time dilatation, on the other hand, was hardly referred to in this context, probably because the relativistic time dilatation, in contrast to the length contraction, was generally regarded as empirically well established by the Ives–Stilwell transversal Doppler effect, the lifetime measurements of muon decay in cosmic rays, and the comparison of moving atomic clocks, even though the strength of this evidence is sometimes called into question (Huang, 1993).

4.3 Philosophical Problems of the General Theory of Relativity

A philosophical analysis of a physical theory has first of all to define the subject matter of the theory. That this is not a trivial issue is shown by the fact that the special theory of relativity has been variously classified as a geometry of light, as a theory of space and time, or as part of the electromagnetic theory of Maxwell. In fact, the German periodical *Fortschritte der Physik* used to list its abstracts of papers on relativity under the heading "Elektrizität und Magnetismus" until Max von Laue (1913) pointed out that the relativity theory deals with all branches of physics and their theories and serves "as a criterion for the admissibility of all of them." More recently, Eugene P. Wigner (1962) compared it with a "superlaw" that restricts the possible forms of laws to satisfy an invariance or symmetry principle.

In order to find out what the general theory of relativity is about, it should be recalled that Einstein's 1905 theory is named "special" or "restricted" because it deals with physical phenomena in inertial systems, a restriction that from the purely kinematical point of view seems unwarranted and philosophically unsatisfactory. The question of how to formulate the laws of physics for arbitrary reference systems motivated Einstein's search for a "general" theory, the "clearest logical characterization" of which is according to Einstein (1955) the statement that it is "the theory which avoids the introduction of the 'inertial system'." Clearly, for Einstein the general theory was an extension or "generalization" of the special theory. Studying at first the simplest noninertial motion, the uniformly accelerated motion of a freely falling body in a homogeneous gravitational field, and being aware of the experimentally well-established equality between inertial and gravitational mass, Einstein postulated the (strong) "principle of equivalence" according to which every freely falling, nonrotating reference system constitutes a local inertial frame. This principle, in turn, led him to the revolutionary discovery that gravitational phenomena are reducible to, and explainable by, the Riemannian geometry of curved spacetime. The fact that the ensuing theory of gravitation was generally convariant, i.e., valid in arbitrary reference systems, justified in Einstein's view calling it the "general theory of relativity."

That this term is misleading and confusing was argued by Vladimir Fock (1959); for already in Newtonian mechanics, he pointed out, "One deals with the generally covariant Lagrange equations of the second kind, so that one would have to say that Newtonian mechanics contains in itself 'general' relativity." Fock's proposal of calling Einstein's 1916 theory a relativistic "theory of gravitation" has been accepted by many physicists.

If one tries to resolve this controversy by investigating the asymptotic approximations of the theory, one will find that for vanishing gravitation the theory reduces to the special theory of relativity, justifying Einstein's point of view, but that for slow motions and weak static fields it reduces to the classical gravitation theory of Newton and Poisson, justifying Fock's point of view. But Newtonian gravitation, based on the notion of actions at a distance, and special relativity, excluding such interactions and even superluminal velocities, are irreconcilable. The general theory exhibits therefore the philosophically interesting feature, rarely encountered elsewhere, of having not only different but even incompatible asymptotic approximations. This poses a problem since quite frequently the meaning of a high-level scientific concept is given its intuitive clarification in terms of its application in an asymptotic approximation of the theory.

No less unsatisfactory than the restriction to inertial systems and "contrary to the spirit of science" was the causal asymmetry between matter and space: Space affects matter, as in the aforementioned bucket experiment performed by Newton, but matter does not affect space. In the general theory of relativity, space and matter, or more precisely mass-energy, become mutually interacting partners: Mass-energy determines the geometry of space-time, and the latter determines the motion of matter. The mathematical expression of this interdependence is provided by the famous covariant field equations, which have been called "one of the greatest achievements of the human mind." Reducing the whole mechanics of gravitation to the solution of a single system of covariant partial differential equations, these field equations proved very successful: Whenever their predictions deviated from those of classical physics, observation confirmed their predictions. The geometry defined by these equations changes constantly in accordance with the changing mass-energy distribution, while its curvature, i.e., the deviation of its space-time metric from the flatness of Euclidean geometry, accounts for the physical phenomena usually ascribed to a gravitational field. General relativity dispelled not only the previously prevailing doctrine of the Euclidicity of physical space—which Kant regarded as an *a priori* necessary condition of experience—but also the erroneous identification of abstract logically formalized geometry with the geometry of physical space, which latter is the product of empirical investigation. Referring to this differentiation, Einstein (1921) declared, "As far as the propositions of geometry refer to reality, they are not certain; and as far as they are certain, they do not refer to reality."

The question of whether geometry is a corollary of physics or physics is a corollary of geometry has been a subject of philosophical discussions long before the advent of geometrodynamics according to which empty curved space-time is the only "stuff" of physical reality (Wheeler, 1980a). Even the fundamental problem of how the geometrical structure of a region of space or space-time can be empirically determined by means of measuring devices that themselves are physical objects and hence subjected to the deforming influence of gravitation, a problem dealt with already by Poincaré, is still a controversial issue. The epistemological holism claims that geometry and physics form an inseparable whole; the validity or nonvalidity, say, of Euclidean geometry cannot be proved by empirical observation, because it is only the whole composed of physics and geometry that can be tested empirically. "We require this whole network of theoretical considerations to arrive at an experimental means of verifications" (Weyl, 1992). This argumentation has been criticized, e.g., on the ground that "it would then have to be acknowledged that there is a sense in which physical geometry itself does not provide a geometric characterization of physics reality" (Grünbaum, 1963).

To generalize the special to the general theory, Einstein (1916) formulated "the postulate of general covariance," demanding that "the general laws of nature are to be expressed by equations which hold good for all systems of coordinates, that is, are covariant with respect to any substitution [coordinate transformation] whatever." This postulate implies, he claimed, what he called "the postulate of general relativity" according to which "the laws of physics must be of such a nature that they apply to systems of reference in any kind of motion." To prove that the latter principle is a logical consequence of the former, he pointed out that "the sum *of all* substitutions [coordinate transformations] in any case includes those which correspond to all relative motions of three-dimensional systems of coordinates." Einstein's argument was soon criticized by Erich Kretschmann (1917) on the ground that all physical theories, independently of the physical content of their laws, are expressible in generally covariant form and hence would have to satisfy the general relativistic principle; this principle could therefore not lead to a new physics entailing factual consequences not encountered before. This controversy initiated extended discussions on the nature and status of the principles of relativity, covariance, invariance, and symmetry, and led to the distinctions between coordinate systems and reference frames, between laws and metalaws (Bunge, 1961), and between "dynamical objects" and "absolute objects" (Anderson, 1967), all designed to resolve the conceptual muddle.

Another principle, that has also played an important, though only heuristic, role in the attempt to extend the relativity principle to all frames of reference, and which has likewise intrigued philosophers of physics, is what Einstein has called "Mach's principle." Briefly stated, it claims that the inertial mass of a body results from its interaction with other bodies in the universe. Because of the vagueness of its formulation and its cosmic connotations, it has never lost its philosophical appeal. True, the field equations of the theory partly incorporate this principle. For according to them the metric tensor, i.e., the geometrical structure of the inertial or gravitational field, is determined by the energy-stress tensor, that is to say, by the distribution of matter and energy in the universe. Since, however, these differential field equations are of the second order, boundary conditions have to be imposed in order to obtain solutions. But the very idea of boundary conditions is contrary to the spirit of the Machian program, according to which the observed universe should self-referentially supply the terms of its own description. Some authors, like Grünbaum (1963), regard the need of boundary conditions as a substitute for absolute space, claiming that the general theory has not at all "exorcised the ghost of Newton's absolute space." Others, like Helmut Hönl (1953), interpret Mach's principle as a constraint to serve as a selection rule to separate admissible from inadmissible solutions of the field equations. Still other philosophers, following Lawrence Sklar (1974), dispose of the principle by simply accepting the existence of inertial and noninertial systems as "just a brute, inexplicable fact about the world."

The question of how to save the general theory from the need of imposing anti-Machian boundary conditions was precisely the issue that led to the establishment of modern cosmology. For it changed the cognitive status of traditional cosmology by shifting it from the realm of poetical, theological, and metaphysical speculations to that of a rigorously established physical science. The pivotal idea, first conceived by Paul Ehrenfest in 1916, but fully elaborated only by Einstein, was to eliminate boundary conditions by conceiving the four-dimensional universe as a spherically closed manifold, finite with respect to its spatial dimensions, and to let matter turn space back on itself—in analogy to the two-dimensional unbounded, but finite, surface of an ordinary three-dimensional sphere.

In his foundational paper "Cosmological Considerations in the General Theory of Relativity," Einstein (1917b) constructed on the basis of the field equations (modified by the addition of the so-called "cosmological constant") an isotropic, homogeneous, unbounded, spatially finite, and static model of the universe. Its material content was thought to exist of a pressureless fluid or "dust," uniformly smeared over all space-time. Surprisingly, not much later, Willem de Sitter found a non-flat solution of the same field equations devoid of all matter. Clearly, the existence of two disparate solutions of the same field equations was a fatal blow to Mach's principle. After strenuous efforts to save the principle, Einstein rejected it and its underlying positivist philosophy and declared that scientific theories are free creations of the human mind; they are not derivable from sense experience but have to be confirmed by it.

The subsequent development of relativistic cosmology, from Aleksandr A. Friedmann's construction of models of an expanding universe as solutions of the field equations (without the cosmological constant), their subsequent observational confirmation by Edwin P. Hubble, until, say, Kurt Gödel's solutions yielding an absolutely rotating universe, disproved not only the validity of Mach's principle, but also that of Einstein's cosmological model of 1917. But the same development also shows that sometimes it is not the answer but the question and method of tackling it that are of lasting importance.

The promotion of traditional cosmology to the status of a respectable physical science with the help of general relativity was greatly enhanced when in the recent decades relativity, in cooperation with particle physics, investigated not only the structure of the universe but also its physical history or what is traditionally called cosmogony. By developing, for example, the by now widely accepted Big Bang theory and studying baryosynthesis and nucleosynthesis, as well as the formation of galaxies and stars, cosmology could scientifically address the age-old problem of how the universe began and how it will end. Like other branches of physics, cosmology made specific quantitative predictions that subsequently have been borne out by observation as, e.g., in the case of the well-known 3-K microwave radiation.

However, the object of these studies is the universe as a whole and not, as in all other branches of physics, a spatially and temporally small-sized portion of it. This raises the question of whether this peculiarity of cosmology allows free use of the research methodology employed in ordinary physics. For if the universe is by its very definition necessarily unique in the sense of not being a member of an ensemble and *a fortiori* not being reproducible, then clearly inductive, statistical, and probabilistic methods, employed in ordinary physics, are inapplicable.

Some philosophers distinguish between essential or necessary and accidental or contingent uniqueness, the former being the case if any imaginable alternatives to the actual universe are necessarily impossible; the latter, if it is conceivable that different kinds of universes might have been formed. In this latter case, the additional question arises: Why is the actual universe just the one that has come into existence?

It is precisely this last question that has recently become a much-debated topic in the philosophy of physics. For modern physics has shown that the universe in which we live is "finely tuned" to the conditions of human life in the sense that, if the values of the fundamental physical constants, like the charge of the electron, the strength of the strong-nuclear force, or the gravitational constant, differed even only slightly from their actual values, life would have been impossible. One may, of course, answer that this state of affairs is simply a matter of pure coincidence, or the result of a purpose or design.

Eschewing teleological explanations, the proponents of what Brandon Carter (1974) called the "anthropic principle" (or "cognizability principle") have given a different answer, which departs, however, from the traditional method of scientific reasoning. It says "that what we can expect to observe must be restricted by the conditions necessary for our presence as observers." More precisely, Carter distinguished between the basic and less controversial *weak* version of the anthropic principle, according to which "our spatio-temporal location in the universe is necessarily privileged to the extent of being compatible with our existence as observers," and the philosophically much more audacious *strong* version, according to which the universe "must be such as to admit the creation of observers within it at some stage."

Historically viewed, both versions generalize Descartes' famous "Cogito, ergo sum" ("I think, therefore I exist") to "Cogito, ergo mundus talis est" ("I think, therefore the world is as it is"), and both versions qualify the so-called (but misnamed) "Copernican principle," which denies any privilege to man's location in the universe, by asserting man's epistemological centrality. Both versions maintain an ontological and nomological compatibility relation between man and the universe as it is; but the strong version affirms in addition that any counterfactual variation of the laws or initial conditions of the universe would exclude the possibility of man's existence. A still stronger version is John A. Wheeler's (1980b) "participatory anthropic principle," "Observers are necessary to bring the universe into being," implying that in a certain sense man "participates" in the creation of the universe. The epistemological basis of Wheeler's self-referential cosmogony, namely that "no elementary phenomenon is a phenomenon until it is observed or registered," is a logical consequence of his interpretation of quantum mechanics, which will be discussed in due course.

4.4 Philosophical Problems of Quantum Mechanics

Since its inception in 1925, modern quantum mechanics, established primarily by Werner Heisenberg, Erwin Schrödinger, Max Born, and Paul A. M. Dirac, has been stupendously successful in accounting for virtually all phenomena in atomic and molecular physics, in solid-state physics, and chemistry, as well as in its contributions to nuclear physics and to the physics of elementary particles. But in no other theory is there such an irreconcilable disagreement among physicists and philosophers as to what the theory tells us about physical reality, and are physics and philosophy so inextricably entangled, as in quantum mechanics. In spite of an unprecedented sharpening of the logical, mathematical, and semantical tools for the philosophical analysis of physical theories, the ontological and epistemological problems of quantum mechanics have not only not been resolved but have even been aggravated in the past few decades. These difficulties are partly the result of the fact that, unlike the situation in any other theory of physics, the formalism of quantum mechanics preceded its interpretation.

Opinions already disagree on the referent of the theory, that is, on what precisely the theory or its formalism is about. According to the standard version, the so-called Copenhagen interpretation, the mathematical formalism in terms of the state vector or Schrödinger wave function provides a description of the individual quantum system, whereas the ensemble interpretation refers the state vector to a statistical collection of systems.

Nor is there any consensus on whether the immediate referent is physical reality itself or merely knowledge of it. Those who agree with Einstein (1949) that "physics is an attempt conceptually to grasp reality as it is thought independently of its being observed," and that "the belief in an external world independent of the perceiving subject is the basis of all natural science," insist that quantum mechanics should be a realist theory. The opposing instrumentalist or subjectivist position is taken by those who agree with Bohr that "there is no quantum world; there is only an abstract quantum physical description; it is wrong to think that the task of physics is to find out how nature *is*, physics concerns what we can say about nature" (Petersen, 1963), or with Heisenberg (1958), that "the subject of research is no longer nature itself, but man's conception of nature." It should be noted that some positivistically inclined critics refuse to attach any philosophical significance to a controversy like that between Einstein and Bohr and regard it rather, as Ernest Nagel (1961) called it, as "a conflict over preferred modes of speech." But, as we shall see at the end of our discussion, the endorsement or rejection of a philosophical position may well be motivated by physical arguments rather than by the predilection for a certain mode of speech.

If the question concerning the referent of quantum mechanics is, indeed, a matter of physical considerations, it may be tempting to search for the answer by way of applying the method of asymptotic approximations, as it has been applied above in the case of general relativity. Although there exist, in fact, different and—surprisingly—nonequivalent approximation methods (Planck's method of $h \to 0$, Bohr's method of $n \to \infty$, where n is the principal quantum number, and Ehrenfest's method of taking the expectation values of the observables), a closer analysis (Liboff, 1984; Ajanopon, 1987) shows that this method cannot supply any answer.

The tenability of the ontology of classical physics and hence also the maintainability of its realism for microphysics have been questioned already by the "old quantum theory." This term denotes the microphysics of the period between 1900 and 1924, i.e., from Planck's explanation of the black-body radiation in terms of the quantum of action h, and Einstein's subsequent interpretation of the photoelectric effect, through Bohr's theory of the hydrogen atom until Louis de Broglie's thesis of the wavelike behavior of material particles. In spite of its name, the "old quantum theory" has never become a full-fledged scientific theory. Its principal fault was its indiscriminate conflation of classical and nonclassical conceptions, making a coherent interpretation impossible.

The development of a conceptually coherent and logically consistent quantum theory began in 1925 with the advent of Heisenberg's matrix mechanics and Schrödinger's wave mechanics, and reached its maturity about 1930 with John von Neumann's rigorous proof that both formalisms, in spite of their apparent disparities, are but different representations of the same operator calculus in Hilbert space. In view of the unvisualizability of matrix mechanics, wave mechanics with its presentation of particles in terms of wave packets gained greater popularity. But the "spread" or instability of these wave packets and other peculiarities caused serious difficulties. To resolve these difficulties, Max Born (1926) proposed the statistical interpretation of the wave function as a "probability wave," the amplitude of which specifies the probability of the particle's location. The wave function thus becomes a catalog of possible probability distributions, where the word "possible" refers to the choice of the observer as to what observable he wishes to measure, while the word "probability" refers to the observer-independent relative frequency of obtaining a specific value of the chosen observable. Born's introduction of the notion of probability into quantum mechanics is generally regarded as marking the demise of the determinism of classical physics. True, classical physics has made ample use of the probability concept, as for instance in the theory of errors in measurement procedures or in statistical mechanics; but classical probability was always thought to be due to human ignorance of a more refined specification of the physical data. In quantum mechanics, however, at least according to Born's interpretation, probability became an objectively existing, intrinsic, and irreducible component of physical ontology and the source of an uneliminable indeterminism of the theory.

Laws of nature no longer, as they do in classical physics, determine the occurrence of an event but only the probability of its occurrence. This raises the problem of the precise ontological status of this probability. Its temporal evolution and spatial propagation in accordance with the Schrödinger equation seem to indicate that it is not merely a mathematical construct. Since probability waves do not transmit energy or momentum and hence can hardly be regarded as physically "real," Heisenberg (1961) compared their ontological status with that of the Aristotelian notion of *potentia*.

Heisenberg's (1927) indeterminacy relations, which exclude the possibility of simultaneously specifying the values of two canonically conjugate observables, like position and momentum, to within arbitrary degrees of accuracy, have also been regarded as a confutation of determinism. For determinism states that *if* the initial state, e.g., position and momentum, of a system is exactly known, then the state of the system at any other time can be predicted. But Heisenberg's principle denies the possibility of ascertaining the initial state. The objection that the falsity of the premise of an implication does not necessarily entail the falsity of the implication was rebuffed by Heisenberg on the ground that any conception of a deterministic universe, hidden behind the statistical universe of perception, is a meaningless speculation since physics deals only with the relationships between perceptions.

The indeterminacy relations are intimately related to Bohr's (1927) complementarity principle and generally regarded as its quantitative aspect. Complementarity requires that the quantum object be described in two different, even contradictory, ways, which are complementary in the sense that both are necessary to exhaust the possibility of obtaining information about the object, even though the two ways are experimentally not simultaneously performable. Complementarity is in Bohr's view the only possibility of generalizing the classical mode of description without ignoring the quantum of action. His belief in the unity of knowledge led him to extend the epistemology of complementarity to other branches of science, like psychology or biology, and even to consider it as a means to reach greater mutual understanding among nations and cultures.

The best-known example of complementary descriptions is the wave-particle duality; and the easiest way to demonstrate it is the well-known two-slit experiment which, according to Richard Feynman (1951), "has in it the heart of quantum mechanics . . . and contains the *only* mystery" of this theory. In fact, this experiment, which, incidentally, has recently been actually performed with neutrons, implies a wave description because of the interference effect if both slits are uncovered, and a particle description if only one slit is uncovered. Moreover, since in any case, the interference case included, the photographic plate records pointlike and not spread-out events, the experiment may be regarded in its final stage also as a measurement of position and as illustrating thereby the so-called "collapse of the wave packet" or "reduction of the wave function," a characteristic feature of every measurement process in quantum mechanics.

The very notion of a quantum-mechanical measurement raises a number of philosophical problems not encountered in classical physics. Every measurement or observation requires an interaction between the measured or observed system and the measuring device or observer. In classical physics, in which the action of the latter on the former is assumed to be negligible or eliminable by correction, this interaction is a one-way process; but in quantum mechanics, because of the indivisibility of the quantum of action, it is a two-way process with the dire consequence that, in general, a measurement of an observation changes the quantum state of the system measured or observed. Furthermore, since such measurements necessarily involve macroscopic measurement devices to yield pointer readings, and since quantum mechanics should include classical physics as a special case, the ensuing logical circularity between quantum and classical concepts questions the self-consistency and conceptual autonomy of quantum mechanics.

Aware of this difficulty, Bohr regarded the measurement outcome as depending upon the entire experimental setup, combining object and apparatus, and conceived the object-apparatus interaction as epistemologically irreducible. In order to eliminate this irreducibility, it has been deemed necessary to include the measurement process into the formal account of quantum mechanics. How to do this is the task of the "measurement theory of quantum mechanics."

Such theories, most of them modifications of a proposal made by von Neumann (1932), face two difficulties, namely the questions of how and where the so-called "collapse of the wave packet" takes place, questions that are controversial issues still today. For if the measuring device itself is treated as a quantum system, it adds to each component of the superposition, which describes the initial state of the object, an additional term instead of reducing it to an eigenstate corresponding to the eigenvalue of the observable that is to be measured. In other words, object and measuring device form a combined system for the measurement of which a second measuring apparatus is required. This process obviously leads to an infinite regress.

Among the numerous suggestions to resolve these difficulties, the proposal made by Fritz London and Edmond Bauer (1939) attracted much attention because of its relevance to the mind-body problem. They suggested that it is the human "faculty of introspection" ("*connaissance immanente*") that actualizes the reduction of the superposition in the consciousness of the sentient observer. The London-Bauer measurement theory has far-reaching philosophical implications. Since according to quantum mechanics every physical interaction between particles involves a superposition, a world without a sentient observer, who reduces the superposition, would be a limbo of mere potentialities that never actualize into factualities; it would be a world in which nothing whatever happens. It was precisely this consideration that led Wheeler to the formulation of his aforementioned "participatory anthropic principle."

Critics objected that this measurement theory, although free from logical inconsistencies, is hardly compatible with the intersubjective agreement among independent observers. Furthermore, they pointed out, the notion of a mental act should not serve as a primitive concept in physics, for too little is known about the mind-body problem or about the brain, which is supposedly the seat of consciousness and probably the most complex system in the whole universe. This observer-dependent measurement theory in their view simply explains a riddle by a mystery.

To avoid this impasse, alternative measurement theories have been proposed, some of them resorting to the irreversibility of macroscopic systems, others to a hypothetical micro-to-macro amplification process, and still others to a modification of the very structure of quantum mechanics into a nonlinear theory. But so far no satisfactory solution seems to have been obtained. The well-known "paradoxes" of "Schrödinger's cat" (1935a) and of "Wigner's friend" (1962) illustrate the bizarre conclusions of such measurement theories.

An attempt to dispense altogether with the reduction of the wave function has been made by Hugh Everett III (1957) and elaborated by Bryce S. DeWitt and Wheeler in the ontologically most daring and epistemologically most provoking theory ever made in physics. By regarding the quantum object, the measuring apparatus, and the observer as one single quantum system, described by a state vector that never collapses, their theory eliminates the need for an extraneous observer or consciousness and affirms that physical reality is rigorously deterministic. The theory implies a continual splitting of the universe into a multitude of noncommunicating worlds, each corresponding to a component of the superposition, and it is therefore called "the many-world interpretation." Since no experiment performed in one branch of the splitting universe can detect the outcome of a measurement obtained in another branch, appearances are saved. The theory has been criticized as violating Ockham's rule that entities should not be multiplied without necessity, as ambiguous in its determination of the branches of the splitting universe because a given state function can be expanded in different sets of functions, and as not providing an explanation of why the observer is just in that branch in which he happens to be.

As is well known, the orthodox interpretation of quantum mechanics has been strongly opposed by physicists, like Einstein and de Broglie, as well as by philosophers, like Karl Popper and Mario Bunge. Most noteworthy in this context is the long-standing debate between Einstein and Bohr (Bohr, 1949), in which Einstein challenged the probability interpretation and the indeterminacy relations by a number of thought experiments that Bohr successfully rebutted on the basis of his complementarity interpretation (Jammer, 1974). One of the highlights of this debate was the argument in which Einstein presented his thought experiment with a photon box in order to disprove the time-energy indeterminacy relation, and which Bohr refuted by referring Einstein to his own general theory of relativity (Bohr, 1949).

Although defeated by Bohr, Einstein did not lose interest in the photon box. To eliminate the troublesome gravitational effect, he regarded the box and the photon as two interacting systems that then move apart along a horizontal line. This led him to the physical scenario of the Einstein–Podolsky–Rosen (EPR) argument against the completeness of quantum mechanics. The published version (Einstein *et al.*, 1935) owes its central idea to Einstein, its mathematical elaboration to Nathan Rosen, and its final formulation to Boris Podolsky. Although Einstein, as we know from his correspondence with Schrödinger, did not fully agree with the printed text, it was, of course, the published version that affected the subsequent conceptual development of the theory.

The paper begins with a necessary condition for the completeness of a physical theory: "Every element of the physical reality must have a counterpart in the physical theory," and defines "physical reality" by the sufficient condition: "If, without in any way disturbing a system, we can predict with certainty . . . the value of a physical quantity, then there exists an element of physical reality corresponding to this physical quantity." Accordingly, physical reality is not to be defined by *a priori* philosophical considerations, "but must be found by an appeal to results of experiments and measurements." In addition to these two explicitly stated stipulations of completeness and reality, a third premise is assumed that is mentioned only *en passant*: If two systems no longer interact, "no real change can take place in the second system in consequence of anything that may be done to the first system." For Einstein this premise or "principle of separation," as he called it in a letter to Schrödinger, was an essential feature of his realist philosophy. "But on one supposition," he wrote (Einstein, 1949), "we should, in my opinion, absolutely hold fast: the real factual situation of the system S_2 is independent of what is done with the system S_1, which is spatially separated from the former." Actually, this supposition is a conflation of two different principles, the "separability principle" and the "locality principle." The former states that the spatio-temporal separation is a sufficient condition for the individuation of a system or its state, and the latter, that the state of a system at a given space-time location can be affected only by events within or on the past light cone of that location. The separability principle is a metaphysical maxim; the locality principle is a physical feature of the special theory of relativity and excludes, in particular, any simultaneous action at a distance.

EPR consider a system of two particles S_1 and S_2 that are widely separated in space after having interacted with each other. They are supposed to be in a state in which their total momentum $p_1 + p_2$ and their relative position $q_1 - q_2$ have definite known values. The existence of such eigenstates is assured by the fact that the operators for this sum and difference commute. From these assumptions, EPR infer that, if they measure the momentum of S_1, they can predict with certainty the momentum of S_2 without disturbing it; "if, instead of this, [they] had chosen" to measure the position of S_1, they could have predicted with certainty the position of S_2 without disturbing it. Hence, the reality criterion implies that the momentum as well as the position of S_2 has reality. Were quantum mechanics a complete theory, it should therefore, in accordance with the completeness criterion, ascribe definite values to the momentum and position of S_2. But quantum mechanics does not do this because the respective operators do not commute. Hence EPR conclude "The quantum mechanical description of physical reality given by the wave function is not complete." The possible objection that this conclusion would be valid only if the momentum and position of S_2 are simultaneously predictable is countered by pointing out that this condition implies simultaneity of the corresponding measurement processes on S_1; but then the reality of p_2 and q_2 "would depend upon the process of measurement carried out on the first system [S_1], which does not disturb the second system in any way. No reasonable definition of reality could be expected to permit this." Obviously, EPR resort to the principles of separability and locality to meet this objection and the related criticism of making use of the counterfactual definiteness, i.e., of the controversial assumption that unperformed experiments have definite results, an assumption ascribed to their above-quoted statement beginning with the words "if, instead . . ."

As might be expected, the EPR paper became the target of numerous criticisms, the most important of which was Bohr's. Faithful to his positivistic philosophy, Bohr (1935) rejected the argument by claiming that in order to speak validly of real properties of particles "it is necessary to take into account the experimental conditions that define the possible types of prediction about the system since these conditions are an inherent element in the description of any phenomenon to which the expression 'physical reality' can meaningfully be attached." In particular, this requirement illegalizes the use of counterfactual implications for defining physical reality. Bohr was particularly interested in refuting the EPR argument for the following reason. If Heisenberg's indeterminacy relations are interpreted not merely as a prohibition of the simultaneous measurability of conjugate observables but rather, in the spirit of the Copenhagen interpretation, as a denial of the very existence of sharp values of such observables, the EPR argument disproves even the consistency of quantum mechanics.

Schrödinger (1935b), in contrast to Einstein and Bohr, saw the importance of the EPR argument in its disclosure of the existence of the nonseparability, or entanglement ("*Verschränkung*") as he called it, of the subsystems or components S_1 and S_2 in a composite system S. This means that a measurement carried out on one of the components, whatever its distance from the other, interacts with S and affects thereby the other component; and it implies holistically that the state of S is not fully described in terms of the states of S_1 and S_2, a situation often epitomized by saying that "the whole is more than its parts." This entanglement, Schrödinger declared, is *the* characteristic feature of quantum mechanics, "the one that enforces its entire departure from classical lines of thought."

Schrödinger's notion of entanglement was eagerly seized by parapsychologists as scientific support for their theses of ESP (extrasensual perception), clairvoyance, psychokinesis, and other paranormal phenomena, as well as by interpreters of quantum mechanics as a revival of Eastern mysticism. Although some reputable physicists, like the Nobel laureate Brian Josephson or Richard Mattuck, expressed some sympathy with such ideas, the majority of physicists strongly reject them. Even Wheeler, whose name is often quoted by parapsychologists because of his participatory anthropic principle, vehemently opposed such ideas with the words ". . . Let no one use the EPR experiment to claim . . . any 'quantum interconnectedness' between separate consciousnesses," and he condemned those ideas as "baseless" and "moonshine."

Certain disadvantages of the published EPR argument have been eliminated in its reformulation by David Bohm (1951) in terms of the states of a pair of spin-$\frac{1}{2}$ particles in the singlet state. Bohm's formulation became the standard presentation of the EPR argument in the philosophical literature on this issue.

The EPR incompleteness argument with its emphasis on "elements of physical reality" was soon regarded as an incentive for the construction of hidden-variable theories "to complete" quantum mechanics, although—as still unpublished documentary evidence shows—the argument was definitely not intended to serve as such an incentive. Attempts to construct such theories had been made already in the late 1920s for the purpose of reinstating classical determinism in quantum mechanics in quantum physics. But as a result of von Neumann's (1932) "proof" of the impossibility of hidden variables, interest in such theories had waned until it was revived by the publication of the EPR paper. Bohm (1952) formulated a logically consistent hidden-variable theory that ascribes to every particle definite values of position and momentum as well as a continuous trajectory by adding to the usual potential a "quantum mechanical potential." By averaging over the values of the hidden variables, he retrieved all empirically testable results of the standard theory. Since in Bohm's theory of measurement the hidden variables depend not only on the state of the observed object but also on that of the measuring device and thus differ from those considered by von Neumann, the latter's impossibility "proof" did not apply.

Still, the status of Bohm's theory and of other hidden-variable theories and their relation to von Neumann's argument were fully understood only when John Stewart Bell clarified the situation. His first contribution to these problems was his proof that von Neumann's reasoning, though mathematically impeccable, rests on a certain premise, the so-called additivity postulate, which need not hold for hidden variables (Bell, 1964a). Furthermore, he drew attention to the fact that in Bohm's theory the quantum potential exhibits the "curious feature of a grossly nonlocal character."

Studying the question of whether local deterministic hidden-variable theories, i.e., theories in which the hidden variables determine unambiguously the result of every single act of measurement and satisfy the locality principle, are possible, Bell made what Josephson called "the most important recent advance in physics" and Henry P. Stapp even "the most profound discovery of science" (Stapp, 1975). Using Bohm's EPR version, Bell showed that every deterministic hidden-variable theory that is local involves a certain inequality that became known as "Bell's inequality." This inequality—and this is the important point—is *not* satisfied by quantum physics. This result, "Bell's theorem," namely that no local deterministic hidden-variable theory can reproduce all the predictions of quantum mechanics, has been formulated by Bell as follows: "In a theory in which parameters are added to quantum mechanics to determine the results of individual measurements, without changing the statistical predictions, there must be a mechanism whereby the setting of one measuring device can influence the reading of another instrument, however remote" (Bell, 1964b).

Bell (1971) subsequently generalized his theorem for the case of stochastic hidden variables. Philippe H. Eberhard (1977) derived a Bell-type inequality without using hidden variables and without the assumption of determinism. Michael Redhead (1987) showed that on this assumption counterfactual conditionals are innocuous. Generalizations of Bell's inequality are still today a widely studied subject in the foundational research of quantum mechanics. But so also are experiments performed to test whether quantum mechanics satisfies these inequalities. Practically all these experiments, and among them the very sophisticated one performed by Alain Aspect (1981) and his team, confirm the predictions of quantum mechanics and violate Bell's inequality. These results imply that the classical world picture of local realism has to be given up irretrievably. For even should ever quantum mechanics turn out to be wrong, its successor must comply with these experimental facts. Moreover, these experiments can be regarded as inaugurating what has been called "experimental metaphysics," the existence of which strikingly disproves the aforementioned thesis that a disagreement between philosophical doctrines about the nature of physical reality is but "a conflict over preferred modes of speech."

As mentioned above, locality is a fundamental requirement of special relativity. The experimentally verified nonlocality of quantum mechanics may therefore be thought to imply the incompatibility of quantum mechanics with special relativity and, moreover, the possibility of sending messages with superluminal velocities. A detailed analysis (Jarrett, 1984) shows, however, that the locality principle used in the proof of Bell's theorem is a logical conjunction of two other conditions, one of which does not violate the principles of special relativity. Since quantum mechanics satisfies only this latter condition, it enjoys a peaceful coexistence with relativity.

The conceptual problems dealt with so far have been discussed in the language of the traditional framework of quantum mechanics. However, there exist other theoretical frameworks in which quantum mechanics, especially if axiomatized, is studied, each of them having its advantages and its deficiencies. Philosophically most remarkable is the so-called quantum logical approach according to which quantum mechanics should be formulated in a logic different from that applied in the description of classical physics.

Proponents of quantum logic (*q.v.*) justify their approach by comparing the relation between logic and quantum physics with the relation between geometry and physics in Poincaré's philosophy of geometry, referred to above in Sec. 4.3. Since always only an inseparable combination of two such components is empirically testable, one of them (e.g., logic) can be altered if also the other component (the formulation of the physical theory) is changed without affecting the factual situation; but the modified physical theory, it is claimed, may turn out to be conceptually more acceptable than its original unmodified version. Garrett Birkhoff and von Neumann (1936) were the first to propose a nonclassical quantum logic. In their logic, the distributivity law with respect to the logical connectives "and" ($\wedge$) and "or" ($\vee$) is not valid. In other words, if p, q, and r denote propositions, then the classical distributive law $p \wedge (q \vee r) = (p \wedge q) \vee (p \wedge r)$ does not always hold. If, e.g., it is known that the spin of a spin-$\frac{1}{2}$ particle is "up" in the sense that the proposition p, "$\sigma_z = +1$," in units of $\frac{1}{2}\hbar$, is true, and if q and r denote, respectively, the propositions "$\sigma_x = +1$" and "$\sigma_x = -1$," then it is easy to confirm that—at least in accordance with the realist interpretation of quantum mechanics—this distributivity law does not hold. A more technical exposition that does justice to the Birkhoff–von Neumann logic would have to specify it as a propositional calculus having the structure of an orthocomplemented nondistributive (modular) lattice, in contrast to the Boolean lattice of classical logic (see QUANTUM LOGIC).

Other versions of quantum logic soon followed. Reichenbach (1944) developed a three-valued logic that contains, in addition to the truth values "true" and "false" of classical logic, a third truth value "indeterminate" that applies to statements that were regarded as "meaningless" in the Copenhagen interpretation: but in Reichenbach's logic the question of whether a system has a certain value for a given observable has three answers: "yes," "no," and "maybe," where "maybe" represents a genuinely irreducible state of affairs. Carl Friedrich von Weizsäcker (1955) proposed a "many-valued complementarity logic" in which truth values correspond to probabilities.

Quantum logic has become an immensely rich and diverse field of new mathematical and philosophical ideas. It has stimulated the development of lattice theory and, more generally, of the theory of partially ordered sets and has even contributed to various mathematical generalizations of existing theories. Pavičić's (1992) bibliography on quantum logic, compiled for the *International Quantum Logics Association* and containing about 2000 entries, is indicative of the immensity of work done in this field.

Nevertheless, there are quite a few critics who challenge the status of quantum logic on the ground that it does not provide satisfactory answers to fundamental questions such as the following: Has quantum logic convincingly shown that the genuine and universally valid logic is non-Boolean and that the traditional logic is merely a kind of asymptotic approximation to it? Can logic be really empirical in the sense of "being read off" from empirical data, in contrast, e.g., to Einstein's famous remark to Heisenberg (1971) that "it is the theory which decides what we can observe"? How can quantum logic differ from classical logic if the mathematics used in quantum mechanics is necessarily based on classical logic? And, after all, does quantum logic truly resolve any of the problematic issues of quantum mechanics instead of explaining a riddle by mystery, as the observer-dependent measurement theory is said to have done?

In conclusion, it should be pointed out that this review of the philosophy of physics has said nothing about the philosophical implications of some physical theories that are at the forefront of current research. In fact, no philosophical comments have been made about quantum field theory or the S-matrix approach with its bootstrap conjecture, or about the standard model of elementary-particle physics, based on gauge theories of the electroweak and strong interactions, or about superstring theories designed to incorporate the standard model with general relativity in a logically consistent way and to unify all known fundamental forces in nature. Nor have any remarks been made on the prospects and philosophical significance of the so-called "Final Theory," which is to explain everything in nature from a minimum of basic assumptions.

These topics are widely publicized in popular magazine articles. But they are also rigorously discussed in professional writings of such competent physicists and philosophers of science as Cushing (1983), Redhead (1983), Stöckler (1984), Brown and Harré (1988), Kanitscheider (1989), Weinberg (1992), and Teller (1994). Since, however, research in these areas is at present making enormously rapid progress, we believe that it is still too early to grasp the full philosophical significance of these developments and that it is still premature to draw well-founded philosophical conclusions. We agree therefore with the statement, made by Teller, that "as yet we have no grip on what these theories are telling us about how to conceive the world."

INTRODUCTION

Philosophy of technology, which only emerged in the nineteenth century as a field of philosophy, investigates interconnections among the human needs that invoke a technology for their satisfaction, the determinants of these needs, and how people come to know them.

The term *technology* is a combination of the Greek *technē*, meaning art, and *logos*, meaning word or discourse. In English, it first (1615) denoted a discourse on an art or arts (*Shorter Oxford English Dictionary*, 1933), later embracing the scientific study of the practical and industrial arts and their methods. In philosophical literature, the terms *technology, technic* (or *technics*), and *technique* are differentiated. Hood gives the traditional definition of technology originating with Aristotle as "a human arrangement of technics—tools, machines, instruments, materials, sciences, and personnel—to make possible and serve the attainment of human ends" (Hood, 1983, p. 347). *Technique* is usually used to convey the method of using *technics*, but because usage varies among different authors and languages, readers may find the terms used interchangeably. Martin Heidegger's concept is broader: "The manufacture and utilization of equipment, tools, and machines, the manufactured and used things themselves, and the needs and ends that they serve, all belong to what technology is." He adds that according to the current conception, technology is "a means and a human activity" (Heidegger, 1977, pp. 4–5).

Heidegger here incorporates two contemporary connotations of *technology*, the most common being the means and methods used to produce and deliver goods and services for industrial, commercial, and military use. An-

other, or anthropological, sense is "the body of knowledge available to a civilization that is of use in fashioning implements, practicing manual arts and skills, and extracting or collecting materials" (*American Heritage Dictionary*, 3rd edition, 1993). This second sense excludes aspects of modern technology, which depends more on the integration of science with technological applications and less on the manual arts and skills. Hidden in the differences among these definitions is a philosophical question: does technology deal with a body of knowledge, only its application, or both?

Technology refers in some usage to "spiritual," religious, and aesthetic needs also. In 1897, Alfred Espinas, noting that the Greeks applied *technē* to both the fine and the applied arts, argued that "we should give the applied arts the name techniques in order to distinguish them from the arts that tend to produce aesthetic emotion" (Espinas, 1897, p. 7). The case of a culture that regards a rain dance as necessary for agricultural production, however, shows that such a distinction is not always clear.

Ferré (1988, p. 26) suggests limiting the term *technology* to the "practical implementation of intelligence." He considers the purpose of "practical intelligence" to be "to survive or thrive," and that of "theoretical intelligence" as "to know or understand" (p. 33). This distinction, however, may obscure the social connections that form the essence of technology and constitute the principal stimulus for its development.

The following definition of *technology* is suggested for our discussion here: *Technology denotes the systematic, conscious application of knowledge by a society to meet its culturally conditioned real and perceived physical, biological, and spiritual needs and to guarantee its continued social existence. This knowledge is the socially accumulated understanding of how human labor and available material resources and artifacts are integrated by a society; the aspect of the society primarily involved here is its particular set of historically conditioned social relations of production.*

The association of technology here exclusively with human activity is deliberate to stress the central role that tool use and toolmaking play in human life, despite the fact that animals use and even make tools. The qualitative difference between these activities by animals on the one hand, and tool use and toolmaking in a deeply social context by humans on the other, is so sharp, however, that one scholar even suggests the term *utensil* be used for objects used or produced by animals, while the term *tool* be limited to objects produced by humans (Tobach, 1993). Only humans consciously create artifacts. Early examples are primitive tools made by combining or reshaping natural objects to be held in the hand for physical protection or for procuring or processing food. Shaped stone objects in the vicinity of fossil bones identify the remains as protohuman. Toolmaking has been a criterion to distinguish humans from other animals at least since the time of Benjamin Franklin, to whom James Boswell attributed the definition that man is "a toolmaking animal" (Boswell, 1934, p. 245). Thomas Carlyle's remark that "Man is a Tool-using Animal" has also been used to distinguish between humans and other animals (Carlyle, 1921, p. 37). Charles Darwin (1981) attributed to tool use a distinctive role in human evolution.

Since technology involves the conscious application of knowledge by a society, ontological and epistemological questions arise: What is this knowledge and how do we come to know it? This body of knowledge, in turn, involves three areas: material objects (frequently referred to in philosophical literature as "artifacts"), skill and knowledge in employing them, and the technological relations of production, that is, the way human labor is organized in the technological process.

Our species emerged in a process of biological evolution. The technology by which we provide our material needs was an integral part of this process. After the emergence and biological stabilization of our species, technological development continued. We begin this article with a discussion of the role of technology in human evolution, then go on to consider the interconnections between technological development and the evolution of human societies through their various stages. Readers are referred to PHYSICS AND TECHNOLOGY, HISTORY OF, for a detailed discussion of that history. Here, we focus our attention on stages of technological development that represent turning points in human history. We consider some theoretical and practical areas in which science and technology interact and conclude the article with a discussion of viewpoints being presented in contemporary philosophical literature on problems arising from technology today.

1. TECHNOLOGY AND SOCIETAL DEVELOPMENT

A principal concern of philosophy of technology is how technological development influences the course of societal interrelationships at different stages of societal organization, as well as how specific stages of societal organization and culture affect technological development. Among philosophical approaches, technological determinism sees technological development as a spontaneous evolutionary process requiring a given society to organize itself so as to make efficient use of the technologies becoming available. It also seizes upon individual technological innovations as immediate and direct causes for fundamental social change. A second approach views technological advance as a consequence of the development of human spirit and culture. The most generally held view is that technological change is the cause of profound societal change at certain points in human history, while at other times societal change stimulates technological development. Followers of this third approach attach widely varying weights to the two sides of this interaction.

The discussion in Sec. 1 of this interaction between technology and society is organized around the historical sequence of key stages of human societal development. The aim here is not to unfold a chronology of technology, but to examine the intricacies of the interrelationships between technology on the one hand, and the complex of science, culture, and socioeconomic organization on the other. (It will be noted that this section and PHYSICS AND TECHNOLOGY, HISTORY OF, are thus very different in content and focus.)

1.1 Role of Technology in Human Evolution

The interconnections between technology and society begin with the evolution of the human species. It is therefore appropriate to begin this section with the three-way interaction of technological, societal, and biological interactions that have led to the emergence of the modern human species *Homo sapiens*.

The unique character of human toolmaking and tool use along with the uniqueness of bipedality suggests these two factors as the primary stimulus for the evolution of the modern human being.

The evolutionary line of the modern human species, *Homo sapiens*, can be traced backward through at least two earlier species of the genus *Homo*, namely *Homo habilis* and *Homo erectus*, to the bipedal genus *Australopithecus*, originating in Africa some five million years ago, branching off from the family of the primates from which the modern chimpanzee descends (Hood, 1993). Bipedality frees the hands for many activities, including using tools. The first fossil evidence for tools appears later—some 2.5 million years ago—stone choppers, scrapers, and sharp flakes, probably used for stripping meat and skin from bones (Napier, 1993, pp. 43–44; Howells, 1993, p. 118; Isaac, 1976, p. 487), leading some scholars to suggest that the development of the brain was a more important factor in human evolution (Lovejoy, 1993). On the other hand, the tools that we observe among pongids like the chimpanzee today such as stripped branches for prodding termite nests or stone anvils for cracking open hard fruits (Candland, 1987; Goodall, 1968) are not likely to leave a fossil trail, so that it is not unreasonable to assume (even without evidence) that the early bipedal hominids not only did not lag behind the pongids in toolmaking, but also had begun to advance in their use of tools.

Apart from structural changes favoring bipedal locomotion, the fossil trail from the australopithecines to *Homo sapiens* is marked by significant increases in brain size (Falk, 1993, p. 64); changes in the bone structure of the hand (Napier, 1993); a lowering of the larynx so as to increase the space between the larynx and the back of the nasal cavity, thereby enhancing the possibility for articulate speech (Laitman, 1993); and a decrease in the size of the canine teeth (Skelton *et al.*, 1993). Toolmaking, development of the hand, socialization of food consumption, increasing differentiation in vocal communication, and mental development move forward in the evolutionary process as an integrative whole, a development in one area contributing to the development of the others.

1.2 Hunting and Foraging Cultures

The term *hunting and foraging* is generally used to characterize both the level of technological development and form of societal organization within which this technology is applied. The first evidence of hunting, probably by *Homo sapiens*, appears some 100 000 years ago in northwestern Germany, where a fossil elephant with a wooden spear nearly eight feet long between its ribs was found. Apart from the weapons themselves, the earliest symbolic representation of their use are the cave paintings with hunting scenes in northwestern Spain and southwestern France painted perhaps some 10 000 to 30 000 years ago.

To overcome the lack of information about the technological culture of ancient hunting and foraging societies, it is necessary to consider recent and contemporary hunting and foraging cultures, such as the Mbuti people in the Ituri rain forest in Zaire. These people lived until the 1980s much as they had thousands of years ago, with a cultural form that is essentially pre–Stone Age. The primary economic standard is one of adequacy, the mobile lifestyle mitigating against accumulation of private property. The adult men, women, and unmarried youth all participate in the hunt. Mbuti net hunters establish their symbiotic relationship with the forest ecology by a culture of minimal hunting, spending a daily average of only four to five hours away from camp (Turnbull, 1983, p. 138).

The close cooperation of women and men in the hunt and the division of labor between them are reinforced in their hunting songs, which are always sung in round form, utilizing a technique that recreates the cooperative patterns required by the hunt. The other major types of song, the foraging song and the death song, also reinforce the appropriate patterns for the corresponding activity. Except for the lullaby, none of the songs can be produced by a single singer. The ritualistic character of the singing suggests that this art form is viewed as a necessary component of the hunt itself.

The egalitarian character of Mbuti society is characteristic of most hunting and foraging societies, generally marked by the absence of hierarchical structures. Group members make decisions collectively or through councils of elders. The prestige of certain individuals is based on respect for their achievements as outstanding hunters or foragers. The individual function of the chief stands out; he gives leadership in dealing with conflict with other groups of people. A second individual function is that of the shaman, who is believed to have special powers in connection with the group's religious beliefs or mythology, and a third is one with skills in rituals practiced by the group, such as a dancer or singer (Coudert, 1991, p. 398). Although a certain degree of social division of labor, partly based on levels of skill, emerges in hunting and foraging societies, the society is essentially free of social conflicts; the disputes and tensions that do arise do so as conflicts among individuals and are frowned upon by the other members of the society. It is for this reason that many social philosophers reject the sociobiological views asserting that humans are genetically conditioned to be aggressive and acquisitive.

1.3 Transition from Mobile to Sedentary Cultures: Crop Cultivation, Animal Domestication, and Social Differentiation

The first major revolution in social organization associated with technological developments appears to have occurred toward the end of the Ice Age in the period 12 000 to 10 000 B.C. in the Near East. Sedentary settlements and the subsequent development of crop cultivation and domestication of animals were accompanied by relatively rapid technological changes in comparison with the preceding millennia, resulting not only in the increase in production above the subsistence level, but also in the emergence and deepening of social stratification within the population. This process, culminating in the formation of great city-states, occurred in Mesopotamia, Egypt, China, India, Mesoamerica, and the Andes.

Donald O. Henry, on the basis of suggestions from Binford (1980) and Gould (1982), sees the first signs of technological change as involving a transition from *simple foraging* to *complex foraging*. Henry (1989, p. 4) summarizes simple foraging as "a high mobility and movement to resources" and *complex* *foraging* as a "collecting strategy in which greater residential permanence is maintained through storage and logistical acquisition of resources."

The increased productivity that resulted from this transition led to both population increase and social differentiation. The new technology involved not only a new level of foraging activity, but also qualitative changes in the handling of the products as a result of the increased quantity of goods and people. Administrative problems seem to arise when more than two hundred people engage in coordinated activity. Structures that appear to have been communal storehouses suggest the need for administering and redistribution of the goods stored. Similarly, ceremonial structures suggest leaders (Henry, 1989, p. 212), and some central management may have been needed for housing the larger population.

A widely accepted model of social development through several stages of the social reorganization that began with the production of a food surplus has been put forward by Fried (1967). Fried suggests that the domestication of animals and plants initiated a series of changes in social organization from the egalitarian societies of hunters and foragers to the formation of what he calls rank societies, then into stratified societies, and finally to the formation of the state.

The rank society is characterized by the emergence of an individual, such as a chief, whose principal function is the redistribution of the products derived from the technological activity. According to Fried, in a stratified society, essential basic resources become the private property of a ranked segment of the community. Fried makes a distinction between what might be called the personal property of an individual or family, that is, objects of immediate use or consumption, and the basic resources that are needed to produce them (pp. 193–196).

The state emerges as an institution that stabilizes the stratification through control over the productive resources and products. Haas (1987, p. 2) defines the state society "as a type of society in which rulers have control over production or procurement of basic resources and as a result exercise coercive power over their respective populations."

Stone-walled dwellings and storage pits are evidence of sedentary settlements; stable storage of food was necessary beyond that immediately consumed (Henry, 1989, p. 19). The production of such a surplus is needed since life cycles of plants and, to a large extent, animals are tied to the seasons of the year. Stored supplies can be exchanged among different communities or even be produced specifically for exchange.

Once the technology to produce a surplus is available, the possibility for continual accumulation of a wealth of products arises, although this potential has not been realized uniformly everywhere, since subsistence-level economies persist to this day. Therefore, Fried's model of social evolution must be viewed as a tendency rather than a specific sequence of stages through which every coherent community of people must pass.

The change from mobile to sedentary cultures involves a division of labor in two distinct areas: the organization of production and the associated infrastructures for production and storage on the one hand, and the administration of the process of redistribution for consumption on the other. The managerial/administrative functions are often combined with the role of leader in ritualistic functions, since the rituals to a large extent are considered necessary components of the technology. The increase in the storable surplus also creates the conditions for the separation of the product from the producers through increasing bureaucratization of the administrative/managerial function. Those appropriating the product ultimately must establish state institutions based on a morality justifying the social stratification and also set in place means of physical force to enforce the new social morality.

1.4 Occupational Specialization in the Bronze and Iron Ages

Bronze metallurgy was introduced about 3300 B.C. in Mesopotamia and Egypt. This technological change was not a revolution in the sense of the speed with which it spread, but in the economic, political, and social consequences of the use of metal in weapons and tools. The new technologies significantly increased the level of agricultural production and thereby stimulated larger-scale irrigation projects. The agricultural surplus made possible an increase in the number of people who could separate themselves from agriculture, thus contributing to the growth of urban settlements. The rank societies turned into stratified state societies by the fourth century B.C., with the political and economic control centered in temple-cities ruled by priest-kings. Iron metallurgy appeared about 2200 B.C. and was in widespread use by 1100 B.C.

During the same period, the plow, the horse, and wheeled vehicles were introduced. The workmen involved in the mining, transport, and smelting of ores and in producing tools may have been the first specialists separated from agriculture who did not raise their own food and were not part of the ruling bureaucracy. It therefore appears that by the third millennium B.C. technological development in Mesopotamia and Egypt had reached a level that could sustain the principal types of social stratification we now find in contemporary populations except, perhaps, for a strata of intellectuals. The first intellectuals, the mathematicians of Babylon, may have also emerged in this period, but evidence for their presence does not appear until the second millennium B.C.

1.5 Reckoning Technology, Mathematics, and the Origins of Writing in Mesopotamia and the Americas

Along with first evidence of the cultivation of cereals in Syria and Iran, the harvesting or hoarding of grain, and the domestication of animals occur finds of small clay objects of various geometrical shapes—spheres, cones, disks, and cylinders. Each type of token served as a counter for a definite quantity of a particular food or other basic commodity stored or delivered. These tokens have been found throughout the Middle East, with the earliest dated about 8000 B.C. in the Zagros Mountains of Iran (Schmandt-Besserat, 1992, pp. 40, 168).

After the emergence of city-states in the fourth millennium B.C., accounting acquired a new importance. The tokens, originally sealed in small clay containers (envelopes) were now impressed on the clay envelopes into which they were placed so that the contents were visible on the envelopes themselves. Ultimately, the tokens became unnecessary, as their shapes and markings were reproduced on clay tablets. A conceptual leap toward abstract thinking then occurred. Quantitative and qualitative aspects of the goods became symbolically separated, so that a token of one shape represented a given commodity, while a second set of tokens represented the quantity. The wedge-shaped impressions developed into the system of writing known as cuneiform (Latin *cuneus*, a wedge).

In the Peruvian Andes in the eighth or ninth century, a period of major state formation, a system of knotted strings called *khipus* (Patterson, 1991, p. 43) was used to keep accounts. The *khipus* did not lead to writing, however. The Mayans later adopted a system of writing from other peoples and refined it with both ideographic and phonetic elements. They used it to record events and dates, deeds involving the nobles, the position of the stars and planets, religious rituals, and calendar reckoning, but there is no evidence of its use for accounting. The failure to develop written accounting and, except perhaps for calendars, the largely noneconomic use of writing were manifestations of different paths of technological development as compared, say, to Mesopotamia. The absence of large domesticated animals restricted the transport of goods, and the resulting fragmentation of the economies further limited technological development (Gille, 1986, p. 424). The Mayan, Inca, and Aztec rulers never developed the technological infrastructure that could tightly link the conquered peoples into vast, geographically expanding empires. The extraction of tribute and the continual pillaging of weaker neighbors by the stronger city-states in the Andes and Mesoamerica evoked resistance that could not be permanently repressed, ultimately allowing a small number of Spanish invaders, with their superior military technology, to form local alliances in order to destroy the Inca, Aztec, and Mayan states (Patterson, 1991).

The first sign of activity that can be called *scientific* (according to our current understanding of scientific knowledge) in antiquity is the development of mathematics in Babylon, known to us from tablets written between 1800 and 1500 B.C. The Babylonian tablets contain lists of conversions of measurement units, multiplication tables, and mathematical exercises. The calculations concerned practical problems, such as work quotas, food requirements, and wages for workers; materials for wells and building construction; weights and measures; and inheritance and compound interest (Hooke, 1954, pp. 786–791). Ancient Egyptian mathematics was more geometrically oriented than was Babylonian, its greater sophistication attributable to greater economic complexity and more diverse technological activity. The availability of mathematical methods coordinating elaborate economic projects made it possible to undertake construction projects of increasing complexity (pp. 790–792).

The tokens, *khipus*, and the types of calculations represented on the tablets seem to indicate that mathematics did not arise as an aesthetic intellectual pastime, but was an integral part of the application of technology to the economy. Subsequently, the Greek philosophers of the fourth to first centuries B.C. separated mathematics from technology and integrated it with logic, a process that culminated with Euclid's hypothetico-deductive system of geometry.

1.6 Technological Development and Blockage in Classical Greece

Despite the emergence of Greek science concurrent with the technological advances between the sixth and third centuries B.C., no revolution in production occurred on the scale that might be expected.

The usual explanations for this "technological blockage" are based on the economic and social structures of the Greek city-states. Most Athenians were peasants, and played no direct role in the political life. *Citizens* lived in the cities and neighboring villages, were generally landowners, and did not engage in manual labor or crafts. Their economic well-being was based on extensive domestic, craft, and field labor by slaves taken as spoils of war (Anderson, 1974, pp. 29–52; Lilley, 1965, pp. 32–33). It was simpler and cheaper to put slaves to heavy work than to construct machines to do it (Lilley, 1965, p. 32). The mechanical arts, increasingly being left to slave labor, could not be respected by the ruling elite. According to Aristotle, since artisans, historically, were slaves or foreigners, the "best form of state will not admit them to citizenship" (*Politics*, III.5.1278a.5–10). "Some men are by nature free, and others slaves, and that for these latter slavery is both expedient and right" (*Politics*, I.5.1255a.39–41). "For that some should rule and others be ruled is a thing not only necessary, but expedient; from the hour of their birth, some are marked out for subjection, others for rule" (*Politics*, I.4.1254a.20–25). "No man can practise virtue who is living the life of a mechanic or labourer" (*Politics*, III.5.1278a.20–25).

Free men, according to Aristotle, would best realize their nature through the sciences—above all, through politics, "truly the master art" (*Ethics*, I.2.1094a.25). Such ideological blockage could only have led to technological blockage. It has also been suggested that the Greek view that mechanics could be reduced to a rational, closed system based on the five simple machines (lever, pulley, screw, winch, and wedge) failed to leave room for the role of experiment in the development of mechanics, which in effect had been limited to statics (Vernant, 1957, p. 217).

The stagnation discussed here is relative to the far more rapid developments in Europe in the second millennium A.D. The gradual improvement in the technological system that characterized Greek technology after the third century B.C. was continued by the Romans, who acquired through their conquests the technological traditions of Greece, the Near East, and Egypt, absorbing whatever was useful for them from other peoples in their expanding empire. Individual Romans did gather information about technological practices in various parts of the empire, but little attempt to coordinate or codify it was made (Gille, 1986, pp. 320–326). Although the towns grew, the propertied classes maintained their traditional disdain for trade (Anderson, 1974, p. 81). While the Romans did not introduce revolutionary changes in the technological system, they did make important improvements in hand tools, agriculture, architecture, city planning, the use of water-powered grain mills on an industrial scale, and the building of aqueducts, cisterns, irrigation canals, and roads.

1.7 Technology and Society in China

The history of Chinese technology paralleled in time and in some fields even excelled the early technological developments of the classical civilizations of the Mediterranean and the Near East and, later, of Europe (Needham, 1954–1967). Chinese interest in philosophy and science unfolded at about the same time as in Greece. The Chinese had already learned to write by the fourteenth century B.C., well before the Greeks (Haudricourt and Needham, 1963, p. 162). Yet by the second half of the second millennium A.D. European technology moved decisively ahead of Chinese technology.

Needham discusses in detail what he sees as the reasons why China took an early lead in so many areas of technology and then failed to maintain it. The country's topography and agriculture required a vast network of waterworks for flood protection and irrigation, especially for wet rice cultivation, and a far-flung canal system whereby the tax grain could be brought to granary centers and to the capital. A highly centralized system emerged in which the emperor assumed the role of one great feudal lord governing and collecting taxes through a gigantic bureaucracy that became known as the "mandarinate." The mandarinate collected taxes and mobilized unpaid labor (similar to corvée labor of European feudalism in which a serf is required to perform a day of unpaid labor by a feudal lord) for the water projects. They enjoyed no hereditary succession, and were recruited afresh in each generation through state examinations based on literary and cultural subjects that rarely included what might be called scientific subjects (1969, pp. 195–197). Under this system, referred to by some Chinese scholars as "bureaucratic feudalism" (pp. 177–179), the economy was based on taxation in kind, so that money was not widely used. The mandarinate was not salaried by the state, but supported itself through its administrative powers over agricultural production and whatever wealth it could garner from its bureaucratic functions in the towns.

The value system that favored the development of merchant wealth in the feudal towns of Europe found no parallel in China. While capital accumulation in Chinese society was possible, "the application of [capital] in permanently productive industrial enterprises was constantly inhibited by the scholar-bureaucrats, as indeed any other social action which might threaten their supremacy" (Needham, p. 197). "There is nothing in Chinese history resembling the conception of a mayor or burgomaster, alderman, councillors, masters and journeymen of guilds, or any of those civic individuals who played such a large part in the development of city institutions in the west" (p. 185).

Since Chinese philosophy was not capable of allowing the mercantile mentality a leading place in the civilization, it was not capable of fusing together the techniques of the higher artisanate with the methods of mathematical and logical reasoning that the scholars had worked out, so that the passage from the Vincian to the Galilean stage in the development of modern natural science was probably not possible.

1.8 The Middle Ages

The scientific and technological heritage of the Egyptian, Greek, Roman, and Mesopotamian civilizations of antiquity was in part preserved and continued by the Byzantine and Arabic scholars. *Arabic* here includes Arab and other scholars of the Near and Middle East, Northern Africa, and Moslem Spain, where Arabic was the scientific language. From its beginnings, Islam encouraged the study of the sky and the earth to find proofs of one's faith (Arnaldez and Massignon, 1963, p. 385). "Arabian schools were organized on the pattern of the Greek, publishing commentaries, encyclopaedias, dictionaries and scientific manuals. The scholars versed in more than one science if not in all ... were the rule rather than the exception" (p. 386). The best known of these encyclopedic minds were the Persian physician and philosopher Avicenna (980–1037 A.D.) and al-Biruni (973–1048 A.D., probably born in Uzbekistan). The Moslem scholars elaborated algebra and passed on Hindu–Arabic numerals from India (p. 407). Like the Romans, the Arabs absorbed the technological knowledge of the peoples they conquered and disseminated this knowledge over their empires, innovating, but not generating a technological revolution of their own.

In Europe proper, the period from the end of classical times following the collapse of Rome to beginning of the eleventh century is commonly referred to as the Early Middle Ages or the Dark Ages. The term *Dark Ages* suggests a darkening relative to Greek and Roman antiquity and in many ways is misleading. The so-called barbaric invaders had already achieved an iron-age culture and had access to the technology of the Roman empire. The principal regression relative to Greece and Rome was the collapse of an elaborate city-state culture. With the collapse of Greece and Rome, literacy in Europe outside of Byzantium retreated significantly.

The principal developments in technology during the early Middle Ages, between the collapse of Rome and the eleventh century, appear to have been the introduction of the heavy iron plow in northern and western Europe; the horse harness, which allowed the replacement of oxen by horses for plowing; and triennial crop rotation and fertilization with marl. These innovations caused a rapid increase in population and an agricultural surplus that permitted the growth of towns (Hilton and Sawyer, 1963; White, 1962; Anderson, 1974, pp. 182–183).

A technological determinist explanation for the specific direction of the development of feudalism in Europe was put forth by White, in his influential *Medieval Technology and Social Change* (1962). White asserts that the introduction of the foot-stirrup in the Frankish kingdom of the eighth century immediately changed the nature of warfare. A mounted knight could deliver a strong blow with a lance, and cavalry replaced foot soldiers as the main fighting force. Since "mounted warriors could only be maintained in large numbers by landed endowment . . . [the] estates of the Church were . . . seized and handed over to an enlarged body of followers on condition that they serve him on horseback. . . . Protofeudal and seignorial elements had, of course, saturated the very fluid Celtic, Germanic, late Roman, and Merovingian societies; but the need for cavalry . . . precipitated and crystallized these anticipations to form medieval feudalism" (pp. 4–5).

Hilton and Sawyer (1963) criticize White's technological determinism as being methodologically at fault, the conclusions based on it not standing up to the historical evidence. They show that the stirrup was not a new arrival in Europe but reached Europe well before the eighth century, and that a complete change in Frankish weapons did not take place at that time—despite the stirrup, mounted shock troops did not become the rule in the eighth century.

Cultural, economic, and environmental factors all interact with technology to affect the rate of historical change. The African Mbuti, for example, satisfied with their traditional hunting methods, rejected the use of guns for hunting despite clear advantages over nets and spears, while the differing circumstances of the Eskimos led them to accept guns.

1.9 Beginnings of the Technological Revolution in Feudal Europe

Toward the end of the ninth century, signs appeared that a new period of technological development was about to begin in Europe. The political disarray of constant invasions, marauding, and remapping of boundaries gave way to greater stability as central governments established authority. In 789, Charlemagne issued edicts to establish schools for the largely illiterate clergy. A ninth century mini-Renaissance produced educational advances, including adoption of a legible script and restoration of a good Latin, but with little or no scientific content (Beaujouan, 1963, p. 471).

Increasing artisan and merchant activity fueled rapid expansion of urban commercial centers in the tenth to thirteenth centuries. The growing use of metals—silver, gold, copper, lead, tin, and iron and steel—put mining, metallurgy, and metalworking in the center of industrial activity and trade. Grain mills powered by water wheels had already appeared throughout Europe, not all concentrated in the towns. They became a traditional source of revenue for the lords, who required that the peasants take their grain to be ground at the lord's mill. The Domesday Book, an English economic census completed in 1086, reported 5624 water mills in 3000 communities south of the Trent and Severn (cited by Forbes, 1956, p. 611). Water-powered cloth-fulling and grain mills and forges (many in monasteries) began in the mountainous regions of southern and central Europe, later spreading into France and northern Europe. By the fourteenth century, water-powered hammers, stamps, and bellows were fairly general in the entire Alpine region. "Such machines," writes Forbes, "entailed heavier capital expenditure than formerly, and the rise of western capitalism was largely tied up with the development of mining and metallurgy." The feudal lords promoted the rise of industrial–commercial towns (pp. 62–69). Manufacturing was at the heart of the urban economy, and initially a symbiotic relationship existed between the social environment of urban industry and trade and the feudal agrarian economy. Although more or less self-governing, the towns were still under the aegis of the feudal lords, who cornered markets or scooped off profits from long-distance trade and obtained their domestic or imported luxury goods from the towns. Production was regulated by the artisan guilds, which emerged in the tenth century.

The first great mathematician of the thirteenth century, and perhaps the most outstanding in the Middle Ages, Leonardo Fibonacci (1170–1250, also known as Leonardo Pisano or Leonardo of Pisa), came from the rising commercial social stratum (Smith, 1923, pp. 214–218). Italian merchants acquired computational methods from their North African counterparts. Double-entry bookkeeping first appeared in 1340 in Genoa (Beaujouan, 1963, p. 516). In parallel with the commercial interest in practical mathematics, the growing application of a variety of mechanical devices to manufacturing contributed to an interest in the representation of spatial relationships. The contributions of Leonardo da Vinci in this connection are well known.

A close relationship thereby developed between the artists and the artisans. This bond among those engaged in the arts and crafts continued to spread through Western Europe in the fifteenth and sixteenth centuries. Consisting of artist-engineers, painters, sculptors, architects, builders of locks and canals and fortifications, and toolmakers, this group of practitioners, who themselves did not study questions of a scientific character, stimulated others to do so. A related group included the instrument makers (who supplied navigators, geodesists, astronomers, and musicians with the instruments they needed), the clock-makers, the cartographers, and the military technicians. "Empirical knowledge did not have to be sought deliberately, but arose naturally from the pursuit of technical trades; the waiting was only for theoretical reflection, which, however, was helped by the fact that there is no single department of physics which calls more urgently for mathematical treatment and lends itself more naturally to it than mechanics. The first essential element of classical physics, the mathematical approach, thus came into its own as spontaneously as the second, the empirical foundation" (Dijksterhuis, 1969, p. 243).

The center of scholarship initially rested in the monasteries, later moving into the universities, themselves Church institutions. Interest in mathematics developed among Church scholars because the Church calculated the date of Easter by combining the lunar cycle with the solar year on the basis of the Ptolemaic geocentric model of the heavens. In the tenth century, the French monk Gerbert of Aurillac (who later became Pope Sylvester II) brought Hindu–Arabic numerals to Christian Europe from Spain. Gerbert also greatly simplified the methods for arithmetic computations. Within the Church, however, conflicts arose between the traditions of classical scholarship and the new approaches needed for the burgeoning crafts and trade.

The English monk Roger Bacon (1214?–1294) was among the first Europeans to recognize the need for empirical verification of theoretical knowledge: "Reasoning does not make a conclusion certain, unless the mind discover it by the method of experiment." He also recognized the need to deal with nature quantitatively: "Nature cannot be known without mathematics" (Beaujouan, 1963, p. 492).

Francis Bacon (1561–1626) may be considered the first to have seen a direct dependence of science on technology. He called for scholars to place technology on a scientific foundation by familiarizing themselves with empirical knowledge accumulated in the crafts (Dijksterjuis, 1969, p. 401). The encyclopedia Bacon proposed was accomplished by Diderot and d'Alembert. By including descriptions of all tools and the methods of their fabrication and utilization, it conferred the status of knowledge and social dignity on that which up to that time was a matter of utility, of spontaneous empiricism (Fontenay, 1982).

1.10 From Feudalism to the Industrial Revolution in Europe

In the historical shift that initiated the most rapid growth in material production in history, the interaction among factors that stimulate or are stimulated by technological development may be seen clearly. Small-scale manufacturing continued to grow throughout Europe and North America, but developments in Britain took on a distinctive character that led to what became known as the Industrial Revolution.

In the middle of the eighteenth century, Britain's manufacturing and commerce, especially the slave-based sea trade in colonial products such as tea, sugar, and tobacco, were prospering. Perhaps one-tenth of all fixed investments other than real estate were in the maritime trade. Britain had several times the number of ships as France, its nearest competitor. The rural economy of Britain developed into a substantial system of cash incomes and sales; tenant farmers employed large numbers of farm laborers, unlike the predominantly subsistence-farming peasant households that persisted on the continent (Hobsbawm, 1968, pp. 10–19). Manufacturing spread throughout rural areas, the typical workers being village artisans or smallholders in their cottages making specific products, such as cloth, hosiery, or metal goods. With rapid urbanization and wood being in short supply (Gille, 1986, p. 590), the growth in the production of coal, primarily for heating and cooking, formed a substantial preindustrial base for subsequent industrial expansion (Galloway, 1969, Chap. 4–5). Coal was the first industrial commodity to be produced at a rate of millions of tons a year (Hobsbawm, 1968, p. 31). Unlike on the continent, the large landowners, rather than the monarch, drew royalties from mining operations and had a direct interest in supporting village manufacturing, as well as canals and turnpikes to facilitate the sale of the goods produced. The British economy was thereby in a unique position to benefit from a major expansion in goods produced cheaply enough to be purchased by the middle classes, instead of the production of luxury goods for the wealthier strata as on the continent.

The main advantage of the preindustrial home market was its size and steadiness. "The domestic market may not have provided the spark, but it provided fuel and sufficient draught to keep it burning" (Hobsbawm, 1968, p. 32). The spark, according to Hobsbawm, was the export market. "Between 1700 and 1750 home industries increased their output by seven per cent, export industries by seventy-six percent; between 1750 and 1770 (which we may regard as the runway for the industrial 'take-off') by another seven per cent and eighty per cent respectively. Industrial production increased—but foreign demand multiplied."

Cotton manufacture was responsible for the bulk of the export trade. All raw material had to be imported, and by the end of the eighteenth century, about two-thirds of the industry's output was exported. Prior to the 1760s, the spinning wheels could not supply enough yarn to keep pace with looms now employing the flying shuttle, introduced in 1733. A breakthrough came with the spinning jenny in 1765. Further improvements in spinning followed, leading finally to the fully mechanized spinning mule in 1777 (Gille, 1986, p. 624). Subsequent improvements in the machines increased the yarn yield per worker 100-fold in relation to the spinning wheel. As the textile industry expanded, its machinery was increasingly driven by the steam engines made possible by James Watt's invention, although water power continued to be used when convenient. The widespread use of steam power made possible industrial activities in regions in which water power was not available. The entire technological basis of British manufacturing thereby shifted from water and wood to iron, coal, and steam.

The rapid advances of science and technology at this time were quickly absorbed by the various branches of manufacturing. The relatively simple technology required for cotton production, however, propelled the Industrial Revolution forward at an unprecedented rate without much interaction with science. The majority of the technological innovations were made by people closely involved with production—foremen, entrepreneurs, and skilled workers (Gille, 1986, p. 594). Scientific advance in eighteenth-century Britain came largely from societies established by craftsmen and industrialists, such as the Lunar Society of Birmingham and the Manchester Literary and Philosophical Society (Hill, 1967, p. 198). James Watt was an instrument maker at the University of Glasgow, where he learned about Joseph Black's discoveries of latent heat. Bernoulli's and Euler's work on ships no doubt influenced ship construction. It should not be forgotten, however, that Carnot's theoretical introduction of the cyclical engine came much later, in 1824, while the distinction between force and energy was not theoretically explained until the 1860s. In general, the sciences during the early years of the Industrial Revolution did not lead to direct results in design, but pinpointed quantitative relations that inventors and innovators could take into account in their empirical work.

The immediate result of the Industrial Revolution was great economic benefit for entrepreneurs and harm for workers. Mechanization of the textile industry threw large numbers of weavers out of work. The shift of the workplace into factories from rural cottages and homes destroyed this source of supplemental income. Wages were kept at subsistence levels. The shift to the cities was precipitous. In 1750, only London and Edinburgh had populations over 50 000. In 1851, there were twenty-nine cities with populations that big and nine with over 100 000. "And what cities! It was not merely that smoke hung over them and filth impregnated them, that the elementary public service—water supply, sanitation, street cleaning, open spaces, etc.—could not keep pace with the mass migration of men into the cities, thus producing, especially after 1830, epidemics of cholera, typhoid, and an appalling constant toll of the two great groups of urban killers—air pollution and water pollution, or respiratory and intestinal disease" (Hobsbawm, 1968, p. 67). As the industrial economy reached new heights quantitatively, qualitative changes in market relationships ushered in an era of cyclical economic crises of unprecedented depth. The first deep crises occurred in the 1810s, in response to which displaced textile workers directed their anger against the machines that replaced them. Crises occurred again in the 1830s, and again in the 1840s, leading to large-scale bankruptcies and high unemployment. The conditions of the laboring population were so harsh that advocates of slavery in North America argued that chattel slavery in the U.S. South was far more humane than wage slavery in Britain. In the 1850s, economists began to conclude that higher wages would put more money in circulation and thereby stimulate industrial production. Growing restiveness among the workers and their reliance on trade unions finally led to higher wages and reform in labor legislation.

Although the Industrial Revolution replaced many skilled workers with unskilled workers, a need arose for a literate segment in the work force able to read and follow somewhat complex instructions, read technical drawings, and perform calculations. Public primary education was therefore initiated in the first half of the nineteenth century in Britain, France, and the United States.

1.11 From the Industrial Revolution to Modern Technology

In the wake of the Industrial Revolution, manufacturing moved into a central position in the dynamics of the national economies of Western Europe, Canada, and the United States, spreading to Japan late in the nineteenth century, bringing with it an infrastructure of transportation, raw material sources, fuel, and finance. Raw materials were secured domestically, from other industrialized lands, or from colonial and semicolonial possessions. The role of the national governments in securing, maintaining, and regulating these infrastructures increased greatly. As the size of the enterprises increased, the pattern of ownership also changed from single owners and partnerships to the corporate form. Toward the end of the nineteenth century, investment banks formed, acquired, or merged with industrial firms. These developments took place simultaneously in the United States, Britain, France, Germany, and Japan; the United States overtook Britain in industrial potential around 1900. Competition for sources of raw materials and foreign markets grew intense. The economic, political, and military subjugation of almost all of Africa, Asia (outside of Russia and Japan), Central and South America, the Pacific, and the Caribbean was essentially completed by 1910 in an atmosphere of great political and military rivalry among the industrial powers, a rivalry that sharpened the interest of national governments in military technology.

Industrial managers near the end of the nineteenth century were not as closely connected personally with technological development as formerly. Research and development laboratories arose within the individual enterprises (see PHYSICS AND TECHNOLOGY, HISTORY OF). The universities remained centers of theoretical research and of the experimental research that necessarily preceded it.

The introduction of the assembly line at the Ford factory in 1913 based on the time and motion studies of Frederick W. Taylor and Frank and Lillian Gilbreth had a profound social and economic impact. The organization of work on the assembly line broke up complex manufacturing operations into simple jobs that could be performed by a worker with little or no training. By 1926, 79% of the Ford workers needed less than one to no more than eight days training (Gille, 1986, p. 1017). The economic success of this method of production led to its use wherever technologically feasible. The dehumanizing reduction of labor to essentially mindless tasks, already foreshadowed in the textile mills, reduced workers to appendages of machines, alienating their spirits from their hands and from the object of production. Assembly-line production continues to this day, but with increasing involvement of the workers in setting up and rotating tasks. Many big manufacturing plants are now experimenting with abandoning assembly lines altogether.

2. ORIGINS OF PHILOSOPHY OF SCIENCE AND PHILOSOPHY OF TECHNOLOGY

From the seventeenth century on, scientific research tended to concentrate in academic institutions, while technological research and development was conducted largely in private industry, but this has become less true since the mid-twentieth century. As the time between scientific discovery and technological innovation decreased, technology became increasingly dependent on science for its innovations. Toward the end of the twentieth century, the dominant view is that science is the primary stimulant to technological development and not the reverse.

Prior to the eighteenth century, no fundamental distinction was made between scientific knowledge and philosophy. The advances in physics, especially Newton's mechanics, stimulated the separation. The theoretical structure of Newton's mechanics is that of the hypothetico-deductive model employed by Euclid. The clearly empirical character of Euclid's postulates and axioms had not been understood, even in Newton's time. The simplicity of the axioms and their fewness of number continually stimulated the quest to find a logical basis for their origin, somewhat reminiscent of today's quest for a grand unification.

Kant (1966) proposed a compromise. Certain kinds of knowledge need not be demonstrated; logic, geometry, and time, for example, exist prior to and independently of material things. Knowledge about the material world is acquired through our senses. How does one identify *a priori* knowledge, however, since if it cannot be proved, it must be asserted? John Stuart Mill straddled the issue: "Axioms are but a class, the most universal class, of inductions from experience; the simplest and easiest cases of generalization from the facts furnished to us by our senses and by our internal consciousness" (Mill, 1904, p. 187).

Two logical problems immediately arise with what on the surface appears to be the experimental or empirical basis of Mill's view. One is the logical basis of facts furnished by our internal consciousness—this can only be a return to the Kantian *a priori*. The other is the source of the sensual stimuli that produce the "facts furnished to us by our senses."

Francis Bacon had already recognized the need to put technology on a scientific basis by incorporating technological experiences into scientific investigation. The early nineteenth-century philosopher Hegel (1969) saw (without pursuing its logical consequences in detail) that properties of space and time are not independent of, but originate with, matter. Riemann, confronted first with the non-Euclidian geometry of Lobachevsky and Bolyai, and then with his own, concluded that only experiment would establish the validity of a geometrical system.

Though known, perhaps, as the leading nineteenth-century proponent of philosophical idealism, Hegel uncharacteristically took a very earthy approach to technology by asserting the importance of means in relation to the ends: "The *means* is *superior* to the *finite* ends of *external* purposiveness: the *plough* is more honourable than are immediately the enjoyments procured by it and which are ends. The *tool* lasts, while the immediate enjoyments pass away and are forgotten. In his tools man possesses power over external nature, even though in respect of his ends he is, on the contrary, subject to it" (Hegel, 1976, p. 747). Thus, in Hegel's view, the ends are established through human reason, but this reason is transcended by the technology created to procure the ends and which can continue to be employed for other ends. Hegel here begins what might be called the praxis philosophy, according to which practical activity of humans serves as the ultimate source of their technology and science.

Karl Marx, the first to incorporate technology philosophically into a world outlook, never explicitly identifies the philosophy of technology in what came to be known as his materialist conception of history. In Marx's scheme, the primary motor of societal evolution is the development of the *productive forces*, by which he means natural resources, raw materials, implements and tools, and human labor. Implied, although not mentioned explicitly, is the technological and scientific knowledge associated with productive processes. Technological development, that is, the development of the productive forces, proceeds under more or less stable relations of production, which Marx equates with the dominant form of property relations associated with the use of the productive forces. He then projects that an incompatibility ultimately arises between the productive forces and the property relations so that property relations cannot be kept stable. Social revolution, to Marx, is simply the resolution of this incompatibility through a relatively rapid change in the dominant property relations. Thus, Marx (1987) explains the evolution of society from its early forms of communal property through slavery, feudalism, capitalism, and ultimately communism. A critical point of Marx's theoretical position is that "it is not the consciousness of men that determines their existence, but their social existence that determines their consciousness." The technological implications of this are profound, because production relations are not limited to property relations. People engaged in production also have technological relations of production to the tools and the object of production, and to one another when several people work together. It is therefore the productive activity of human beings that ultimately shapes their understanding of their relations to the material world around them and of the entire complex of social relations that they have to one another.

Such a view of the relationship between existence and consciousness leads Leonard Goldstein to attribute the changes in the way the Renaissance artists viewed space to the need to understand the spatial relationships for the design and use of large machines driven by natural power and for manufacturing processes involving the coordinated labor of a group of workers. Goldstein notes that linear perspective depicts the view grasped by the eye of an individual observer. He identifies the source of this one-point view as a reflection of the individualism that is necessarily shaped by vigorous activity of the ownership of a successful enterprise (Goldstein, 1988).

A propensity to mechanical innovation has sometimes been seen as a character trait common in some nations; Marx, however, would look rather to the conditions motivating people to engage in production as the stimulus for innovation. One source of motivation is production to meet one's own needs for direct consumption; another is the production of commodities for exchange for other commodities for direct consumption. Still another, and this is the principal characteristic of the capitalist economy, is the production of commodities for exchange at a profit on a continuing basis. Since the goal is accumulation, not consumption, the appetite for profit is unsatiable and technological improvements will help feed it. Marx regards technological development as intrinsically neutral, but leading to property relationships that provide the social dynamic. "The hand-mill gives you society with the feudal lord; the steam-mill society with the industrial capitalist" (Marx, 1935, p. 355). Fundamentally, Marx was not a critic of the application of technology or of the various types of social inequality that he associated with given levels of technological development. His radicalism was associated with his conviction that the level of the productive capacity under capitalism had reached a point where the market relations produced a conflict between distribution and consumption that manifested itself in periodic economic crises, that these crises would become deeper and deeper, and that public ownership, as distinct from private ownership, of capital resources was the next stage of the socioeconomic evolutionary process that began with the appearance of the surplus product. He is often incorrectly characterized as a technological determinist. If this were the case, he would not have had to assume the role of a political radical. He did so because he rejected Laplacian determinism in regard to the human spirit, so that he did not consider that the radical social consciousness necessary to bring about this next social transformation would emerge spontaneously, but required a political movement to bring it about, even if history was on its side.

In 1877, the term *philosophy of technology* appears first in the title of a German work, *Grundlinien einer Philosophie der Technik* by Ernst Kapp, who was strongly influenced by Hegel's concept of history being the realization of the Idea. He wrote that human beings using their first tools, their hands, in producing their first works became historical human beings progressing toward self-consciousness (Kapp, 1877, p. 39).

The goal of technology as a field of human endeavor is, like science, not the same for all its practitioners. For some, the "tinkerers," it can be an end in itself, just as mathematicians will sometimes say that they are interested only in the beauty of the logic and do not care if their work has any practical use. On the other hand, it is rare for successful tinkerers to neglect patenting the results of their tinkering.

The empiricist view of John Stuart Mill was further refined by the Austrian physicist Ernst Mach and, subsequently, further developed by a group of scientists and philosophers known as the Vienna Circle into what became the most influential school of philosophy of science in the first half of the twentieth century, *logical positivism*. According to this view, in its application to physics, "quantities such as the charge, temperature, mass, and length of a body are *defined* as the objective results of certain prescribed operations that can be carried out in the laboratory. . . . This *operational viewpoint* is the basis of this philosophy." Further, "physical *laws* are relationships between operationally defined quantities that always occur when certain experiments are performed" (Halliday, 1955, pp. 4–5).

In the logical positivist view, the question of the source of our sense impressions or observations is meaningless, since there is no operational way of establishing existence of objects external to us. The attractiveness of logical positivism to the scientist is its apparent rejection of speculative activity. The practical task of scientific theory is to provide correlations between observational data.

3. CONTEMPORARY VIEWS ON PHILOSOPHY OF TECHNOLOGY

By the middle of the twentieth century, the logical problems connected with operational definitions began to lead to their demise. One objection, for example, was that an operational definition of a field would require an infinite set of measurements. Another objection was that no two instruments are identical and no two measurements by the same instrument of infinite precision would be identical; therefore each act of measurement would produce its own unique operational definition. It can be argued that operational definitions are means for standardizing scales of measurement of physical properties, the meaning of which arise from the laws that embrace them.

With the collapse of logical positivism, scientific realism rose to the fore. Realism itself is not one particular philosophical current but a category of approaches to what is often called the mind–body problem. Realism, in general, recognizes the relative independence of our ideas from that which exists outside our minds. At the same time, realism does not necessarily exclude the dependence of one on the other. Some realist philosophies may give primacy to the world of ideas in the sense that it is ideas that ultimately engender the world outside our minds, while others can argue that it is the world outside our minds that ultimately gives rise to our ideas, allowing for various degrees of this dependence.

According to Don Ihde, philosophy of science has been historically linked to the three prejudices that he associates with a *theory bias* that affects the attitude toward technology. The first goes back to Greek antiquity, according to which "the aim of highest humanity was, in effect to achieve the deepest knowledge and, once attained, meditate upon it." The second is more recent and holds that modern technology is both essentially different from all ancient or traditional technologies, and therefore in some fundamental sense, "better." The third prejudice is the belief that modern technology differs from all previous technology in that it is derived from modern science (Ihde, 1993, p. 20). Ihde cites the Platonic view, reflected by Aristotle, which holds that anything associated with the body and the material is inferior to the realm of ideas and forms, the latter being associated with the mind or soul.

Philosophical attention to technological concerns grew slowly during the first half of the twentieth century. Among the important commentators on the question were Friedrich Dessauer (1927), Ernst Jünger (1932), and José Ortega y Gasset (1941). Renewed interest developed after World War II, stimulated at first by the social, political, and economic concerns resulting from nuclear weapons. Simultaneous with the introduction of nuclear technology was the beginning of the computer age, large-scale application of electronic computers having begun during World War II in connection with coupling artillery (naval and land) to radar.

One work that attracted immediate attention was an essay by Martin Heidegger (1953), "The Question Concerning Technology." Heidegger begins his discussion of technology by pointing to the inadequacies today of the earlier instrumental and anthropological definitions of technology, the instrumental definition being the means to achieve particular ends, while the anthropological definition refers to the human activities employing these means. He thinks that it is necessary to go beyond these definitions to arrive at a deeper understanding of the relationship between humans and the technology they employ. This is because as humans attempt to control technology and bring it spiritually within their power, it continually slips through their fingers no matter how hard they try. It is necessary, above all, to distinguish modern technology from past technologies. What is fundamentally different in modern technology is that it views both nature and human labor as a continually available and extendible standing reserve whose possibilities confront humanity as a challenge for further disclosure or uncovering. Modern technology challenges and stockpiles the sun's warmth stored in coal "for heat, which in turn is ordered to deliver steam whose pressure turns the wheels that keep a factory running" (Heidegger, 1977, p. 15). The windmill of classical technology is of a different character. "Its sails do indeed turn in the wind; they are left entirely to the wind's blowing. But the windmill does not unlock energy from the air currents in order to store it" (1977, p. 14). "The gathering together of that setting-upon that sets upon man, i.e., challenges him forth, to reveal the real, in the mode of ordering, as standing reserve" is the way of revealing "which holds sway in the essence of modern technology and which is itself nothing technological" (p. 20).

Modern and classical technology are both ways of disclosure (or uncovering), but only in modern technology are humans challenged to this uncovering. This already occurred with the development of physics as an exact science, on which modern technology is based (p. 21). Heidegger, however, does not see science as the primary stimulant of technology. He points out that modern physics involves experiment and is therefore dependent on the development and application of technical apparatus. Since the essence of technology lies in the uncovering process that constitutes technological activity, technology must be seen as applying natural science, rather than being considered as applied natural science (1977, p. 14).

Heidegger sees the main danger from modern technology not so much in the threats of environmental disasters resulting from its applications but in human beings surrendering themselves to what is technologically revealed and being absorbed into the revealed technology, all the while believing that they are the masters and in full control of the earth. This is the illusion generated by looking at the technological world merely as a collection of objects and means to be set in motion by human activity, and it is this viewpoint that threatens to reduce humans themselves to a mere standing reserve. It is not enough to acquaint oneself with external objects and the relations among them, including their relationships to humans themselves. It is necessary to be conscious of how our own being is grounded in the complex of relationships among ourselves and the objects around us. An airplane is not merely an object of a given shape and construction. When revealed, it is a standing reserve for the transportation of people and goods, and to fulfill this role, it must be fully appropriate in structure and readied for flight. It needs airports from which to take off and land, and these airports must be planned for and constructed by persons who do not necessarily travel in the planes, etc. Heidegger argues that this type of understanding is necessary before we can do anything to dispel the illusion that humans are the masters of the world, and uncover the paths to reverse the domination that technology maintains.

By his repeated stress on the concept of uncovering, Heidegger in essence projects an *a priori* character onto that which can be uncovered. Moreover, he regards continual involvement in technological uncovering as human destiny, but not in a deterministic way. The danger of technology that he sees is therefore that people see themselves challenged to uncover technology in a one-sided way, a way that contributes to their virtual enslavement by technology and obliterates any free will. He sees human destiny to be the confrontation of the challenge for technological uncovering and thus has to reject the possibility of abandoning technological development. Rather, he calls for the implementation of human free will to proceed along a path of technological uncovering "that in no way confines us to a stultified compulsion to push on blindly with technology or, what comes to the same thing, to rebel hopelessly against it and curse it as the work of the devil" (1977, p. 26). Heidegger does not, however, see this enactment of human "free claim" as a purely human undertaking. That which is there to be uncovered was not put there by human beings. This last point underscores the essentially mystical character of Heidegger's philosophy, since the human response to an objectively existing situation will be indifferent to the process by which this objective situation arose if no knowledge of its supposed purpose, assuming there was one, is available.

Heidegger's *a priori* concept of technology was disputed by Herbert Marcuse in *One-Dimensional Man* (1964). "The technological *a priori* is a political *a priori* inasmuch as the transformation of nature involves that of man, and inasmuch as the 'man-made creations' issue from and re-enter a society ensemble" (p. 154). Marcuse saw the inherent rationality of modern technology as a source of human enslavement. "Scientific management and scientific division of labor vastly increased the productivity of the economic, political, and cultural enterprise. Result: the higher standard of living. At the same time and on the same ground, this rational enterprise produced a pattern of mind and behavior which justified and absolved even the most destructive and oppressive features of the enterprise. Scientific–technical rationality and manipulation are welded together into new forms of social control" (1964, p. 146). Marcuse criticizes the harm done by relying on positivist criteria in assessing technological performance. What is quantitatively measurable is profit and efficiency, not the toll in human suffering.

The views of another important writer on technology, Jacques Ellul, continue to be influential today. According to Ellul's summary of his own views (1983), first expressed in his book *The Technological Society* (1964), technology replaces nature by creating the specific milieu in which humans must exist. Technology thus becomes artificial, autonomous with respect to values, ideas, and the state, self-determining, growing in a process that is causal, but directed to ends. "It is incorrect to say that economics, politics, and the sphere of the cultural are influenced or modified *by* Technique; they are rather situated *in* it, a novel situation modifying all traditional social concepts. Politics, for example, is not modified by Technique as one factor among others which operate upon it; the political world is today defined through its relation to the technological society. Traditionally, politics formed a part of a larger social whole; at the present the converse is the case" (1983, p. 86). Ellul argues that technological progress is in itself neither good nor bad. "The fact is that, viewed objectively, technological progress produces values of unimpeachable merit, while simultaneously destroying values no less important. As a consequence it cannot be maintained that there is absolute progress or absolute regress" (p. 98). In summary, Ellul maintains that all technological progress exacts a price, raising more problems than it solves, pernicious and generally unforeseeable effects being inseparable from its favorable effects. The technological society cannot not be a humanist one. There is a contradiction between technological perfection and human development because technological perfection "is only to be achieved through quantitative development and necessarily aims exclusively at what is measurable. Human excellence, on the contrary, is of the domain of the qualitative and aims at what is not measurable" (p. 90). Ellul sees no escape from this situation. "There is no possibility of turning back, of annulling, or even arresting technical progress. What is done is done. It is our duty to find our place in our present situation and in no other" (p. 91).

The most widely read contemporary philosopher of technology is Landon Winner (1977, 1986), who also focuses on the theme of the autonomous character of technology, viewing it as self-moving and self-evolving according to its own laws. Megatechnical systems like the electric power system dominate humanity by exerting demands for their own maintenance. Humans can monitor and guard the system against destruction and deterioration, or introduce innovations to improve its efficiency, but are unable to replace it by another. "We indeed 'use' telephones, automobiles, electric lights, and computers in the conventional sense of picking them up and putting them down. But our world soon becomes one in which telephony, automobility, electric lighting, and computing are forms of life in the most powerful sense: life would scarcely be thinkable without them" (1986, p. 11).

In the 1950s and 1960s, the environmental hazards associated with the unrestricted development of nuclear and chemical technologies became evident. Problems also arose in connection with the disposal of nuclear and toxic chemical waste. The growing quantity of nonbiodegradable plastic waste created additional problems. The growing integration of electric power systems into national and even international networks generated the threat of a national and international catastrophe from a major breakdown in the electrical grid. With the development of supertankers, ecological disasters produced by oil spills became a reality. Standing above all other threats facing humanity was that of nuclear war. These developments stimulated a number of philosophers to focus their attention on the scientific and societal implications of contemporary technological development. Philosophy of technology, which hitherto was generally limited to sporadic study by philosophers primarily interested in other areas, emerged as a field of specialization within philosophy, with international organizations and publications.

One set of strategies put forward, according to Ihde (1993, pp. 119–27), to deal with environmental issues involves returning to some previous lower level of technology or to minimalist technologies. Ihde argues that such a strategy would produce social disruption as well as an immediate drastic worldwide decline in population comparable to times of vast warfare and plagues.

An *ameliorationist* set of strategies accepts high-technology developments, but turns them into regional and decentralized modes for such activities as food and energy production. Ihde believes that such strategies can only have limited success, since the rate of technological change outpaces the possibilities of such alternative strategies.

The third set of strategies Ihde calls *hi-tech reformist*. Solutions to the problems of continued technological development are to be provided by miniaturization, clean-up technologies, and alternative energy production. These strategies require a centralized administration and planning on an international scale and continual technological development of "clean" solutions. Efforts to deal with global problems must be approached with a multicultural perspective and, according to Ihde, a holistic view of the interconnections of technology, environment, and nature.

4. UNRESOLVED PROBLEMS OF TECHNOLOGICAL DEVELOPMENT

Modern technology is now capable of eradicating human life on earth through a number of separate paths. The most obvious has been through nuclear war. Although the principal sources of political tension that posed this threat were removed at the beginning of the 1990s, production and maintenance of nuclear weapons continues. New sources of political tension may emerge and pose the threat of nuclear war once again. Further development of chemical and biological weapons may bring them to the point that they pose the same scale of danger to human existence as nuclear weapons.

Scientists in the United States are divided over the question of nuclear power, although a majority of physicists probably believe that current technologies carry an unacceptable risk of nuclear disaster. The potential danger from commercial application of genetic engineering, which began on a significant scale in the 1980s, is twofold. Unanticipated effects of scale may occur—that is, harmful effects appearing only when artificially created genetic strains are available in much larger quantities and concentrations than in the research and development stage. The second danger is of accidental release of harmful organisms. Richard Leakey has pointed out how fortunate it is for humanity that the AIDS virus is not transmitted through sneezing. What if an accidental release occurred of some potentially lethal experimental microorganism capable of such rapid transmission?

The most commonly acknowledged threat to human existence at present is from industrial chemicals. International agreements designed to halt the release of chemical agents that destroy ozone in the upper atmosphere are now in effect. No international agency, however, has the authority to act independently to meet other dangers as they arise; each hazard requires a separate international agreement. Differences in the assessment of dangers arising among different countries, based on political and economic pressures rather than scientific considerations, may prevent averting the ultimate disaster.

Between 1700 and the end of World War II, industrialized countries pursued economic policies denying the export of technology. The breakup of the colonial systems, increasing resistance in the Third World to such imperialistic policies, and export of capital seeking lower wage scales are now bringing technological development to previously underdeveloped regions. Global resource and environmental crises loom, such as the destruction of the Brazilian rain forests. As the peoples of these countries aspire to the level of commodity consumption that they see in the industrialized countries, the potential for international conflicts is obvious.

An area of crisis limited to the industrialized countries is the growth of unemployment as a result of automation, robotization, and computerization of industrial and office work. The still-growing replacement of metal and wood by the less labor-intensive polymers in manufacturing and construction exacerbates this problem. In the early 1990s, over a period that is not usually characterized as a time of deep economic crisis, unemployment in the industrialized countries of Europe was often above 10%, while in the United States (with less strict statistical measures for unemployment), unemployment held at about 6%. While the financial consequences of this unemployment can be offset in part by social insurance and social welfare programs, the shifting of skilled labor into unskilled labor at lower pay as well as threatened future displacement for those not yet affected has spread insecurity among employees in all income levels.

The source of these problems lies outside of technology itself, in the driving force behind the application of technology. The application of technology to production is not stimulated directly by the need for products, but by the profit that can be made from the sale of products that satisfy real or imagined needs. The "unseen hand" that classical laissez-faire economics saw balancing economic life seems no longer to function. Various degrees of economic regulation and intervention by the state have been introduced into otherwise free-market economies. Marx suggested that such measures would not eliminate the business cycle with its growing swings of prosperity and depression and that the solution would lie in replacing production for profit by production for need, displacing private ownership of the capital resources by public ownership and planned utilization of these resources. The effort to establish such a system on a wide scale beginning in the U.S.S.R. in 1917, extending to Eastern Europe and China and some other countries in the 1940s and later, collapsed completely in the U.S.S.R. and Eastern Europe. It has survived in modified form in the less-industrialized countries of China, Vietnam, North Korea, and Cuba, where various mixtures of market and planned economies are being tried. Chinese, Vietnamese, and Cuban leaders attribute the European collapse to the extreme bureaucratization of political and economic life and excessive centralization of the economic planning mechanisms. Whether they can produce different results is still to be seen.

As long as economies function within a capitalist framework, technological development must proceed, for the inanimate corporation or its animate principal stockholders cannot consume all profits from a successful year of activity, but must continually reinvest them on an expanding scale. Global environmental and resource problems must ultimately be solved by limiting reinvestments in material production to levels that can be technologically tolerated. Expansion of economic activity in directions that minimally absorb material resources offers at present a partial solution to the problem. Commodities and services that take largely nonmaterial forms, such as computer software and artistic production, are of this character. Perhaps the welfare of humanity in the immediate future lies in the expansion of the range of such activities.

INTRODUCTION

Crystal-lattice vibrations are quantized in much the same way that electromagnetic waves are, with the counterpart of the photon being the *phonon*. As one might expect, there are a number of parallels between the two classes of phenomena. For example, the phonon energy flux radiated into the interior of a cold crystal from a heated surface varies as the fourth power of the absolute temperature, just as for blackbody electromagnetic radiation. The blue of the sky has its counterpart in that small crystal inhomogeneities give rise to Rayleigh scattering of phonons, which varies with the fourth power of the frequency. It is common for an atom undergoing a transition between two quantum levels to conserve energy by absorbing or emitting a phonon rather than a photon.

There are, however, limits to how far the analogy can be taken. In contrast to electromagnetic waves in vacuum, lattice vibrations have a lower bound to their wavelength, equal to twice the lattice spacing in principal crystallographic directions, and associated with this is an upper cutoff in the spectrum of vibrational frequencies. For wavelengths approaching this limit, there is pronounced dispersion. Nonlinearity is important for lattice vibrations, leading in particular to phonon–phonon scattering.

The main emphasis of this article is on the interaction between phonons and other excitations or particles, on how these interactions influence the physical properties of crystals, and on how the scattering of x rays, neutrons, and other particles can be used to determine phonon dispersion relations. The concept of the phonon is introduced in Sec. 1, which also contains a synopsis of the main *lattice dynamics* results that are drawn on in this article. For a fuller discussion of lattice dynamics, the reader is referred to LATTICE VIBRATIONS, STATISTICS OF (hereafter cited as LV). Subsequent sections deal with scattering and absorption processes involving phonons, γ rays, x rays, optical and infrared photons, neutrons, electrons, neutral atoms, and localized spin and other excitations. A major aspect of phonon physics that is touched on

only very briefly in the present article is *phonon transport*. This subject is treated extensively in LV and in HEAT PULSE PROPAGATION IN SOLIDS (HP).

1. THEORETICAL BACKGROUND

We start by recalling that in the harmonic approximation the Hamiltonian for the *vibrations of a crystal lattice* takes the form (LV)

$$H_L = \sum_{l\kappa\alpha} \frac{p_\alpha^2(l\kappa)}{2M_\kappa} + \tfrac{1}{2} \sum_{l\kappa\alpha} \sum_{l'\kappa'\beta} \Phi_{\alpha\beta}(l\kappa;\, l'\kappa') u_\alpha(l\kappa) u_\beta(l'\kappa'), \qquad (1)$$

where $u_\alpha(l\kappa)$ are the displacements of the atoms from their equilibrium positions, with α denoting the Cartesian component, l the cell index, and κ ranging over the r atoms in the unit cell; $p_\alpha(l\kappa) = M_\kappa \partial u_\alpha(l\kappa)/\partial t$ are the momenta of the atoms, where M_κ are the atomic masses; and $\Phi_{\alpha\beta}(l\kappa;\, l'\kappa')$ are the *atomic force constants*, given by the derivatives

$$\Phi_{\alpha\beta}(l\kappa;\, l'\kappa') = \frac{\partial^2 \Phi}{\partial u_\alpha(l\kappa) \partial u_\beta(l'\kappa')} \qquad (2)$$

of the lattice potential energy Φ at equilibrium. The equations of motion derived from this Hamiltonian are

$$M_\kappa \frac{\partial^2 u_\alpha(l\kappa)}{\partial t^2} = -\sum_{l'\kappa'\beta} \Phi_{\alpha\beta}(l\kappa;\, l'\kappa') u_\beta(l'\kappa'). \qquad (3)$$

Because of the *translational invariance* of the lattice, the normal modes can be taken as plane waves, and the displacements and momenta expressed in terms of *normal coordinates* $Q(\mathbf{k}j)$ and their *conjugate momenta* $P(\mathbf{k}j)$ thus:

$$u_\alpha(l\kappa) = \frac{1}{\sqrt{NM_\kappa}} \sum_{\mathbf{k}j} e_\alpha(\kappa|\mathbf{k}j) Q(\mathbf{k}j) e^{i\mathbf{k}\cdot\mathbf{x}(l)}, \qquad (4)$$

$$p_\alpha(l\kappa) = \frac{1}{\sqrt{NM_\kappa}} \sum_{\mathbf{k}j} e_\alpha(\kappa|\mathbf{k}j) P(\mathbf{k}j) e^{i\mathbf{k}\cdot\mathbf{x}(l)}. \qquad (5)$$

The factor N comes from invoking *cyclic boundary conditions* over a macrocell of $N = L \times L \times L$ unit cells. The sum extends over a regular grid of N values of the wave vector $\mathbf{k}$ within the first Brillouin zone and $3r$ values of the branch index j. The $e_\alpha(\kappa|\mathbf{k}j)$ for each value of $\mathbf{k}$ are the $3r$ normalized eigenvectors of the *dynamical matrix*

$$D_{\alpha\beta}(\kappa\kappa'|\mathbf{k}) = \frac{1}{\sqrt{M_\kappa M_{\kappa'}}} \sum_{l'} \Phi_{\alpha\beta}(l - l', \kappa;\, 0\kappa') \times e^{-i\mathbf{k}\cdot[\mathbf{x}(l)-\mathbf{x}(l')]}. \qquad (6)$$

These eigenvectors satisfy the linear equations

$$\omega^2(\mathbf{k}j) e_\alpha(\kappa|\mathbf{k}j) = \sum_{\kappa'\beta} D_{\alpha\beta}(\kappa\kappa'|\mathbf{k}) e_\beta(\kappa'|\mathbf{k}j), \qquad (7)$$

with the normal-mode frequencies $\omega(\mathbf{k}j)$ being determined by the secular equation

$$|D_{\alpha\beta}(\kappa\kappa'|\mathbf{k}) - \omega^2 \delta_{\alpha\beta}\delta_{\kappa\kappa'}| = 0. \qquad (8)$$

Since $D^*_{\alpha\beta}(\kappa\kappa'|\mathbf{k}) = D_{\alpha\beta}(\kappa\kappa'|-\mathbf{k})$, we may choose the phases of the eigenvectors such that

$$e^*_\alpha(\kappa|\mathbf{k}j) = e_\alpha(\kappa|-\mathbf{k}j). \qquad (9)$$

It follows from Eqs. (4), (5), and (9) and the requirement that $u_\alpha(l\kappa)$ and $p_\alpha(l\kappa)$ are real that

$$Q^*(\mathbf{k}j) = Q(-\mathbf{k}j), \qquad (10)$$

$$P^*(\mathbf{k}j) = P(-\mathbf{k}j). \qquad (11)$$

Three of the solutions $\omega(\mathbf{k}j)$ of Eq. (8) go to zero in the limit $\mathbf{k} \to 0$ and represent the *acoustic branches* of the *dispersion relation.* They pertain in the long-wavelength continuum limit to longitudinal and transverse acoustic waves. The remaining $3r - 3$ solutions $\omega(\mathbf{k}j)$ approach finite limiting values as $\mathbf{k} \to 0$ and represent the *optic branches.* In these latter modes near $\mathbf{k} = 0$ the sublattices vibrate against one another, and this motion can generally be detected by infrared absorption or Raman scattering.

In order to solve Eq. (8), the atomic-force constants are required. There are some successful *ab initio* theories, but most lattice dynamics calculations are based on a parametrized model of some kind (see Bilz and Kress, 1979). Over the years, many different models have been devised. The *valence force field* model is one of the simplest and is based on intuitive ideas that have a foundation in molecular vibrational studies. One pictures the atoms in the crystal as joined together by bonds and expresses the interatomic forces in terms of the forces and torques required to stretch, bend, and twist these bonds. This model has been applied with some success to covalent crystals such as diamond, silicon, and germanium. By and large though, most successful models incorporate long-range Coulomb forces in some form. This is obviously necessary for treating ionic crystals, but even in the case of covalent crystals the number of parameters required for a successful fit tends to be less when Coulomb forces are incorporated explicitly in the model in some way. The *rigid-ion model* is the simplest approach to ionic crystals, and there are a number of more sophisticated models that allow for deformation of the electron wave functions of the atoms as they move relative to one another. These include dipole models, various shell and deformation-shell models, and the bond-charge model. In metals, the interaction between the ions and the conduction electrons has to be taken into account. In the de Launay (1953) model for instance, the electron gas is attributed a finite bulk modulus and is assumed to adjust adiabatically to the motion of the ions, screening their long-range Coulomb interactions in the process. This coupling has a pronounced effect on the longitudinal lattice modes, while pure transverse modes are unaffected.

Whatever model is adopted for a particular application, it commonly features a number of parameters such as bond force constants, shell charges, atomic polarizabilities, or whatever. These parameters have to be determined from experiment. The phase velocities $v(j) = \omega(\mathbf{k}j)/k$ of long-wavelength acoustic modes are a function of the *bulk elastic constants* of the crystal, and this provides as many constraints on the parameters of the model as the crystal has independent elastic constants. Measured Raman frequencies, dielectric tensor, and optical absorption often provide further constraints on the parameters. If the model is simple enough, this information may be sufficient to determine all the parameters. The ultimate test of a model, though, is that it should fit the dispersion relations measured by neutron scattering or one of the other techniques discussed in Sec. 3. As an example, Fig. 1(a) shows dispersion curves for silicon in a number of principal crystallographic directions

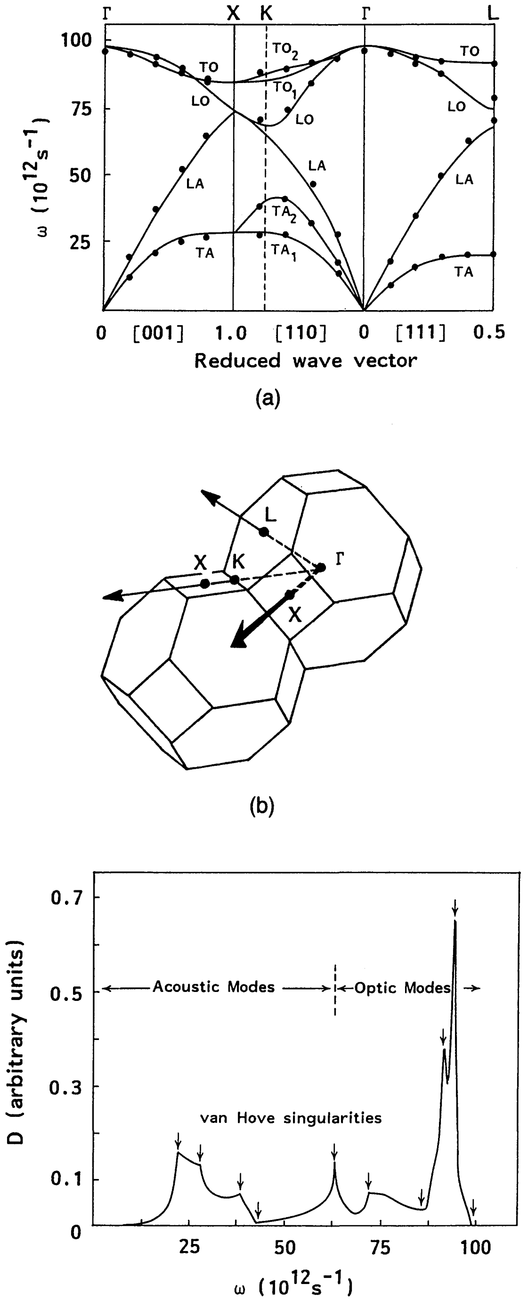

FIG. 1. (a) Phonon dispersion curves for silicon (adapted from Bilz and Kress, 1979). The directions are referred to the face-centered cubic (fcc) Brillouin zone shown in (b). The branches are distinguished as longitudinal acoustic (LA), longitudinal optic (LO), transverse acoustic (TA), and transverse optic (TO). The two TA and two TO branches are degenerate in the [001] and [111] directions because of symmetry. (c) Calculated frequency-distribution function $D(\omega)$ for Si.

[see Fig. 1(b)]. The points denote neutron-scattering data, and the lines represent calculations on the basis of a four-parameter *bond-charge model.*

Many thermodynamic quantities can be calculated from a knowledge of the *frequency distribution function* or *density of states $D(\omega)$*, defined as the number of normal-mode frequencies per unit frequency interval at ω. Figure 1(c) shows $D(\omega)$ calculated for Si. The region below about $20 \times 10^{12}\ \mathrm{s}^{-1}$ corresponds to long-wavelength acoustic modes. Here $D(\omega)$ is roughly proportional to ω^2, in accordance with the Debye model. At higher frequencies, $D(\omega)$ is punctuated by a number of sharp features known as *van Hove singularities* (Maradudin *et al.*, 1971). These correspond to critical points at the zone boundaries (and elsewhere) where the dispersion relation has an extremum. To one side of the critical frequency ω_0, $D(\omega) \sim \sqrt{|\omega - \omega_0|}$, giving a divergence in the derivative of $D(\omega)$ at ω_0, while on the other side there is no singular behavior. These singularities carry over to other spectral quantities such as defect-activated infrared absorption, and this provides scope for experimentally determining zone-boundary frequencies.

1.1 Quantization; the Phonon

Quantization of the lattice vibrations is effected by regarding the normal coordinates $Q(\mathbf{k}j)$ and their conjugate momenta $P(\mathbf{k}j)$ as operators satisfying the commutation relations (LV)

$$[P(\mathbf{k}'j'), Q(\mathbf{k}j)] = (\hbar/i)\,\delta_{jj'}\Delta(\mathbf{k} - \mathbf{k}'), \tag{12}$$

where $\hbar$ is Planck's constant, $\delta_{jj'}$ is the Kronecker delta, and

$$\Delta(\mathbf{k}) = \begin{cases} 1 & \text{if } \mathbf{k} = \mathbf{G}, \\ 0 & \text{otherwise,} \end{cases} \tag{13}$$

where $\mathbf{G}$ is a reciprocal lattice vector. The Hamiltonian is given in terms of these conjugate operators by

$$H_L = \tfrac{1}{2} \sum_{\mathbf{k}j} [P(\mathbf{k}j)P^*(\mathbf{k}j) + \omega_j^2(\mathbf{k})Q(\mathbf{k}j)Q^*(\mathbf{k}j)] \tag{14}$$

and is in the form of a sum of $3rN$ independent harmonic oscillator Hamiltonians. The eigenstates of H_L can thus be represented as products of eigenstates of the individual oscillators.

The usual approach to the harmonic oscillator, found in most elementary textbooks on quantum mechanics (see, e.g., Schiff, 1955), is to solve Schrödinger's equation in the coordinate or momentum representation and thereby obtain the eigenstates and eigenenergies. In the present context, of more interest than the form of eigenstates are the energy eigenvalues and the matrix representations of operators such as Q, Q^2, and P, etc., in the energy basis. This information is required for calculating expectation values and thermal averages, carrying out perturbation calculations, and many other purposes. The terms P and Q both appear quadratically in the Hamiltonian, and this symmetry allows the energy spectrum and required matrix representations to be obtained by purely algebraic means.

The trick, which goes by the name of *second quantization*, is to introduce operators $a^\dagger(\mathbf{k}j)$ and $a(\mathbf{k}j)$ for each mode $\mathbf{k}j$ by means of the equations

$$Q(\mathbf{k}j) = \sqrt{\frac{\hbar}{2\omega(\mathbf{k}j)}}\,[a^\dagger(-\mathbf{k}j) + a(\mathbf{k}j)], \tag{15}$$

$$P(\mathbf{k}j) = i\sqrt{\frac{\hbar\omega(\mathbf{k}j)}{2}}\,[a^\dagger(\mathbf{k}j) - a(-\mathbf{k}j)]. \tag{16}$$

It is easily verified (see, e.g., Ghatak and Kothari, 1972) that these operators satisfy the commutation relations

$$[a(\mathbf{k}'j'), a^\dagger(\mathbf{k}j)] = \delta_{jj'}\Delta(\mathbf{k} - \mathbf{k}') \tag{17}$$

and that the Hamiltonian is given in terms of them by

$$H_L = \sum_{\mathbf{k}j} \hbar\omega(\mathbf{k}j)\,[a^\dagger(\mathbf{k}j)a(\mathbf{k}j) + \tfrac{1}{2}]. \tag{18}$$

Considering an individual oscillator, it may be shown using the commutation relations that $a^\dagger(\mathbf{k}j)$ and $a(\mathbf{k}j)$ operating on an eigenstate of the Hamiltonian yield other eigenstates that are higher and lower in energy respectively by $\hbar\omega(\mathbf{k}j)$, that the complete set of eigenstates can thereby be generated, and that there is a ground state. The eigenstates can thus be denoted $|n(\mathbf{k}j)\rangle$, and the associated eigenvalues are given by

$$E(n(\mathbf{k}j)) = [n(\mathbf{k}j) + \tfrac{1}{2}]\hbar\omega(\mathbf{k}j), \tag{19}$$

where the quantum number $n(\mathbf{k}j)$ takes on all positive integer values and is zero for the ground state. When the oscillator undergoes a transition, energy is added or removed in multiples of $\hbar\omega(\mathbf{k}j)$. This quantum of energy is called the *phonon*, and $n(\mathbf{k}j)$ is known as the *phonon occupation number* for the state. The operators $a^\dagger(\mathbf{k}j)$ and $a(\mathbf{k}j)$ are called the *phonon creation* and *annihilation* (or *destruction*) *operators* respectively, and raise and lower the phonon occupation number of a mode in accordance with

$$a^\dagger(\mathbf{k}j)|n(\mathbf{k}j)\rangle = \sqrt{n(\mathbf{k}j) + 1}\,|n(\mathbf{k}j) + 1\rangle, \tag{20}$$

$$a(\mathbf{k}j)|n(\mathbf{k}j)\rangle = \sqrt{n(\mathbf{k}j)}\,|n(\mathbf{k}j) - 1\rangle. \tag{21}$$

The product $a^\dagger(\mathbf{k}j)a(\mathbf{k}j)$ is called the number operator because it extracts the phonon occupation number of a state:

$$a^\dagger(\mathbf{k}j)a(\mathbf{k}j)|n(\mathbf{k}j)\rangle = n(\mathbf{k}j)|n(\mathbf{k}j)\rangle. \tag{22}$$

Eigenstates of the combined system of all the oscillators can be represented as products of the individual oscillator states: $|\cdots n(\mathbf{k}j)\cdots n(\mathbf{k}'j')\cdots\rangle = |\cdots\rangle|n(\mathbf{k}j)\rangle|\cdots\rangle|n(\mathbf{k}j)\rangle \times |\cdots\rangle$, with the energy being the sum of the energies of the individual oscillators, i.e.,

$$E(\{n(\mathbf{k}j)\}) = \sum_{\mathbf{k}j} [n(\mathbf{k}j) + \tfrac{1}{2}]\hbar\omega(\mathbf{k}j). \tag{23}$$

The phonon can in many respects be regarded as a particle. If one thinks of it as occupying a wave packet centered on some value of $\mathbf{k}$, rather than an infinitely extended plane wave, then the phonon can be ascribed an instantaneous position in space. The more precisely that point is specified, the greater of course is the spread of $\mathbf{k}$'s in the wave packet, which is a manifestation of the Heisenberg uncertainty principle. The rate at which the position of the phonon changes with time is its group velocity, which is given by $\mathbf{V} = \nabla_{\mathbf{k}}\omega(\mathbf{k}j)$. The quantity $\hbar\mathbf{k}$ is called the *pseudomomentum* or *crystal momentum* of the phonon. Although not momentum in the true sense, it nevertheless plays a role very similar to that of physical momentum. For instance, when a photon of light is scattered inelastically from a crystal with the loss of energy being taken up in the creation of a phonon, the change in momentum of the photon is equal to the value of $-\hbar\mathbf{k}$ for the phonon, which seems to signify the conservation of total momentum. Momentum conservation is a consequence of translational invariance, and a crystal lattice is only invariant under a discrete set of translations, not all translations. The upshot of this is that in general a scattering event involving phonons takes place with conservation of real plus crystal momentum, but only to within $\hbar\mathbf{G}$, where $\mathbf{G}$ is a reciprocal-lattice vector. An inelastic neutron-scattering event, for instance, might involve a combination of Bragg scattering by $\mathbf{G}$ together with the creation of a phonon of wave vector $\mathbf{k}$, so that the momentum transfer to the lattice, $\hbar(\mathbf{G} + \mathbf{k})$, differs from the phonon momentum by $\hbar\mathbf{G}$.

1.2 Statistical Properties of Phonons

Collectively, phonons can be ascribed a phase-space distribution function $n(\mathbf{k}j;\ \mathbf{x})$, from which quantities such as energy density, heat current, and momentum flux can be derived. Phonon scattering can lead to a rearrangement of the distribution, the process being governed by the Boltzmann equation (LV). Phonons obey Bose statistics, with the chemical potential being zero. The average number of phonons in any mode in thermal equilibrium depends on the local temperature T and is given by the *Planck distribution function* (LV)

$$\bar{n}(\mathbf{k}j) = \{\exp[\hbar\omega(\mathbf{k}j)/k_{\mathrm{B}}T] - 1\}^{-1}, \tag{24}$$

where k_{B} is Boltzmann's constant. It follows that

$$\begin{aligned}\langle Q(\mathbf{k}j)Q^*(\mathbf{k}j)\rangle &= \frac{\hbar}{2\omega(\mathbf{k}j)}[2\bar{n}(\mathbf{k}j) + 1]\\ &= \frac{\hbar}{2\omega(\mathbf{k}j)}\coth[\hbar\omega(\mathbf{k}j)/2k_{\mathrm{B}}T].\end{aligned} \tag{25}$$

The evaluation of thermodynamic quantities such as the Helmholtz free energy, the internal energy, heat capacity, and entropy with the aid of the partition function is discussed in LV.

The thermal expectation values of operators of the form $\exp[isu_\alpha(l\kappa)]$, where s is a parameter, are met in many situations. In treating the scattering of x rays and neutrons from a vibrating crystal, for instance, the phase factor for each atom is multiplied by $\sim\exp[isu_\alpha(l\kappa)]$ to take account of the instantaneous displacement of that atom from equilibrium, and the result has to be averaged over the ensemble of vibrational states of the crystal.

The evaluation of this expectation value entails expanding the exponential in powers of $u_\alpha(l\kappa)$, calculating the diagonal matrix elements, and then averaging over all oscillator states with their Boltzmann weighting factors. The details of the calculation can be found in Maradudin *et al.* (1971), and the result is

$$\langle\exp[isu_\alpha(l\kappa)]\rangle = \exp[-\tfrac{1}{2}s^2\langle u_\alpha^2(l\kappa)\rangle]. \tag{26}$$

This quantity exhibits a reduction with temperature as the mean square displacement of the atom increases and there is a growing degree of phase cancellation. Equation (26) is the basis of the *Debye–Waller factor* for the decrease in the intensity of x-ray Bragg peaks with temperature, related effects for neutron and other types of scattering, the temperature dependence of the recoil-free fraction in the Mössbauer effect, and zero-phonon line intensities in color center spectra. These phenomena are discussed individually in subsequent sections.

2. PHONON–PHONON INTERACTIONS

For any real crystal, the Hamiltonian considered thus far represents only part of the full picture. To arrive at Eq. (1), the lattice potential energy has been expanded in powers of the displacements of the atoms from equilibrium, and only the quadratic terms retained. Moreover, interactions between the atoms and other particles or excitations that might be present in the crystal have not been considered. These additional terms account for many interesting physical phenomena. They constitute the coupling to the probes such as light, neutrons, and x rays that are used to study lattice vibrations, they are the means by which thermal equilibrium is established, and they give rise to scattering processes that play a central role in phonon transport phenomena. In this and subsequent sections, we consider the forms that these interactions take, and some of their consequences.

Continuing the expansion of the lattice potential energy beyond second order, the terms of third order can be grouped together as $\Phi^{(3)}$, those of fourth order as $\Phi^{(4)}$, and so on. Expressed in terms of the previously defined normal coordinates, $\Phi^{(3)}$ takes the form (LV)

$$\Phi^{(3)} = \sum_{\mathbf{k}j}\sum_{\mathbf{k}'j'}\sum_{\mathbf{k}''j''} V^{(3)}(\mathbf{k}j,\mathbf{k}'j',\mathbf{k}''j'') \times Q(\mathbf{k}j)Q(\mathbf{k}'j')Q(\mathbf{k}''j''), \tag{27}$$

where $V^{(3)}(\mathbf{k}j,\mathbf{k}'j',\mathbf{k}''j'')$ are a set of coefficients that preserve the translational invariance of the lattice. A number of effects can be handled by treating $\Phi^{(3)}$ by perturbation theory. In the first place, the vibrational states form a quasicontinuum, and Fermi's "golden rule" can be used to calculate transition rates. It follows from Eqs. (15) and (27) that a matrix element of $\Phi^{(3)}$ between eigenstates of the harmonic Hamiltonian will be zero unless precisely three phonon occupation numbers in the one state differ by $+1$ or -1 from the corresponding occupation numbers in the other state. The three occupation numbers cannot all increase or all decrease in a transition, since that would violate energy conservation. A transition in which, say, $n(\mathbf{k}j)$ decreases and $n(\mathbf{k}'j')$ and $n(\mathbf{k}''j'')$ both increase, i.e., phonons $\mathbf{k}'j'$ and $\mathbf{k}''j''$ are created whose combined energies equal that of the original phonon $\mathbf{k}j$, has transition probability

$$p = \frac{2\pi}{\hbar^2}|V^{(3)}(\mathbf{k}j,-\mathbf{k}'j',-\mathbf{k}''j'')|^2 \times \frac{\hbar^3}{8\omega(\mathbf{k}j)\omega(\mathbf{k}'j')\omega(\mathbf{k}''j'')}n(\mathbf{k}j)[n(\mathbf{k}'j')+1] \times [n(\mathbf{k}''j'')+1]\delta(\omega(\mathbf{k}j)-\omega(\mathbf{k}'j')-\omega(\mathbf{k}''j'')). \tag{28}$$

Because of the translational symmetry of the lattice, $|V^{(3)}(\mathbf{k}j,-\mathbf{k}'j',-\mathbf{k}''j'')|^2$ is proportional to $\Delta(\mathbf{k}-\mathbf{k}'-\mathbf{k}'')$, and so there is conservation of crystal momentum to within a reciprocal-lattice vector times $\hbar$. The transition can be represented diagrammatically as shown in Fig. 2(a). Transitions represented by Fig. 2(b), in which two phonons are annihilated and one created, are calculated in a similar way. The total *decay rate*, or *inverse lifetime* of a phonon against two-phonon decay under thermal equilibrium conditions, is then obtained by summing p over all decay channels, using the thermal expectation values for the n's.

Phonon–phonon scattering processes play a central role in phonon transport. Transitions in which $\mathbf{k} - \mathbf{k}' - \mathbf{k}'' = \mathbf{G} \neq 0$ are termed *Umklapp* (U) processes and require that the participating phonons have wave vectors that are comparable with the zone-boundary values. Crystal momentum is not conserved in these processes, and they are the dominant source of thermal resistance in most insulating crystals at room temperature, where large–wave-vector phonons are present in appreciable numbers. Transitions in which $\mathbf{k} - \mathbf{k}' - \mathbf{k}'' = 0$ are termed *normal* (N) processes and conserve crystal momentum. They will rearrange a nonequilibrium distribution of phonons without changing the total momentum, and on their own do not represent a source of thermal resistance.

As a general observation, in thermal equilibrium at a temperature T well below the Debye temperature Θ_D, the average phonon lifetime against two-phonon decay is proportional to T^{-5} or $\bar{\omega}^{-5}$. The requirements of energy and momentum conservation, though, place constraints on the channels by which a specific phonon can decay, and there are considerable differences in lifetime depending on the particular phonon branch. The phonon dispersion curves for silicon shown in Fig. 1(a) are fairly representative of a large class of insulating crystals, in that the acoustic branches curve downward with increasing $|\mathbf{k}|$ (soft-mode materials discussed below provide exceptions to this rule). This being the case, a phonon cannot decay into two other phonons of the same branch with collinear momenta, since in order for momentum to be conserved the combined energies of the two phonons would exceed that of the original one. For an isotropic crystal, or in a slow direction in an anisotropic crystal, noncollinear decay would leave an even greater energy shortfall. Elaborating on this idea, Lax *et al.* (1981) have proved that a phonon cannot decay by anharmonic processes of any order into phonons each of whose phase velocities are higher than that of the original phonon. This is true for U as well as N processes. Slow transverse phonons can therefore, in the absence of other forms of scattering, be very long lived. This has important implications for *ballistic transport.*

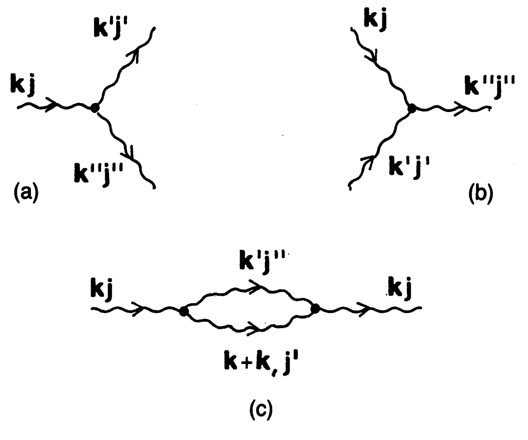

FIG. 2. Anharmonic processes involving $-\Phi^{(3)}$ in (a,b) first order and (c) second order.

Perturbation theory predicts a mixing of phonon states, and in second order a *renormalization of the phonon energies*, which can be represented by diagrams such as the one shown in Fig. 2(c). The phonon dispersion relations, phonon velocities, and thermodynamic quantities such as the elastic constants thereby become temperature dependent. In *quantum crystals* such as solid He, the effects of renormalization are pronounced, even at the absolute zero of temperature (Guyer, 1969). The anharmonic terms in the lattice potential account for thermal expansion, which in the Grüneisen approach is treated by considering the volume dependence of the phonon frequencies and minimizing the total free energy (Ashcroft and Mermin, 1981).

Phonon–phonon interactions play an important role in second-order *structural phase transitions* (see PHASE TRANSITIONS, STRUCTURAL). Many of these are accompanied by a *soft mode* in the high-temperature symmetrical phase, which shows up as a pronounced dip centered on a particular value $\mathbf{k}_0$ in the phonon dispersion relation. The soft-mode $Q(\mathbf{k}_0)$ has a negative harmonic restoring force constant $\omega_0^2(\mathbf{k}_0)$ but is dynamically stabilized through interactions with all the other modes.

The stabilization is most easily accounted for in terms of the quartic terms in the lattice potential, specifically those with $\mathbf{k} = \mathbf{k}' = \mathbf{k}_0$ and $\mathbf{k}'' = \mathbf{k}'''$. On taking a statistical average over the latter modes and summing, the mode $Q(\mathbf{k}_0)$ comes out to have a quasiharmonic frequency $\omega(\mathbf{k}_0)$ given by (Dorner and Comes, 1977)

$$\omega^2(\mathbf{k}_0) = \omega_0^2(\mathbf{k}_0) + \sum_{k''} V^{(4)}(\mathbf{k}_0,-\mathbf{k}_0,\mathbf{k}'',-\mathbf{k}'') \times \langle Q^*(\mathbf{k}'')Q(\mathbf{k}'')\rangle. \tag{29}$$

In the high-temperature phase, the second term in Eq. (29) is positive and exceeds the first in magnitude, and so $\omega(\mathbf{k}_0)$ is real. The soft-mode frequency is usually fairly small, though, and the mode heavily damped. As the temperature is lowered, $\omega(\mathbf{k}_0)$ approaches zero, the lattice becomes unstable, and a transition to a lower-symmetry structure takes place. In simple cases, the order parameter for the transition corresponds fairly closely to the soft-mode normal coordinate.

Varying the isotopic composition of a substance changes the phonon frequencies and zero-point motion amplitudes, and coupled with anharmonicity this results in changes to the lattice constant, elastic constants, and related physical quantities. The isotope effect in superconductivity is a classic example that is discussed later. Recently, the properties of isotopically enriched diamond have attracted much attention (see Hass *et al.*, 1992, and references contained therein).

3. SCATTERING METHODS FOR DETERMINING PHONON DISPERSION RELATIONS

Thermal diffuse scattering of x rays provided the earliest means of measuring the bulk phonon dispersion relations of crystals. Coherent inelastic neutron scattering arrived later on the scene but is a more powerful technique and has largely supplanted x-ray scattering in this task. Neutron scattering is also a valuable source of information on the displacement eigenvectors $e_\alpha(\kappa|\mathbf{k}j)$, phonon lifetimes, vibrations at defects, mode softening, and many other physical phenomena. Helium-atom and electron scattering are widely used in the study of lattice vibrations at surfaces.

The above-mentioned methods share certain common features. To permit measurement of the phonon dispersion relation over the entire Brillouin zone, the wavelength of the probe (de Broglie wavelength in the case of a particle) has to be comparable to the lattice spacing. The scattering is consequently dominated by elastic Bragg scattering from the crystal planes. Information about lattice vibrations is gleaned from the much weaker diffuse background scattering. This background is caused by inelastic scattering in which some of the energy of the probe is given over to the creation or annihilation of one, two, or more phonons. In the case of x rays, the limited wavelength resolution does not permit the energy shift to be measured directly, and the phonon frequencies are inferred from the temperature dependence of the diffuse intensity. For inelastic neutron and atom scattering, the energy shift is measured as a matter of course, and the phonon frequencies are obtained directly. As the temperature is raised, the vibrational amplitudes increase and the crystal appears less and less ordered to the probing particle. This results in a reduction in the intensities of the Bragg peaks and a compensatory increase in the inelastic scattering.

3.1 Inelastic X-Ray Scattering

In treating x-ray scattering from a vibrating crystal, the frequency shift is ignored. This change is of the order of the phonon frequency, $\sim 10^{12}$ Hz, which is small compared with the x-ray frequency, $\sim 10^{18}$ Hz. For simplicity, we will consider scattering from a monatomic Bravais lattice, which entails dropping the index κ. The scattering from any point within an atom is proportional to the local electron probability density, which is assumed to accompany the atom as it vibrates. The resulting scattering amplitude for an instantaneous configuration of all the atoms, taking into account the phase relationships between the scattering amplitudes for the individual atoms, is

$$\Psi \sim f(\mathbf{S}) \sum_{l} \exp\{i\mathbf{S}\cdot[\mathbf{x}(l) + \mathbf{u}(l)]\}, \tag{30}$$

where $f(\mathbf{S})$ is the *atomic structure factor*, $\mathbf{S} = \mathbf{q} - \mathbf{q}'$ is the scattering vector, and $\mathbf{q}$ and $\mathbf{q}'$ are the wave vectors of the incoming and outgoing radiation. The time-averaged *scattering intensity*

$$I = \langle \Psi^* \Psi \rangle = f^2 \sum_{ll'} \langle \exp\{i\mathbf{S}\cdot[\mathbf{x}(l) - \mathbf{x}(l') + \mathbf{u}(l) - \mathbf{u}(l')]\}\rangle \tag{31}$$

is obtained as an ensemble average over all vibrational states. Making use of Eq. (26) and expressing the atomic displacements in terms of the normal coordinates, and then expanding the exponential in powers of the averaged displacements, one obtains (see Maradudin *et al.*, 1971)

$$I = f^2 e^{-2W} [I_0 + I_1 + \ldots], \tag{32}$$

where

$$2W = \frac{2}{NM} \sum_{\mathbf{k}j} [\mathbf{S}\cdot\mathbf{e}(\mathbf{k}j)]^2 \langle Q^2(\mathbf{k}j)\rangle, \tag{33}$$

$$I_0 = \sum_{ll'} \exp\{i\mathbf{S}\cdot[\mathbf{x}(l) - \mathbf{x}(l')]\} = N^2 \Delta(\mathbf{S}), \tag{34}$$

$$I_1 = \frac{\hbar}{M} \sum_{j=1}^{3} [\mathbf{S}\cdot\mathbf{e}(\mathbf{K}j)]^2 \frac{\coth[\hbar\omega(\mathbf{K}j)/2k_B T]}{\omega(\mathbf{K}j)}, \tag{35}$$

with $e(\mathbf{k}j)$ standing for the mode eigenvector.

The scattering for the static lattice is $f^2 I_0$, which is zero except in the direction of the *Bragg peaks* where the *Laue condition* $\Delta(\mathbf{S}) = 1$ is satisfied. As a result of zero-point and thermal motion, the intensities of the Bragg peaks are reduced by the *Debye–Waller factor* e^{-2W}. The second term, I_1, describes the diffuse background due to one-phonon scattering, with $\mathbf{K}$ being the distance of $\mathbf{S}$ from the nearest reciprocal-lattice point. The term I_1 increases rapidly as $\mathbf{S}$ approaches the reciprocal-lattice point, and its behavior is determined by the three lattice modes of wave vector $\mathbf{K}$. For $\mathbf{K}$ along a symmetry axis, $\mathbf{S}\cdot\mathbf{e}(\mathbf{K}j)$ is nonzero except for the longitudinal mode, and so a measurement of the diffuse intensity as a function of temperature yields $\omega(\mathbf{K}j)$ for that mode. Measurements in other directions in reciprocal space yield data on the transverse branches. A drawback of this technique is that corrections have to be made for other sources of diffuse scattering. These include second-, third-, and higher-order processes, whose contributions to the diffuse background grow relative to the one-phonon scattering the further from the reciprocal-lattice point.

3.2 Coherent Inelastic Neutron Scattering

Coherent inelastic neutron scattering represents the most effective method for measuring phonon dispersion relations. The source is a collimated beam of monochromatic neutrons of wavelength comparable to the interatomic spacing. The crystal specimen is placed in the beam and gives rise to Bragg scattering, as well as inelastic scattering in which the change in energy and momentum of the neutron is taken up in the creation or annihilation of one or more phonons. Neutron scattering differs from x-ray scattering in the important respect that for given momentum transfer $\hbar\mathbf{k}$ the energy shift $\hbar\omega(\mathbf{k}j)$ is measured directly, usually with an accuracy of a few percent.

In neutron scattering, one measures the *differential cross section* $d^2\sigma/dEd\Omega$, which is the probability per unit solid angle and energy interval that an incoming neutron of wave vector $\mathbf{q}$ and energy $E = \hbar^2 q^2/2m$ is scattered into wave vector $\mathbf{q}'$ and energy $E' = \hbar^2 q'^2/2m$. For a single stationary nucleus, this is equal to $b^2\delta(E - E')$, where b is a quantity called the scattering length, which is independent of the neutron wavelength or angle of scattering.

For scattering from a vibrating monatomic crystal, in which there may be a change in the magnitude of the wave vector, the ensemble-averaged cross section taken over all possible initial vibrational states i of the crystal, with their Boltzmann probabilities p_i and final vibrational states f, is given by (Lovesey, 1977)

$$\frac{d^2\sigma}{dEd\Omega} = b^2 \frac{q'}{q} \sum_{if} p_i \left| \left\langle i \left| \sum_{l} \exp\{i\mathbf{S}\cdot[\mathbf{x}(l) + \mathbf{u}(l)]\} \right| f \right\rangle \right|^2 \times \delta(\hbar\omega + E_i - E_f), \tag{36}$$

where $\mathbf{S} = \mathbf{q} - \mathbf{q}'$ is the scattering vector and $\hbar\omega = E - E'$ is the energy transfer to the crystal.

The evaluation of Eq. (36) proceeds along similar lines to that of Eq. (31) for x-ray scattering. There are the Bragg diffraction peaks, whose intensities are reduced by the Debye–Waller factor e^{-2W}. The inelastic scattering is obtained by expanding the exponential in Eq. (36) in powers of the $\mathbf{u}(l)$ and expressing the $\mathbf{u}(l)$ in terms of the normal-mode phonon creation and annihilation operators. The linear terms yield energy- and momentum-conserving one-phonon creation and annihilation processes. The scattering cross section for these one-phonon processes is (Cowley, 1969)

$$\frac{d^2\sigma}{dE d\Omega} = b^2 \frac{q'}{q} \frac{N\hbar e^{-2W}}{2M\omega(\mathbf{k}j)} [\mathbf{S}\cdot\mathbf{e}(\mathbf{k}j)]^2[\bar{n}(\mathbf{k}j) + \tfrac{1}{2} \pm \tfrac{1}{2}] \times \delta(\hbar\omega \mp \hbar\omega(\mathbf{k}j))\Delta(\mathbf{S} - \mathbf{k} - \mathbf{G}), \tag{37}$$

with the upper sign corresponding to energy loss by the neutron through the creation of a phonon $\mathbf{k}j$, and the lower sign to energy gain through annihilation of that phonon.

The dispersion relations of a great many crystals have been measured with neutron scattering (see Bilz and Kress, 1979, for a survey of results). The measurements are fairly time consuming and are usually confined to principal crystallographic directions. Figure 1(a) shows the measured phonon dispersion relation of Si.

3.3 Helium-Atom and Electron Scattering; Surface Phonons

In recent years, a great deal has been learned about lattice vibrations at crystal surfaces using helium-atom scattering and *electron energy-loss spectroscopy* (EELS). The He atoms in these experiments are given energies of the order of 0.02 eV, which permits them to approach no closer than about 3–4 Å from the crystal surface, and they thus effectively sense only the motion of the top layer of atoms. In EELS, on the other hand, the electrons have energies of the order of 100 eV, which allows them to penetrate two to three atomic layers into the crystal and sense the motion of all of those atoms. The surfaces that are studied are usually parallel to principal crystallographic planes such as (001) and (111), and the scattered particles are generally measured in the plane of incidence, which is located in another principal plane (Toennies, 1991).

A bounded crystal retains the translational symmetry of the lattice parallel, but not perpendicular, to the boundary, and so it is only the component of the wave vector parallel to the surface, $\mathbf{k}_\parallel$, that serves for labeling the vibrational modes. There has to be another quantum number taking on a quasi-continuum of values, but it does not represent the perpendicular component of the wave vector. Surface-phonon dispersion relations thus have the general appearance of that of platinum (111) shown in Fig. 3. Corresponding to each value of $\mathbf{k}_\parallel$ there is a continuous band of modes, which far from the surface match up with the subset of bulk modes of the crystal whose wave vectors have $\mathbf{k}_\parallel$ as their in-plane component. There may be resonances in the continuum, for which the displacements of the associated modes become very large near the surface. In addition, there is a discrete Rayleigh branch, which is separated from the band modes from below. This corresponds to true surface modes for which the displacements fall off more or less exponentially with distance from the surface.

Both He atoms and electrons undergo elastic Bragg scattering in which the change in the in-plane component of the momentum of the projectile is equal to $\hbar\mathbf{G}$. The Bragg intensities are, as usual, reduced by a Debye–Waller factor. In addition, there is inelastic scattering accompanied by the creation or destruction of a surface phonon. The kinematic conditions are conservation of energy and of momentum in the surface to within $\hbar\mathbf{G}$.

The experimental data in Fig. 3 show res-

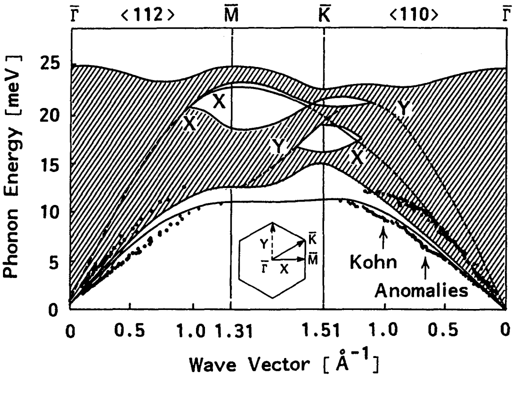

FIG. 3. Surface-phonon dispersion relation for Pt(111) (adapted from Toennies, 1991). Dots represent experimental data: curves and shaded area are theoretical. The letters X and Y indicate the polarization at the edge of the bulk bands.

onances that have been measured with He-atom scattering. These show a number of interesting features. In the ⟨110⟩ direction, there are two dips in the Rayleigh branch that have been ascribed to *Kohn anomalies* (see Sec. 5). In both the ⟨110⟩ and ⟨112⟩ directions, there is a resonance in the continuum due to a longitudinal mode concentrated near the surface by a weakening of the interatomic force constants there.

Helium-atom scattering has revealed a soft mode in tungsten (001) that precedes *surface reconstruction* as the temperature is lowered to 300 K. This is the first observation of a soft mode in a two-dimensional phase transition. Kress (1991) contains an extensive compilation of results obtained with He-atom scattering and EELS.

4. INFRARED ABSORPTION AND LIGHT SCATTERING

Phonons feature importantly in the infrared absorption and reflectivity of crystals, and in the Raman and Brillouin scattering of light.

The infrared properties of polar crystals are dominated by motion of the charged sublattices against each other. In the case of the alkali halides, for example, the near–zone-center longitudinal optical (LO) mode gives rise to an alternating electric field, which causes this branch to split away from the degenerate transverse optical (TO) branches, which are not accompanied by such a field. The well-known Lyddane–Sachs–Teller theory has these zone-center frequencies related by (Kittel, 1986)

$$\omega_L^2/\omega_T^2 = \epsilon(0)/\epsilon(\infty), \tag{38}$$

where $\epsilon(0)$ and $\epsilon(\infty)$ are the values of the dielectric constant at frequencies well below and well above ω_T, respectively. Electromagnetic waves, being transversely polarized, couple very strongly to the TO modes, but not to the LO mode. A coupled-mode polariton approach is required to describe wave propagation in the crystal, and this yields a band gap between ω_T and ω_L, where the crystal ideally should be perfectly reflecting to electromagnetic radiation. High values of reflectivity are indeed measured in this frequency range.

In nonpolar diamond-lattice–type crystals, one-phonon absorption is forbidden because there is a center of inversion midway between each pair of neighboring atoms, and there is therefore no electric dipole moment associated with the vibration of the two sublattices against each other. The presence of defects in the crystal breaks the symmetry, and all modes become infrared active, though not all to the same extent.

Two-phonon absorption is allowed in perfect crystals subject to the kinematic constraints of energy and momentum conservation. An infrared photon with the right energy to be absorbed will have a wavelength that is extremely large compared with the lattice spacing, and hence its wave vector $\mathbf{q}$ can be taken to be zero. The absorption is mediated mainly by the quadratic dependence of the electric dipole moment on the atomic displacements, which consists of momentum-conserving terms of the form $b(0)[a^\dagger(-\mathbf{k}j) + a(\mathbf{k}j)][a^\dagger(\mathbf{k}j') + a(-\mathbf{k}j')]$, where $b(0)$ is the photon-destruction operator. The absorption consists of a difference band, in which one phonon is created and another destroyed, and a summation band, in which two phonons are created. The absorptivity for the latter is given by (Reissland, 1973)

$$\alpha(\omega) = \sum_{\mathbf{k}jj'} \frac{A(\mathbf{k}jj')}{\omega(\mathbf{k}j)\omega(-\mathbf{k}j')}\{1 + n(\mathbf{k}j) + n(-\mathbf{k}j')\} \times \delta(\omega - \omega(\mathbf{k}j) - \omega(-\mathbf{k}j')), \tag{39}$$

where $A(\mathbf{k}jj')$ are not very easily determined coupling coefficients. As a crude first approximation, taking the combination of factors preceding the delta function as a constant, the absorption comes out to be proportional to the joint frequency distribution function $D_2(\omega)$. One can think of $D_2(\omega)$ as pertaining to a dispersion relation with $r(r + 1)/2$ branches representing $\omega(\mathbf{k}j) + \omega(-\mathbf{k}j')$ as a function of $\mathbf{k}$ for all combinations of j and j'. As with $D(\omega)$, $D_2(\omega)$ possesses critical points, but in much greater profusion, and it is a complex combinatorial exercise to extract the critical points of $D(\omega)$ from those of $D_2(\omega)$. Figure 4 shows the two-phonon infrared absorption spectrum of silicon and identifies some of the critical-point features.

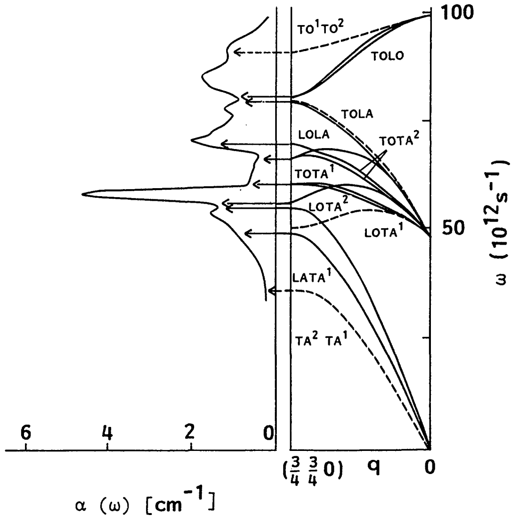

FIG. 4. Two-phonon infrared absorption $\alpha(\omega)$ in silicon at 20 K and the identification of some of the critical points in terms of the two-phonon dispersion relation in the [110] direction (adapted from Bilz, 1966).

4.1 Raman Scattering

In Raman scattering, a photon of light is scattered inelastically from a crystal, with the change in energy and momentum being taken up in the creation or destruction of one or more phonons. In the case where a single acoustic phonon is involved, the process is termed Brillouin scattering. Raman scattering comes about through the modulation of the frequency-dependent electronic polarizability and hence refractive index by the lattice modes. In first order, the interaction terms take the form $b(\mathbf{q}_i)b^\dagger(\mathbf{q}_f)[a^\dagger(-\mathbf{k}j) + a(\mathbf{k}j)]$. For all practical purposes, the wave vectors $\mathbf{q}_i \approx \mathbf{q}_f \approx 0$ for the incident and scattered photons, and so it is only the near–zone center optical modes, whose frequencies are independent of $\mathbf{k}$ to first order, that are affected.

The spectrum of the inelastically scattered light consists of two sets of lines with frequency shifts

$$\Delta\omega = \omega_i - \omega_f = \pm\omega(\mathbf{k}j), \quad \mathbf{k} \approx 0, \tag{40}$$

where ω_i and ω_f are the incident and scattered photon frequencies. The + sign denotes the *Stokes component*, which corresponds to phonon creation and has intensity proportional to $n(\mathbf{k}j) + 1$, and the − sign denotes the *anti-Stokes component*, which corresponds to phonon destruction and has intensity proportional to $n(\mathbf{k}j)$.

The quadratic dependence of the polarizability on the lattice displacements gives rise to second-order Raman scattering comprising Stokes and anti-Stokes summation and difference bands. In the Stokes summation band, for instance, the scattered intensity is given by (Hayes and Loudon, 1978)

$$\begin{aligned} I(\omega_f) = \sum_{\mathbf{k}jj'} & \frac{B(\mathbf{k}jj')}{\omega(\mathbf{k}j)\omega(-\mathbf{k}j')} \\ & \times \{1 + n(\mathbf{k}j)\}\{1 + n(-\mathbf{k}j')\} \\ & \times \delta(\omega_i - \omega_f - \omega(\mathbf{k}j) - \omega(-\mathbf{k}j')), \end{aligned} \tag{41}$$

where $B(kjj')$ are a set of coupling coefficients. Much the same comments apply here as earlier to two-phonon infrared absorption.

4.2 Brillouin Scattering

Brillouin scattering involves scattering by acoustic modes whose frequencies are proportional to k, and so the frequency shifts depend sensitively on the scattering geometry and incident photon frequency ω_i. Since these shifts are small compared with ω_i, it follows that $|\mathbf{q}_i| \approx |\mathbf{q}_f|$, and momentum conservation implies that $k = 2q_i \sin(\theta/2)$, where θ is the scattering angle (see Fig. 5). By changing θ, the direction of $\mathbf{k}$ can be varied. For each scattering geometry, there are in general three Stokes and three anti-Stokes components with frequency shifts (Reissland, 1973)

$$\Delta\omega = v(\mathbf{k}j)k = \frac{2v(\mathbf{k}j)\eta\omega_i}{c}\sin(\theta/2), \tag{42}$$

where η is the refractive index of the me-

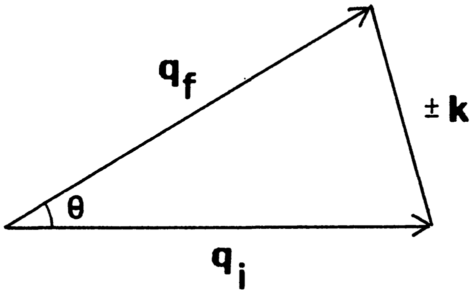

FIG. 5. Momentum-conservation condition for Brillouin scattering.

dium, c is the velocity of light in vacuum, and $v(\mathbf{k}j)$ are the three directionally dependent acoustic phase velocities. These velocities are functions of the bulk elastic constants, and this has led to Brillouin scattering being one of the more important methods for measuring the anisotropic elastic constants of crystals (see Every, 1994a). Such measurements, carried out under variable conditions of temperature and pressure, are a valuable source of information on phase transitions (see, e.g., Dil, 1982; Comins *et al.*, 1990).

There is considerable interest at present in *surface Brillouin scattering* (Nizzoli and Sandercock, 1990). The kinematic conditions are similar to those of He-atom scattering, except that because of the long wavelengths involved, the crystal behaves like an elastic continuum and there are only normal (N) processes to consider. One of the advantages of surface Brillouin scattering is that it can be applied to opaque materials. A drawback of the technique is that because the scattering volume is small, the scattered intensity is weak and sophisticated detection techniques are required.

5. ELECTRON–PHONON INTERACTION

Electrons are an inseparable part of any solid and lie at the very heart of lattice dynamics. They determine the crystal-lattice spacing and contribute in large part to the effective interatomic potential Φ. The problem of the coupled motion of the electrons and the nuclei is made manageable by the fact that the electrons are 2000 or more times less massive than the nuclei, move very fast in comparison, and are by and large able to adjust adiabatically to the instantaneous positions of the nuclei. These ideas are formalized in the *adiabatic* or *Born–Oppenheimer approximation* (see Maradudin, 1974). For many purposes, as we have seen earlier, the contribution of electrons to lattice vibrations can be treated phenomenologically by picturing them in bonds, or rigidly attached to atoms, or in shells that can be displaced relative to ion cores. Our concern in this section is with the more subtle effects that arise from the interaction between phonons and mobile electrons located within $\sim k_B T$ of the Fermi surface in metals and in semiconductors. These interactions come from small residual terms that are neglected in the Born–Oppenheimer approximation. This is a very extensive field, and we will merely touch on some of the many interesting effects that there are.

5.1 Metals

In a perfect metallic crystal, we may as a first approximation consider the electrons to be noninteracting and occupying Bloch states $\psi_{\mathbf{q}\sigma}$, which are characterized by crystal momentum $\hbar\mathbf{q}$ and a band index σ. The electrons are not scattered by the ions in their lattice positions, since the periodic potential of the lattice is already taken into account in constructing the Bloch states. Crystal-lattice vibrations represent departures from perfect periodicity and therefore do cause the electrons to be scattered, and this is the dominant source of temperature-dependent electrical resistance in most metals.

For small displacements of the ions from their equilibrium positions, the change in the potential the electrons experience at any point $\mathbf{x}$ is linear in the displacements. The electron-lattice interaction can thus be expressed as (Ziman, 1965)

$$H_{eL}(\mathbf{x}) = \sum_{\mathbf{k}j} U_{\mathbf{k}j}(\mathbf{x})(a^{\dagger}_{-\mathbf{k}j} + a_{\mathbf{k}j}), \tag{43}$$

where the form of the functions $U_{\mathbf{k}j}(\mathbf{x})$ depends on the specific model being considered, subject to preserving the symmetry of the lattice. In first order of perturbation theory, H_{eL} gives rise to the scattering processes depicted in Figs. 6(a) and 6(b), in which an

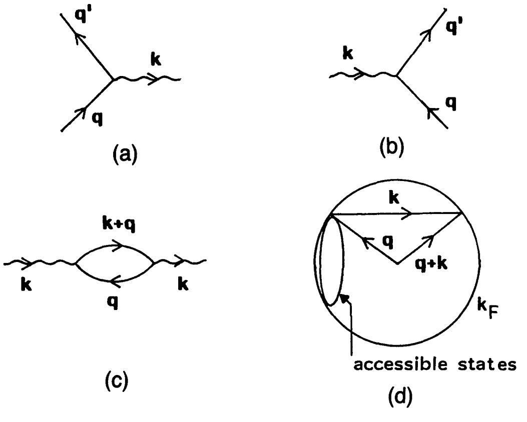

FIG. 6. The electron–phonon interaction in metals.

electron undergoes a transition from one Bloch state $\psi_{\mathbf{q}\sigma}$ to another $\psi_{\mathbf{q}'\sigma'}$, with the simultaneous creation or destruction of a phonon. Conservation of energy and momentum require that

$$E_{\mathbf{q}\sigma} - E_{\mathbf{q}'\sigma'} = \pm\hbar\omega(\mathbf{k}j), \tag{44}$$

$$\Delta(\mathbf{q} - \mathbf{q}' - \mathbf{k}) = 0. \tag{45}$$

The scattering probability is proportional to $n(\mathbf{k}j) + \frac{1}{2} \pm \frac{1}{2}$.

Electron–phonon scattering limits the electron mobility and is responsible for the *ideal electrical resistance* of metals, which at temperatures well below the Debye temperature is proportional to T^5 (Ziman, 1965). Likewise, phonons have greatly reduced mean free paths because of their coupling to the electrons, and so contribute minimally to thermal conduction in metals, and ballistic phonon transport is not observed. At low temperatures, where phonon U processes are rare, the displaced momentum distribution of the electrons associated with an electrical current is communicated to the phonons, so that they too acquire a skewed momentum distribution. This is known as the *phonon drag effect* and is observed as a heat flux in the direction of the current.

In second order of perturbation, H_{eL} leads to a renormalization of the phonon frequencies and electron effective masses. The change in phonon frequencies comes from the type of process depicted in Fig. 6(c), in which the intermediate state is that of the phonon **k** destroyed and an electron scattered from **q** to **q** + **k**. Figure 6(d) depicts these wave vectors in relation to a spherical Fermi surface, near which **q** and **q** + **k** must be located in order to make a significant contribution. Evidently, it is only when k is less than the diameter of the Fermi sphere that there is an effect. A singularity appears in the phonon dispersion relation as k crosses this threshold. The precise form and location of this singularity, which is known as a *Kohn anomaly*, depends on the geometry of the Fermi surface (Ziman, 1965). There may be more than one anomaly in a particular direction in the Brillouin zone, as is the case with the surface-phonon dispersion relation of Pt in Fig. 3.

5.2 Metallic Superconductors

The electron–lattice interaction is the origin of the attractive potential that is responsible for Cooper pair formation and superconductivity in metals. As the first of the two electrons in a *Cooper pair* moves through the lattice, it pulls the positive ions inward, and the second electron is then drawn toward the slightly compacted positively charged region. The net result is an attraction between the two electrons.

The effective interaction between the electrons is characterized by the matrix elements representing scattering of one electron from **q** to **q** − **k**, and a second electron from **q**′ to **q**′ + **k**. The scattering is mediated by the exchange of a *virtual phonon* of wave vector **k**. The process is second order in H_{eL} and involves intermediate states in which one of the electrons is scattered with the creation or destruction of a momentum-conserving phonon. The two processes, which have energy denominators $E_{\mathbf{q}} - E_{\mathbf{q}-\mathbf{k}} \mp \hbar\omega(\mathbf{k})$, are additive, and the resulting scattering matrix element therefore has the form (Ziman, 1965)

$$\begin{aligned}&\langle \mathbf{q} - \mathbf{k}, \mathbf{q}' + \mathbf{k}|V|\mathbf{q}, \mathbf{q}'\rangle \\ &\quad = \frac{|(U_{-\mathbf{k}j})_{\mathbf{q},\mathbf{q}-\mathbf{k}}|^2 2\hbar\omega(\mathbf{k})}{\{E_{\mathbf{q}} - E_{\mathbf{q}-\mathbf{k}}\}^2 - \{\hbar\omega(\mathbf{k})\}^2}.\end{aligned} \tag{46}$$

For

$$|E_{\mathbf{q}} - E_{\mathbf{q}-\mathbf{k}}| < \hbar\omega(\mathbf{k}), \tag{47}$$

the effective interaction is negative, corresponding to an attractive force between the two electrons. The details of how this coupling leads to the formation of an energy gap and superconductivity lie beyond the scope of this article, but certain salient features of superconductivity are already evident in the form of Eq. (46). One is that high electrical resistance in the normal metal and a high superconducting transition temperature T_c go hand in hand, since they both depend on the electron lattice interaction H_{eL} being large. Another is that because of the factor $2\hbar\omega(\mathbf{k})$ in the numerator of Eq. (46), which is proportional to $M^{-1/2}$, where M is the atomic mass,

$$T_c \propto M^{-1/2}. \tag{48}$$

The observation of the dependence of T_c on the isotopic composition has been one of the crucial tests of the Cooper pairing model of superconductivity in metals.

5.3 Semiconductors

The electron–phonon interaction plays an important role in the dynamics of electrons and holes in semiconductors. At low temperatures and in the absence of external excitation, it is the coupling to long-wavelength acoustic modes that is most important, and this is usually modeled by the *deformation potential* (see, e.g., Challis *et al.*, 1987). To illustrate the basic idea, let us consider electrons in a conduction band that has an energy minimum at $\mathbf{q} = 0$. For small lattice displacements, the band is assumed to be shifted vertically in proportion to the lattice dilatation $\Delta = \Sigma_\alpha \, \partial u_\alpha / \partial x_\alpha$, while the band curvature, which determines the electron effective mass m^*, is unaffected to first order. The electron–lattice interaction is thus given by

$$
\begin{aligned}
H_{eL}(\mathbf{x}) = \Xi\Delta = \Xi \sum_{\mathbf{k}j} i\mathbf{k}\cdot\mathbf{e}(\mathbf{k}j) \\
\times \sqrt{\frac{\hbar}{2NM\omega(\mathbf{k}j)}}\, e^{i\mathbf{k}\cdot\mathbf{x}} \\
\times [a^\dagger(-\mathbf{k}j) + a(\mathbf{k}j)], \qquad (49)
\end{aligned}
$$

where Ξ is the deformation-potential constant.

As in the case of metals, H_{eL} gives rise to electron scattering with the creation or annihilation of a phonon. This limits the carrier mobility and is a determining factor in the electrical resistance. There has been considerable work done at low temperatures on phonon emission and absorption and phonon drag by two-dimensional electron gases (2DEGs) in the inversion layer of Si MOSFETs, in GaAlAs heterostructures, and elsewhere (Challis *et al.*, 1987). The converse of phonon drag, known as the *phonon wind effect*, has been very beautifully demonstrated in germanium (Markiewicz *et al.*, 1980). Under intense optical excitation at low temperatures, a condensed state of electrons and holes known as electron-hole liquid is formed. Droplets of this liquid are propelled into the crystal by the capture of momentum from phonons generated in the region of excitation, and this motion is revealed by the spreading recombination luminescence (for a review, see Keldysh and Sibeldin, 1986).

Interband optical absorption in semiconductors involves predominantly direct or "vertical" transitions, in which the wave vector of the electron is unchanged. *Indirect band-gap transitions* take place with much lower probability, and do so because of the slight mixing of different electron–phonon product states of the same total momentum by H_{eL}. Conservation of momentum requires that a transition involving a change in electron momentum by $\hbar\mathbf{q}$ is accompanied by the creation or annihilation of a phonon of momentum $-\hbar\mathbf{q}$ or $\hbar\mathbf{q}$ respectively (Ziman, 1965). The optical absorptivity near an indirect band-gap threshold is thus much weaker than for direct band-gap transitions, and the lifetime of carriers against radiative recombination is much larger.

5.4 Insulators

In polar insulators such as the alkali halides, the effective mass of conduction electrons is increased by the electron–lattice interaction by as much as a factor of 2 or more (Kittel, 1986). An electron pulls the nearby positive ions toward itself while pushing the negative ions away, and this adds to the inertia of the electron, thereby increasing its effective mass. The combination of the electron and ion displacements is known as a *polaron*.

6. PHONON–DEFECT INTERACTIONS

Lattice imperfections such as vacancies, interstitial and substitutional impurities, isotopic differences, dislocations, and grain boundaries, etc., have a marked effect on the vibrational properties of crystals. They destroy the translational symmetry of the lattice, thereby giving rise to momentum-nonconserving phonon scattering, defect-activated infrared absorption, and various other phenomena. They modify the local dynamical response of the lattice, resulting under certain conditions in the appearance of in-band resonances or local vibrational modes. Local electronic and spin states couple to the vibrations of nearby atoms, allowing an exchange of energy between these states and the phonons. This gives rise to *energy relaxation* to the phonon bath and provides a mechanism for doing *phonon spectroscopy* on defects. When the coupling is strong, the local electronic and vibrational states need to be considered as a composite system of *vibronic states*, and optical transitions occur in which the electronic and vibrational states simultaneously change. An extensive review covering most of these topics is Maradudin (1966).

6.1 Local Modes

The vibrational properties of crystal lattices containing defects are usually treated by the *dynamical response-function* approach (Maradudin, 1966; Elliott, 1966). The method involves expressing the dynamical response of the defective crystal in terms of the response of the perfect crystal and the local modification to the dynamical matrix brought about by the presence of the defect, thus obviating the need to determine from scratch the eigenvalues and eigenvectors of $3rN$ coupled oscillators.

The method can be illustrated in a simple way with the example of an isotopic defect. Consider an otherwise perfect silicon crystal in which the atom at the origin is replaced by one of a different mass without altering any of the force constants. For the unperturbed crystal, the dynamical response of the silicon atom to a sinusoidal force $\exp(i\omega t)$ is given by

$$G_0(\omega) = \frac{1}{6NM}\sum_{\mathbf{k}j}\left\{\frac{1}{\omega^2(\mathbf{k}j) - \omega^2} + \frac{i\pi}{2\omega(\mathbf{k}j)}\delta(\omega - \omega(\mathbf{k}j))\right\}, \quad \omega > 0. \tag{50}$$

The terms in the sum represent the real and imaginary parts of the response function of an individual harmonic oscillator, and the factor $1/6\,NM$ comes from projecting the force acting on the atom in question onto each normal coordinate of the lattice, and then projecting the displacement response of that mode back onto that atomic coordinate. More generally, there would be a factor of the form $e_\alpha^*(\kappa|\mathbf{k}j)e_\beta(\kappa'|\mathbf{k}j)$ inside the sum, but this comes out to be equal to $\frac{1}{6}$ because of the symmetry of the Si lattice.

If the atom at the origin is now replaced by one of different mass $M + \delta M$, then the applied force has the additional inertia of δM to contend with, and it is readily shown that the perturbed lattice response function is given by (Elliott, 1966)

$$G(\omega) = \frac{G_0(\omega)}{1 - \delta M\omega^2 G_0(\omega)}. \tag{51}$$

Force-constant changes can be handled in a similar way. If the impurity is charged, it will give rise to one-phonon infrared absorption proportional to $\omega Im(G(\omega))$. For $\delta M = 0$, it follows from Eqs. (50) and (51) that the absorptivity is proportional to the lattice frequency distribution function $D(\omega)$. For $\delta M \neq 0$, the absorption still extends over the entire band of frequencies of the perfect lattice but is modified in intensity. In the case of a light impurity for which $\delta M < 0$, there may in addition be absorption outside the perfect-lattice spectrum at a discrete frequency ω satisfying (Elliott, 1966)

$$1 - \delta M\omega^2 G_0(\omega) = 0. \tag{52}$$

This corresponds to a local mode in which the displacement is mainly confined to the impurity atom and its first few shells of neighbors. Conversely, for a heavy impurity there may be an in-band resonance. These resonances feature in infrared absorption and also in the resonant scattering of bulk phonons. Figure 7 shows calculated infrared absorption spectra for various substitutional

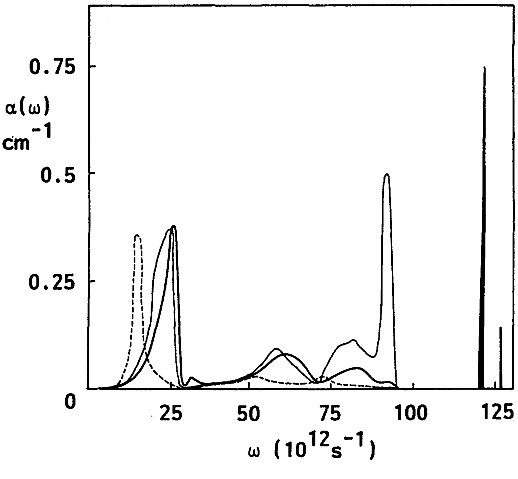

FIG. 7. Calculated infrared absorption spectra for substitutional boron and antimony in silicon (adapted from Elliott, 1966).

impurities in silicon. The full curves are for ^{10}B and ^{11}B in their natural abundances, which are lighter than the host lattice Si atom and give rise to the local modes above 10^{14} s^{-1}. The dashed curve is for Sb, which is heavier than Si and gives rise to the low-lying *in-band resonance* at $\sim 15 \times 10^{12}$ s^{-1}. Quantities such as correlation functions and mean square displacements, etc., are readily calculated once the modified response functions are known. For long-wavelength bulk acoustic modes well below any resonance, the scattering rate from point defects is proportional to $1/\lambda^4$, in accordance with the *Rayleigh scattering* law.

6.2 Electronic States

Electronic states localized at a defect are perturbed by the motion of neighboring atoms, and this provides a mechanism for the exchange of energy. In the case where the electronic energy level splitting lies within the band of vibrational frequencies, transitions can occur with the emission or absorption of a single phonon. The Cr^{3+} laser impurity center in ruby is a case in point that has a transition at 29 cm^{-1} between two excited states (see Renk, 1986; Kaplyanskii and Basun, 1986). By means of optical pumping into the upper of the two excited states and subsequent phonon emission, very high occupation numbers for 29-cm^{-1} phonons can be achieved, leading to *stimulated phonon emission*. The coupling also gives rise to the resonant scattering and *trapping* of 29-cm^{-1} phonons.

The effect of coupling between the localized electronic states and phonons is also seen in the optical absorption and fluorescence spectra of crystals. A grossly oversimplified model, which nevertheless conveys some of the essential features, is to assume that there is a single lattice mode of frequency ω_0 that is linearly coupled to the electronic states. The equilibrium positions about which the oscillations occur in the ground and excited electronic states are thus displaced relative to one another, by ΔQ, say. There are now a multitude of transitions possible, determined by the matrix of overlap integrals between the two sets of oscillator states, in which the optical and vibrational states simultaneously change. At $T = 0$, the probability of a transition occurring in which p phonons are created is proportional to (Fitchen, 1968)

$$W_p = e^{-S_0} S_0^p/p!, \tag{53}$$

where

$$S_0 = M\omega_0(\Delta Q)^2/2\hbar. \tag{54}$$

The $p = 0$ transition is called the *zero-phonon line*, and it remains sharp even when a band of coupled modes rather than a single mode is considered and the temperature is finite, whereas the $p > 0$ transitions are broadened. The temperature dependence of the zero-phonon line intensity is dominated by a Debye–Waller factor $\sim\exp(-S_0 \coth[\hbar\omega_0/2k_BT])$, known as the *Huang–Rhys factor*. Many such *vibronic spectra* have been observed in solids (see Fitchen, 1968; Maradudin, 1966).

In fluorescence, the mirror-image spectrum is observed, with p phonons being created, and the remaining energy being carried away by the photon. Figure 8 shows the absorption and emission spectra of the 4150-Å system in diamond, which is associated with a nitrogen impurity complex (Dyer and Matthews, 1957). *Nonradiative transitions* in which all the excitation energy is dumped as phonons occur at an increasing rate as the temperature is raised, thereby decreasing the luminescence efficiency.

6.3 Spin-Lattice Relaxation

Relaxation processes play an important role in paramagnetic resonance. A nuclear or unpaired electron spin belonging to an atom

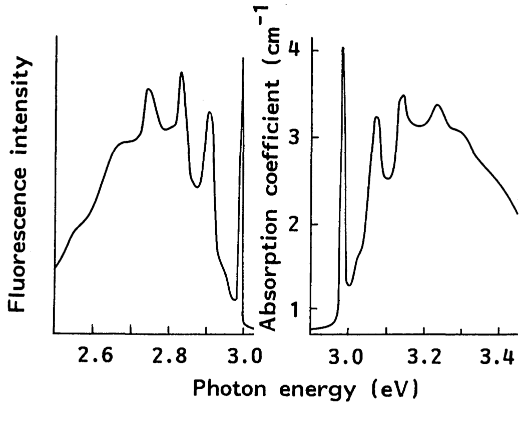

FIG. 8. The fluorescence and absorption spectra of the 4150-Å system in diamond (adapted from Dyer and Matthews, 1957).

in a crystal can exist in various states whose level splittings depend on the crystal field and the external magnetic field. A microwave or radio-frequency field is used to excite the spin system, and various relaxation processes then come into play to return the spin population to equilibrium. Of the many different relaxation processes that there are, we only discuss two that have a direct bearing on phonons.

An important relaxation process for isolated paramagnetic spins in the case where the level splitting is fairly large (which by and large excludes nuclear paramagnetism) is single-phonon emission into long-wavelength acoustic modes (Stevens, 1967). The parameters of the spin Hamiltonian depend on the precise location of the neighboring atoms around the paramagnetic atom and are thus functions of the strain field accompanying acoustic waves in the medium. The linear coupling to the strain yields a spin-lattice interaction Hamiltonian H_{SL} of the form

$$H_{SL} = \sum_{\mathbf{k}j} H_{\mathbf{k}j}(\mathbf{S})|\mathbf{k}| \sqrt{\frac{\hbar}{2NM\omega(\mathbf{k}j)}} \times [a^\dagger(-\mathbf{k}j) + a(\mathbf{k}j)], \tag{55}$$

where $H_{\mathbf{k}j}(\mathbf{S})$ is a spin operator. In first order of perturbation theory, the transition probability p between two spin levels separated in energy by $E = \hbar\omega_0$ is proportional to $D(\omega_0)\bar{n}(\omega_0)\,|\mathbf{k}|^2/\omega_0$. For $k_B T \gg \hbar\omega_0$, it follows that $p \propto \omega_0^2 T$.

If the rate at which phonons are pumped into the narrow band of frequencies around ω_0 exceeds the ability of the lattice to thermalize them, then there is a *phonon bottleneck* effect, in which repeatedly the phonons emitted by one paramagnetic spin are absorbed by another (Stevens, 1967).

For nuclear spins, where ω_0 tends to be relatively small, the number of lattice modes in that frequency region is very small, and the direct relaxation rate is extremely slow. Under these conditions, Raman processes, in which a phonon is absorbed and another of slightly higher frequency emitted, become important. The coupling for this process comes from the quadratic dependence of the spin Hamiltonian on the local strain. All phonons from $\omega = 0$ to $\omega \sim k_B T/\hbar$ contribute, and for $T \ll \Theta_D$ the relaxation rate is independent of the splitting and has a temperature dependence $p \propto T^7$.

6.4 Mössbauer Effect

The Mössbauer effect can be thought of as the nuclear analog of vibronic spectra, in which it is the nucleus rather than the electrons of the atom that undergoes a transition, and the photon that is absorbed or emitted is that of a γ ray rather than of visible light. Corresponding to the zero-phonon line there is a certain fraction of the γ rays that are emitted recoil-free, i.e., without any energy being absorbed by the vibrations of the lattice. The recoil momentum from these γ photons is taken up by the crystal as a whole, and because the crystal is so massive, the associated kinetic energy is totally negligible. The *recoil-free fraction* is given by the Debye–Waller factor (Maradudin, 1966)

$$f = \exp - \langle [\mathbf{K} \cdot \mathbf{u}(l\kappa)]^2 \rangle, \tag{56}$$

where K is the wave vector of the γ ray and $\mathbf{u}(l\kappa)$ is the displacement coordinate of the resonant nucleus. With increasing temperature, as the mean square displacement of the atom increases, f decreases. At higher temperatures, anharmonicity plays an important role in this temperature dependence (Kolk, 1984). There has been considerable theoretical speculation concerning the single- and multi-phonon sidebands, which has greatly outstripped the technical means for measuring them. Part of the problem is that to measure directly a phonon energy shift of ~0.01 eV in a ~10 keV γ ray requires the velocity of the moving stage to be $\sim 10^{-6}c = 300$ m/s.

7. CLOSING REMARKS

This article has mainly concentrated on the interaction between phonons and other "-ons", the physical properties that these interactions impart to crystals, and how the scattering of x rays, neutrons, and other probes can be used to determine phonon dispersion relations. In an article of this nature, it is not possible to give complete coverage to the whole of phonon physics. There has in particular been very little discussion here of phonon transport, which is covered extensively in the articles LV and HP. The first of these two articles contains an extensive discussion of the interplay between boundary scattering, defect scattering, and anharmonic processes in limiting thermal conduction in dielectric crystals. The latter article contains a lot of recent material on *ballistic phonon transport* and its investigation by means of *phonon imaging*. This has shed light on various phenomena, including phonon transmission through surfaces, the scattering of phonons by dislocations, and electron–phonon scattering in semiconductors (for reviews on phonon imaging, see Wolfe, 1989; Every, 1994b). HP also discusses second sound, which is a collective mode of the phonon gas that comes about when *N* processes dominate over *U* and other momentum-nonconserving scattering processes.

A development that is attracting considerable attention at the present time is that of *phonon-mediated elementary-particle detection* (for a review, see Cabrera, 1990). This offers the possibility of much greater energy resolution than can be achieved by other available means, and the prospect of being able to detect the hypothetical particles that are invoked as an explanation of the missing dark matter in our galaxy. While much progress has been made, the technical difficulties are formidable, and the final word on this subject is some way off.

INTRODUCTION

An optical communications system requires both a source—laser or light-emitting diode (LED)—and a receiver—a photodetector. Historically, photomultiplier tubes and vacuum photodiodes were available as receivers, but smaller, less expensive, wide-bandwidth semiconductor devices are now widely used. The gas-filled tube devices are limited in bandwidth to around 10 kHz (Melchoir, 1972), and in the case of the vacuum photodiode to relatively high minimum detectable optical powers. The wavelength range over which a device functions is determined by its material structure. Choice of a photodetector is governed by the operating wavelengths of the system, the response to these wavelengths, the speed or frequency response requirements, and the dark current or noise performance of the device.

This article discusses the basic operation of a photodetector, the parameters commonly used for its characterization, semiconductor material systems, design and fabrication techniques for different types of photodetectors, and applications in optical receivers. This first section concentrates on basic photodetector physics. Section 2 covers semiconductor material choices and the properties of photodetectors that need to be characterized to understand their operation. Section 3 focuses on the operation of different types of photodetector devices, the semiconductor fabrication techniques for producing them, and high–speed-device trends. Finally, Sec. 4 examines applications for photodetectors in optical receivers.

1. PHYSICS OF PHOTODETECTORS

The function of a photodetector is to convert incoming modulated light energy into modulated electrical current. Light incident on a semiconductor photodetector is absorbed, and if the photon energy is greater than the band-gap energy, electron–hole pairs

---

are generated. These carriers, created in a region of high electric field within the depletion region of the device, are swept out by an applied reverse bias resulting in a photocurrent.

In photomultipliers, vacuum photodetectors, and phototubes, electrons are excited by photons over the energy barrier, or work function, of the material and become free electrons in a process called the external photoeffect (Melchoir, 1972). Semiconductor photodiodes operate on a principle known as the internal photoeffect, where the electrons and holes excited by the photon to higher energy levels remain within the material and contribute to photocurrent. The incident photon absorbed by the semiconductor generates a free electron, which is excited from the valence to the conduction band while a hole is generated in the valence band. The carriers created in the depletion region drift in opposite directions as they are separated by the electric field, and carriers created within a diffusion length of the depletion region diffuse to the edges of the region and are collected. Under reverse bias, the carriers' drift in the electric field induces a photocurrent in the load, R_L. The photocurrent is given by

$$I_P = \frac{P_0 q(1 - r')}{h\nu}(1 - e^{-\alpha d}), \qquad (1)$$

where P_0 is the incident optical power, q is the electrical charge, r' is the Fresnel reflection at the semiconductor–air interface, $h\nu$ is the photon energy, α is the absorption coefficient of the material, and d is the width of the depletion layer.

Figure 1 illustrates a photon incident on a double-heterojunction *p-i-n* photodiode. The photon passes through the larger–band-gap cap material, shown here as *p* type, and is absorbed in the active layer, the *i* region, below, creating the electron–hole pair. As reverse bias is applied, the electron moves toward the *n* side of the device (cathode) and the hole toward the *p* side (anode), creating a photocurrent.

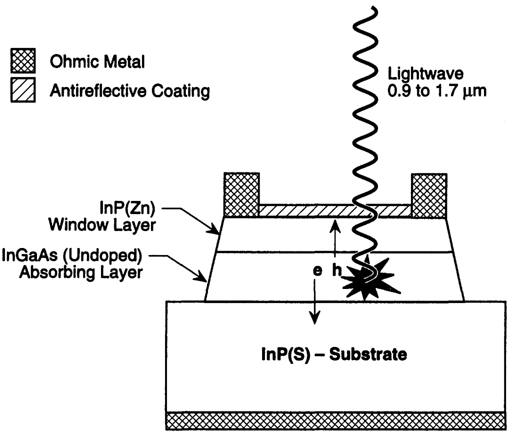

FIG. 1. A cross-sectional view of a *p-i-n* double-heterojunction photodiode illustrating the absorption of the photon, the creation of the electron–hole pair, and their respective motion under influence of the electric field (Sloan, 1989).

2. MATERIALS, DESIGN, AND PROPERTIES OF PHOTODETECTORS

2.1 Semiconductor Material Systems

The photodetector properties are strongly influenced by the choice of the semiconductor material system. For the device active layer, the material band gap is chosen to absorb photons in the wavelength range of interest. Figure 2 illustrates properties of various materials used for optical devices. The left vertical scale shows the energy gap or band gap E_g of materials, in electron volts (eV), the horizontal axis gives lattice constant values in ångströms, and the right vertical scale shows the usable wavelength range in microns. For example, the telecommunications market wavelengths of 1.3 and 1.55 μm can be detected by Ge or InGaAs active-region photodetectors. When InGaAs active regions are used, the III-V material InGaAs is lattice matched to InP substrate material by using 53% In and 47% Ga as the group III element, and As as the group V element, written as $In_{0.53}Ga_{0.47}As$. Germanium is also used for the telecommunications wavelengths, but its response to longer wavelengths, beyond 1500 nm, drops off sharply whereas the curve of response vs wavelength for InGaAs extends to 1700 nm.

The maximum wavelength for which a material will absorb is determined by its band-gap energy—the energy gap between the bottom of the conduction band and the top of the valence band. For wavelengths

$$\lambda_0 > hc/E_g, \qquad (2)$$

the material will not absorb, but becomes transparent. The light absorption is depen-

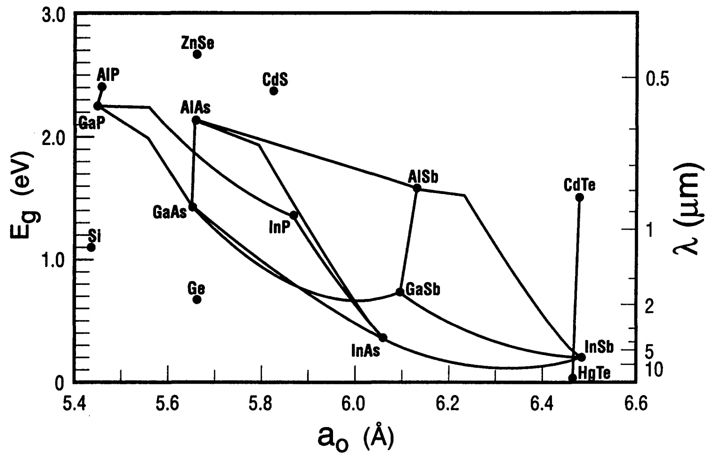

FIG. 2. Common optical-device materials showing their energy band gaps in eV along the left vertical scale, the lattice constants on the horizontal axis, and the usable wavelength range in microns along the right vertical axis. Compositions of the tertiary and quaternary III-V materials may be changed in order to change their detection range as shown by the curves joining the single-III/single-V element compounds (Manasreh, 1993).

dent upon the material absorption coefficient α. In direct–band-gap materials, transitions can occur between the conduction-band minimum and the valence-band maximum with the same wave vector. Indirect materials, where the conduction-band minimum is not at the same value of the wave vector as the valence-band maximum, require a phonon to conserve momentum in addition to the photon of energy $>E_g$. The direct transitions are more probable. The active layer must be thick enough, on the order of $1/\alpha$ (Lucovsky *et al.*, 1964), to absorb the light and create electron–hole pairs. The short-wavelength response cuts off because the absorption coefficient becomes very large at shorter wavelengths; thus absorption occurs near the surface and recombination time is short, and the carriers recombine before they are collected (Sze, 1981).

2.2 Properties of Photodetectors

This section describes important test parameters for photodetectors. A detector's operation is characterized by the wavelength range over which it operates, the response to these wavelengths, the speed of the response, and its noise performance. Low dark current for devices operated under reverse bias and high dynamic resistance for devices operated at zero bias are important for low noise in a receiver system. This section examines sources of noise in photodetectors. For the greatest signal-to-noise performance, responsivity or quantum efficiency should be maximized and reflections minimized. Capacitance, series resistance, and active-layer thicknesses are important considerations for determining the speed of response of the detector.

2.2.1 Dark Current Under reverse bias, the leakage current present in the device in the absence of illumination is referred to as dark current. Low dark current is important for low-noise performance of photodetectors in optical receivers. Dark current of the photodetector is given by the following equation:

$$I_d = I_{d\text{-}G\text{-}R} + I_{d\text{-diffusion}} + I_{d\text{-surface}}, \qquad (3)$$

where $I_{d\text{-}G\text{-}R}$ is the dark current resulting from generation and recombination of carriers, $I_{d\text{-diffusion}}$ results from carrier diffusion, and $I_{d\text{-surface}}$ is dark current contributed by surface leakage (Muller, 1981). By testing devices of various sizes, the dominant dark-current mechanism can be determined for a particular device. A current proportional to the circumference of the device, $I_d \propto r$, where r is the radius of the device (assumed to be round), indicates that surface leakage is dominant; current proportional to the area, $I_d \propto r^2$, is indicative of bulk leakage mechanisms (Carey *et al.*, 1989).

Dark-current measurements are performed by probing or making other electrical connection to the device and applying bias voltage while keeping the device in the dark. Mesa-etched devices, where the active area is defined by removing the surrounding epitaxial material and the *p-n* junction is exposed (such as the InGaAs *p-i-n* structure shown in Fig. 11), typically are dominated by surface leakage. Dark currents in diffused-junction diodes are more likely due to bulk currents.

The following equations describe the dark-current terms in more detail (Forrest *et al.*, 1980; Sze, 1981). The generation-recombination current is given by

$$I_{d\text{-}G\text{-}R} = \frac{qn_iAd}{\tau_{\text{eff}}}\left[1 - \exp\left(\frac{-qV_r}{2kT}\right)\right], \tag{4}$$

where q is the charge, A is the photodetector area, d is the width of the depletion region, τ_{eff} is the effective generation-recombination lifetime, V_r is the applied reverse bias, k is Boltzmann's constant, T is the temperature in kelvins, and n_i, the intrinsic carrier concentration, is given by

$$n_i = 2\left(\frac{4\pi^2 m_e m_h k^2}{h^4}\right)^{3/4} T^{3/2} \exp\left[-\frac{E_g}{2kT}\right], \tag{5}$$

where m_e and m_h are the effective masses of the electron and holes, respectively, and h is Planck's constant. The diffusion current is given by

$$I_{d\text{-diffusion}} = \frac{qn_i^2(D_n/\tau_m)^{1/2}A}{N_a}\left[1 - \exp\left(\frac{-qV_r}{kt}\right)\right], \tag{6}$$

where the additional terms in this equation are D_n, the minority-carrier diffusion constant, τ_m, the minority-carrier lifetime, and N_a, the acceptor concentration. When the photodetector is operated under a reverse bias, the temperature dependence of the generation-recombination and diffusion currents is dominated by the n_i terms. That means that

$$I_{d\text{-}G\text{-}R} \propto \exp[-E_g/2kT] \tag{7}$$

and

$$I_{d\text{-diffusion}} \propto \exp[-E_g/kT]. \tag{8}$$

Plots of the logarithm of the dark current vs $1/T$ in kelvins show that the surface leakage-current behavior is due to generation currents believed to be due to traps near the mesa edge (Carey *et al.*, 1989; Forrest *et al.*, 1980).

2.2.2 Photocurrent A photodiode is generally operated under reverse bias in order to increase the width of the depletion region, thereby lowering the capacitance, and making a stronger electric field to increase the drift velocity of the electrons and holes and minimize the carrier transit time (Saleh and Teich, 1991). The photocurrent produced, I_p, is given by

$$I_p = \frac{P_0q(1 - r')}{h\nu}(1 - e^{-\alpha d}) = \eta q\frac{P_0}{h\nu}, \tag{9}$$

where η is the quantum efficiency discussed in Sec. 2.2.5. The current–voltage (I-V) characteristic for a photodiode is given by

$$I = I_d\left[\exp\left(\frac{eV_0}{n_0kT}\right) - 1\right] - I_p, \tag{10}$$

including the photocurrent portion I_p, and the normal diode diffusion current discovered by Shockley (1949) where I_d is the dark current, n_0 is the diode ideality factor (Sze, 1981)

$$n_0 \equiv \frac{q}{kT}\frac{\partial V}{\partial(\ln I)}, \tag{11}$$

and V_0 is the junction voltage (Lee and Li, 1979).

2.2.3 Dynamic Resistance For photodetectors operated at 0 V bias, the parameter of interest becomes the dynamic resistance, sometimes called shunt resistance, instead of dark current. The zero bias allows for low-noise receiver designs because little or no dark current is present. Dynamic resistance R_d is measured by examining the I-V curve of a device and taking the slope of the curve ($\Delta V/\Delta I$) around the zero-volt region. R_d is controlled by the steepness of the forward voltage characteristic of the diode vs current and the reverse leakage current of the device. For the case of only thermal (Johnson) noise,

$$\langle i_t^2\rangle = 4kTB/R_d, \tag{12}$$

where i_t is the thermal noise current and B is the bandwidth of the measurement. For low-noise operation, R_d should be maximized. Typical dynamic resistance values for 500-μm–active-area InGaAs *p-i-n* photodiodes are ~100 MΩ.

2.2.4 Capacitance Measuring a photodetector's capacitance vs voltage is a way to look at the degree to which the active region of the device is depleted of carriers. For a photodiode, the junction capacitance is given by

$$C = A\left[\frac{2}{q\epsilon}(\Phi + V_a)\left(\frac{1}{N_a} + \frac{1}{N_d}\right)\right]^{-1/2} = \frac{\epsilon A}{d} \tag{13}$$

(Lee and Li, 1979), where A is the junction area, q is the charge, ϵ is the dielectric constant of the i-layer material, Φ is the built-in voltage, V_a is the applied voltage, N_a and N_d are the acceptor and donor concentrations, respectively, and d is the width of the depletion region. Capacitance can be reduced by lowering the doping in the i layer or by increasing the applied voltage. Minimizing capacitance for a *p-i-n* photodetector means minimizing device active area and using a thick, low-doped i layer. The RC time constant of the device, series resistance times capacitance, is key in determining the frequency response of the device. This must be traded off against the increased carrier transit time due to a thicker i layer.

2.2.5 Responsivity and Quantum Efficiency Responsivity is a measure of photodetector sensitivity to incoming light energy. To be most efficient, the photodetector should turn as many of the incoming photons as possible into detectable photocurrent. Responsivity is measured by illuminating the device with a known optical power at a known wavelength, and measuring the magnitude of the resulting photocurrent at a particular bias value; the units are amperes/watt.

The thickness of the *p-i-n* device i layer determines the response. If the i layer is not thick enough to absorb the incoming photons, the response will be less than the maximum calculated value. The absorption coefficient is given as a function of wavelength. For InGaAs at the wavelengths of 1.06 and 1.3 μm, the absorption coefficients are $\alpha(1.06\ \mu\text{m}) = 1.8\ \mu\text{m}^{-1}$ and $\alpha(1.3\ \mu\text{m}) = 1.15\ \mu\text{m}^{-1}$. At a thickness of $1/\alpha$, the light intensity falls to $1/e$ of the original value. The fraction of power absorbed in a depth d is given by

$$P_{\text{abs}} = P_0[1 - \exp(-\alpha d)]. \tag{14}$$

The photon energy must be greater than the semiconductor band gap in order for absorption to occur and carriers contributing to photocurrent to be produced.

The number of electron–hole pairs created by a single incident photon is called the quantum efficiency,

$$\eta = (I_p/q)(h\nu/P_0), \tag{15}$$

where I_p is the photocurrent, q is the magnitude of the charge on a carrier, and P_0 is the optical power at the wavelength corresponding to the photon energy given by $h\nu$. Some authors and manufacturers quote responsivity values while others quote quantum efficiency as the measure of the device optical sensitivity. Quantum efficiency is related to responsivity R by

$$\eta = \frac{1}{q}\frac{hc}{\lambda}R = \frac{1.24}{\lambda}R. \tag{16}$$

By definition, the maximum value of η is 1. Maximum response values for a particular wavelength may be found by setting $\eta = 1$ and finding R.

Responsivity or quantum efficiency vs wavelength is measured using a spectrometer and large–wavelength-range sources. The power is monitored by using an optical coupler to sample a portion of the light energy, which is incident on a power meter. The photocurrent from the photodetector is measured and recorded at each wavelength. The resulting plot for two different InGaAs devices is shown in Fig. 3. One is a conventional *p-i-n* with an InP cap layer, and one has been modified to extend its range to shorter wavelengths. Here, the response was measured from 600 to 1700 nm. Figure 4 shows responses for a variety of material systems (Melchoir, 1972; Sze, 1981) allowing the receiver designer to select the material appropriate for her application. Maximizing response in a receiver system is a way of achieving high signal-to-noise performance.

2.2.6 Reflectivity If the surface of the photodetector is highly reflective, a large part of the incoming light will not be absorbed and not result in the creation of electron–hole pairs, or photocurrent. This will limit the device responsivity. The reflected light may also be coupled back into the light source, perturbing it. This is highly undesirable for laser sources. To prevent this, an antireflective

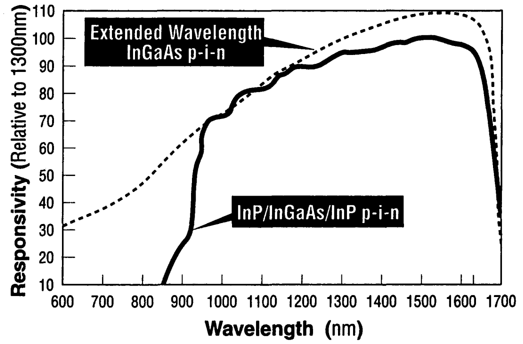

FIG. 3. Plot of dc responsivity vs wavelength for two InGaAs devices. The solid line illustrates a standard InP/InGaAs/InP response, and the dashed line shows an extended-wavelength InGaAs device. Both are used for the long telecommunications wavelengths (measurements courtesy of Mike McClendon and Norm Brewer, Hewlett-Packard Lightwave Operation Standards Lab).

coating is applied to the device surface. The goal is to minimize the percentage of optical power reflected or maximize the optical return loss (ORL). Reflection is measured as a percentage of incident light reflected or in optical receivers as the figure of merit optical return loss (ORL), which is in units of dB and is given by

$$\mathrm{ORL} = 10 \log(P_0/P_r), \tag{17}$$

where P_0 is the incident power and P_r is the reflected power. With no coating, a semiconductor surface reflects about 30% of the light that is incident upon it.

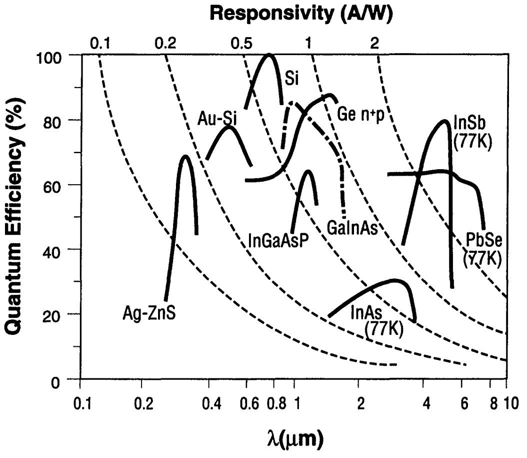

FIG. 4. Response curves for various detector materials (Sze, 1981).

Antireflective coatings are usually made of dielectric materials deposited on the surface of the device. To first approximation, a quarter wavelength of dielectric material is deposited. A plot of the modeled power reflected vs wavelength is shown in Fig. 5 for a single-layer antireflection coating of silicon nitride on an InP/InGaAs/InP photodetector. If optimized for InP/InGaAs/InP devices, dielectric coatings can lower the reflected light to on the order of 0.5% at 1300 and 1550 nm (Braun, 1988). To improve the coating further, multiple layers are used. To prevent the reflected light from the detector from coupling back to the laser source, the device is usually tilted. A 6- to 8-degree angle of the device relative to the normal will prevent light from being coupled back into an optical single-mode fiber from the device.

2.2.7 Response Time Photodetector response time is governed by the transit time of carriers in the active region and the *RC* time constant of the device. The carrier transit time is the distance the carriers travel across the *i* layer divided by the velocity at which the carriers travel. Both electrons and holes are present, and each has a saturation velocity at which it travels:

$$t = d/v_{sat}. \tag{18}$$

To maximize the speed of response, the transit time needs to be minimized. This means making the active layer thin. By making the active region thin, the capacitance of the de-

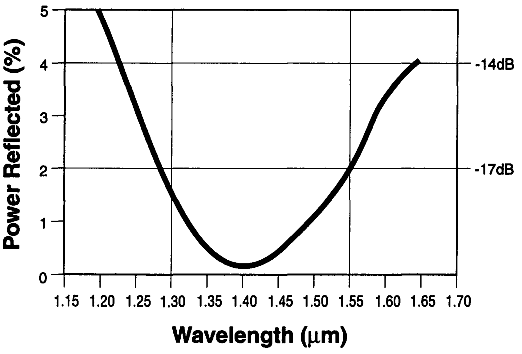

FIG. 5. Reflection vs wavelength characteristic for modeled single-layer antireflection coating for the telecommunications wavelength range (Beck, 1993).

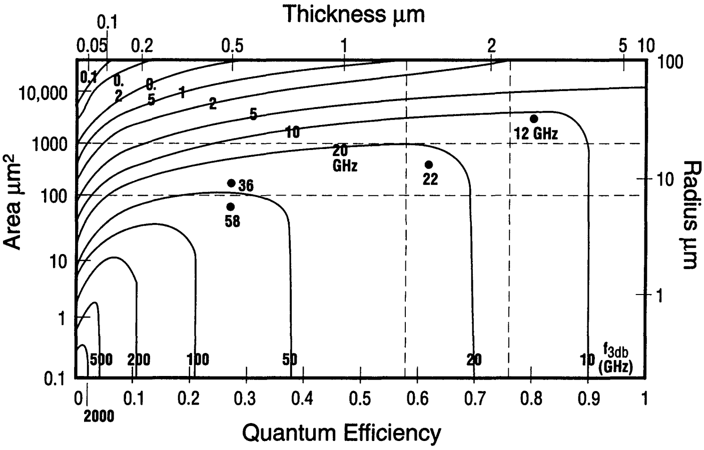

FIG. 6. Frequency-response contours vs active-area diameter, active area, and quantum efficiency (Bowers *et al.*, 1986a).

vice is increased and the quantum efficiency of the device is decreased. The increasing capacitance causes the *RC* time constant to rise and the speed is slowed. Tradeoffs must be made between transit time and *RC* considerations in order to optimize the photodetector speed of response. These tradeoffs have been modeled for InP/InGaAs/InP p-i-n devices and are plotted in Fig. 6 (Bowers *et al.*, 1986) where the device area, *i*-layer thickness, and active-area diameter are examined and frequency contours are established.

2.2.8 Noise Low-noise performance is important for photoreceivers where low power levels need to be detected. The minimum detectable optical signal is determined by the photodetector quantum efficiency and the noise sources present in the receiver. Sources of noise in photodetectors include shot noise and thermal or Johnson noise. Shot noise consists of noise due to dark current, surface leakage current, and quantum effects (Lee and Li, 1979). Assuming dark current and surface leakage are negligible by design, shot noise is due to the fluctuations in the photoexcitation of carriers. It is present whenever current is flowing, as a result of fluctuations in the arrival rate of electrons which in turn lead to random changes in the current flow (Wilson and Hawkes, 1989). This is the lowest noise achievable in the system. For devices with gain such as avalanche photodetectors (APDs), excess shot noise exists due to the multiplication process. Thermal noise from the load resistor in a receiver limits noise in a device without internal gain.

A simple model of a photodetector receiver is shown in Fig. 7. The photodiode is modeled as a current source with a small series resistance R_s due to the resistance of the *p* contacting layer and the metal–semiconductor resistance, a junction capacitance C_j, and a load resistance R_L. The amplifier capacitance and resistance are labeled as C_a and R_a respectively. When a time-varying optical power is incident, the resulting photocurrent is

$$i_{ph}(t) = \eta q p(t)/h\nu, \tag{19}$$

where η is the quantum efficiency, q the electrical charge, and $p(t)$ the modulated incident power, and $h\nu$ is Planck's constant times the frequency (Lee and Li, 1979). The term $i_{ph}(t)$ has a dc component

$$I_p = \eta q P_0/h\nu \tag{20}$$

(Sze, 1981), and a time-varying current, or signal component, i_p. For a device with gain,

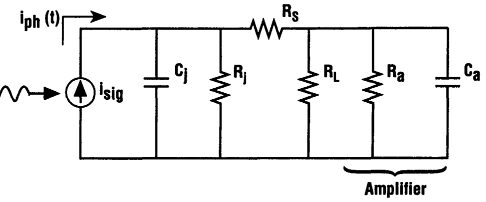

FIG. 7. Model of a photodetector as a current source with a junction resistance, junction capacitance, series resistance, resistance due to the load, R_L, and the resistance and capacitance due to the amplifier following the photodiode.

the signal current is multiplied by the internal avalanche gain. The average value of the signal current is then

$$\langle t_{sig}\rangle = i_p\langle m\rangle, \tag{21}$$

where $\langle m\rangle$ is an average of the varying multiplication factor. For devices without gain such as *p-i-n*, $\langle m\rangle = 1$.

The shot-noise current is determined by the dc component of the photocurrent, I_p, and is given by

$$\langle i_{sp}^2\rangle = 2qI_p\langle m^2\rangle B, \tag{22}$$

where $\langle m^2\rangle$ is the mean square multiplication factor and B is the bandwidth of the noise measurement. Noise-current terms are commonly written as mean squares ($\langle i^2\rangle$). The shot noise from photocurrent and dark current can be combined into a single expression. Dark currents can arise from different sources. Electrons and holes thermally generated in the *p-n* junction of a device contribute to bulk dark current (Keiser, 1983) and currents originating from surfaces due to mesa conditions, trapping, or surface recombination are referred to as surface leakage currents. The bulk currents I_{db} are subject to the avalanche gain mechanism, while the surface currents I_{ds} are not. The shot-noise expression becomes

$$\langle i_{spd}^2\rangle = 2q(I_p + I_{db})\langle m^2\rangle B + 2qI_{ds}B. \tag{23}$$

Random current fluctuations due to background radiation, stray light in the system striking the device active area and being collected by the photodetector, denoted here as I_b, can also be included in the shot-noise term (Sze, 1981):

$$\langle i_{spdb}^2\rangle = 2q(I_p + I_{db} + I_b)\langle m^2\rangle B + 2qI_{ds}B. \tag{24}$$

Thermal noise arises from all resistances present in the system. The series resistance is usually small compared with the other resistance values in the system and will be neglected. The equivalent resistance for the parallel combination is given by (Sze, 1981)

$$\frac{1}{R_{eq}} = \frac{1}{R_j} + \frac{1}{R_L} + \frac{1}{R_a}, \tag{25}$$

where R_j is the junction resistance. The mean square thermal, or Johnson, noise is

$$\langle i_T^2\rangle = 4kTB/R_{eq} \tag{26}$$

(Sze, 1981), where k is Boltzmann's constant, T is the temperature in kelvins, and B is the bandwidth of the measurement.

In a receiver, the signal-to-noise ratio determines its sensitivity and low-power detection capabilities. The signal-to-noise ratio is defined as the signal due to the photocurrent divided by the mean squared noise components from the photodetector and the amplifier. It is important to have high quantum efficiency in the detector and low noise in the amplifier in order to maximize receiver sensitivity. The signal-to-noise ratio is then

$$\frac{S}{N} = \frac{\langle i_p^2\rangle\langle m^2\rangle}{2q(I_p + I_{db} + I_b)\langle m^2\rangle B + 2qI_{ds}B + 4kTB/R_{eq} + \langle i_{amp}^2\rangle}, \tag{27}$$

where i_{amp} is the amplifier current. The minimum detectable power associated with a particular S/N ratio can be found [for $m = 1$, $I_{ds} + I_{db} = I_d$, i_{amp} negligible, and $\langle i_p^2\rangle = \frac{1}{2}(nqP_0/h\nu)^2$] (Sze, 1981) as

$$\frac{S}{N} \approx \frac{\frac{1}{2}(q\eta P_0/h\nu)^2}{2q(I_p + I_d + I_b)B + 4kTB/R_{eq}} \tag{28}$$

and

$$P_{omin} = \frac{2h\nu B}{\eta}\left(\frac{S}{N}\right)\left[1 + \left(1 + \frac{I_{eq}}{qB(S/N)}\right)^{1/2}\right], \tag{29}$$

where

$$I_{eq} = I_d + I_b + 2kT/qR_{eq}. \tag{30}$$

If the receiver is in the shot-noise–limited regime, the dark-current shot noise sets the minimum detectable power limit. For $m = 1$, this is

$$P_{omin} = \frac{2qI_dB}{R} = \frac{2hcI_dB}{\eta\lambda} \tag{31}$$

in units of watts.

If the background radiation or thermal noise is the dominant noise source, a figure of merit for the receiver is the noise-equivalent power (NEP). The NEP is the rms optical power ($P_0/\sqrt{2}$). To calculate NEP, Eq. (29) is used where the bandwidth is assumed to be 1 Hz, $S/N = 1$, and $I_{eq}/qB(S/N)$ is assumed to be $\gg 1$:

$$\mathrm{NEP} = (\sqrt{2}h\nu/\eta)(I_{eq}/q)^{1/2} \tag{32}$$

in units of W/cm^2 Hz$^{1/2}$.

3. TYPES OF PHOTODETECTORS

The choice of a photodetector for a specific optical receiver application depends on the performance and cost tradeoffs for the design. The wavelength range of interest will determine the material used. More mature technologies with simple fabrication processes in Si, and Ge, and GaAs usually mean lower-cost devices with adequate performance. High-performance devices for the telecommunications wavelengths of 1300 and 1550 nm typically have more involved fabrication processes and more difficult-to-control dark currents. Speed of response, noise, quantum efficiency, and gain are parameters to consider in the choice of a photodetector.

3.1 Photoconductors

A photoconductor is fabricated by placing Ohmic contacts onto a semiconductor material. When the material is illuminated, electron–hole pairs are produced and the electrical conductivity of the material increases. The greater the photon flux, the greater the increase in conductivity (Saleh and Teich, 1991; Sze, 1981). When voltage is applied to the contacts, the electrons and holes move in opposite directions resulting in a photocurrent. The anode and cathode may be placed on opposite ends of the semiconductor or both on top in an interdigitated pattern as illustrated in Fig. 8.

Photoconductive detectors have photoconductive gain defined as the flow of electrons per second from the device divided by the rate of generation of electron–hole pairs within the device (Wilson and Hawkes, 1989). The device gain is expressed as

$$G = \tau_m/\tau_e, \tag{33}$$

where τ_m is the excess carrier recombination lifetime and τ_e is the electron transit time ($\tau_e = 1/v_e$) (Saleh and Teich, 1991). Gain may be larger than unity.

Photoconductive detectors have the advantages of photoconductive gain and ease of fabrication over *p-n* or *p-i-n* devices, but lack their speed capabilities. The transit time in a photoconductor is set by the peak velocity of the fastest carrier, as contrasted with the case of *p-i-n*'s where it is limited by the slowest carrier. In III-V materials where the velocity of electrons is greater than the velocity of holes, and low-field electron velocity is greater than the high-field peak saturation velocity, high gain–bandwidth products can be obtained, but the *p-i-n* (with no gain) has much higher bandwidth (Forrest, 1988).

3.2 *p-n* Junction Photodiodes

The *p-n* junction photodiode is formed by doping layers of semiconductor material *n* type and *p* type. When a photon is absorbed, it creates an electron–hole pair as in the photoconductive device. Here, the electric field is formed only in the depletion region of the

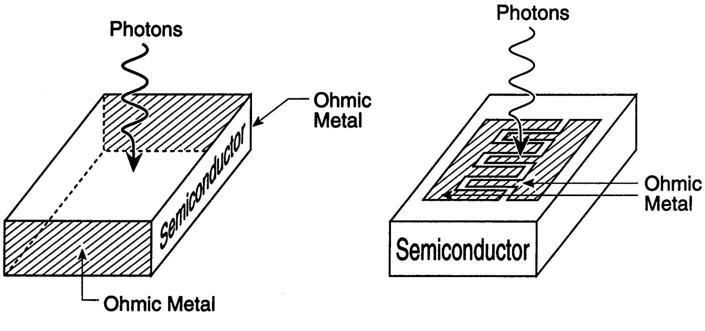

FIG. 8. Two designs for photoconductors showing Ohmic contacts on the ends of a semiconductor slab, and interdigitated contacts on the surface of a semiconductor.

device, and only carriers generated there, or near there (within a diffusion length), have the ability to be moved in a specific direction. The device is operated under reverse bias and the electrons are moved toward the *n* region while the holes drift to the *p* region under the influence of the electric field.

Response time of a *p-n* junction device is faster than a photoconductive detector as a result of the strong electric field in the depletion region giving carriers a larger velocity. The wider depletion region of the *p-i-n* photodetector makes it a better choice for high-speed devices.

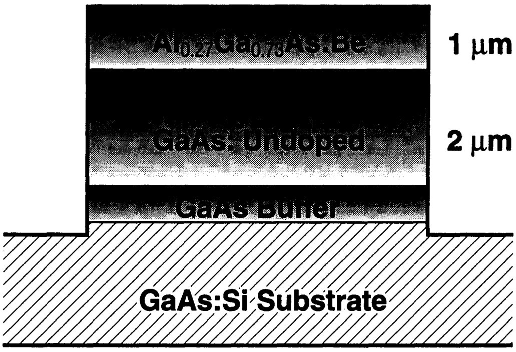

FIG. 9. The epitaxial layer structure for an AlGaAs/GaAs heterojunction *p-i-n* detector.

3.3 *p-i-n* Photodetectors

A *p-i-n* detector is typically formed by growing an intrinsic (lightly doped) layer on top of a highly doped n^+ substrate and growing a p^+ layer on top of the intrinsic layer or diffusing the *p* dopant into the top layer. The detector structure will also work in reverse, that is, growing an *i* layer and an n^+ layer on a p^+ substrate. The *p-i-n* has advantages over the *p-n* junction device in that it has a wider depletion region (thickness of *i* layer) and, therefore, a lower capacitance and lower *RC* time constant. The transit time, however, will increase (Saleh and Teich, 1991). High bandwidths, in excess of 100 GHz (Wey, 1993), are achievable with *p-i-n* photodetectors.

When the *p-i-n* device is formed out of a single semiconductor material, as in silicon *p-i-n*'s, the device material is homogeneous and it is referred to as a homojunction device. A photodetector composed of two different semiconductor materials is referred to as a heterojunction device. An example of this structure is the $Al_{0.27}Ga_{0.73}As/GaAs$ device for use from about 680 to 880 nm. This structure, which can have high bandwidths (>22 GHz) and high external quantum efficiency (73%) (Johnsen *et al.*, 1991), is shown in Fig. 9 and can be grown using molecular beam epitaxy (MBE). The higher–band-gap material sits on top where light incident at

$$\lambda_0 > hc/E_g \qquad (2)$$

is not absorbed, but passes through to the intrinsic layer, which, under bias, is depleted of carriers as they are continuously swept out. This top transparent layer, the heterojunction window layer of higher–band-gap material, allows for the photons to pass through and be collected in the *i* layer below. A double heterojunction is formed when there are two junctions of differing semiconductor materials as in the $InP/In_{0.53}Ga_{0.47}As/InP$ detector material system (Wang *et al.*, 1987).

p-n or *p-i-n* junction photodiodes can be formed using a planar diffusion process. These diffused devices can have high response and very low dark current or high dynamic resistance for low-noise receiver performance.

The fabrication process for InP/InGaAs/InP diffused heterojunction devices will be used to illustrate a typical planar device process (Beck, 1993). The epitaxial structure used is an InP buffer layer on the InP:S (InP sulfur doped) substrate, followed by the InGaAs active layer, which has a low (1×10^{15} cm^{-3}) background doping, and then the window layer of InP, which will be diffused with the *p*-type dopant zinc. To form the diffusion barrier, silicon nitride is deposited on the wafer, patterned using a photoresist mask, and removed from the areas where Zn is diffused into the semiconductor. The diffusion depth is targeted to be through the InP window layer and into the InGaAs layer beneath. An antireflection coating is used to provide low reflections from the top surface and also to act as passivation for the device. The *p* contact is formed by etching away a small region of the antireflection coating and depositing Ti/Pt/Au metallization by a liftoff process. A bonding pad can then be formed by gold plating. The wafer is lapped and polished to provide the desired chip thickness and polish on the back side. The *n*-side metal contact (AuGe alloy) is deposited on the back side of the wafer on the InP:S substrate. A cross sec-

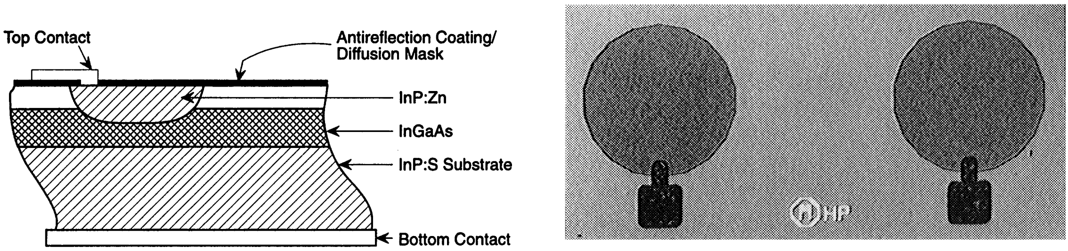

FIG. 10. (Left) Cross section of a diffused InGaAs detector showing the double-heterojunction material structure, Si_xN_y diffusion mask, AR coating, *p*-metal bondpad, and back-side *n* metals. (Right) Photograph of a pair of diffused detectors fabricated in this way (Sloan, 1989).

tion of the device and a photograph of a pair of diffused detectors are shown in Fig. 10.

Photodetector mesa structures provide a low-capacitance design for high-frequency performance. Mesa devices can be front-side or back-side illuminated. They can have grown-in doped layers or diffused layers (Ohnakea *et al.*, 1987) with mesas etched outside the diffused region. Mesa devices often have higher dark currents than diffused-junction devices because of the exposed junction surface.

A typical process for a *p-i-n* structure (Sloan, 1989) with a grown-in *p* layer involves deposition of the metal contact on the *p* layer by a lift-off process, deposition of an antireflection coating, etching the mesa with wet-chemical etches or by reactive-ion etching, deposition of the *n*-metal contact, and passivation of the mesa surface. A cross section and scanning electron micrograph of the device are shown in Fig. 11.

3.4 Metal–Semiconductor–Metal (Schottky Barrier) Photodetectors A thin metal layer deposited on a semiconductor can form a Schottky barrier (see SCHOTTKY BARRIERS). This metal–semiconductor contact can act as a *p*- or *n*-type layer forming a *p-n* junction photodetector. If made thin enough, the metal is transparent to the incident light, and a depletion region is formed at the semiconductor surface. An example of a Schottky or metal–semiconductor device fabricated in the GaAs material system is given as follows (Wang and Bloom, 1983). An n^+-GaAs layer and an *n*-GaAs layer are grown on a semi-insulating GaAs substrate. The area under the Schottky and Ohmic contacts is left active and conductive, while the surrounding area is isolated by proton bombardment, which destroys the ordered atomic lattice. This also minimizes the capacitance, which is necessary for high-speed performance. The Ohmic contact is placed on the n^+ layer after etch-

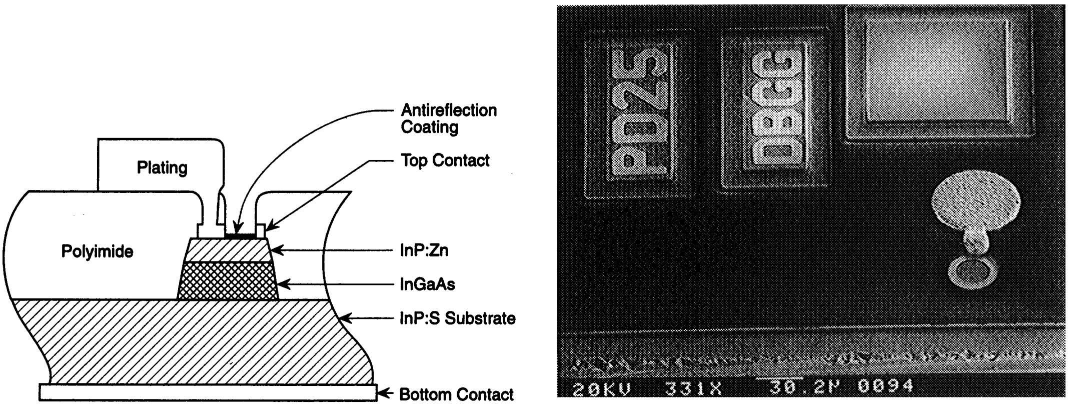

FIG. 11. (Left) Cross section of a mesa InGaAs detector showing the fabrication process steps—*p* metal, AR coating, wet-etched mesa, polyimide passivation, bond pad, and back-side metal. (Right) Photograph of a mesa *p-i-n* using this process (Sloan, 1989).

ing away the n layer of GaAs. A AuGe-type Ohmic contact to the n^+ layer is deposited using a liftoff process. The transparent contact to the n-GaAs layer is made by depositing a thin layer (100 Å) of platinum and patterning using photoresist and etching with an Ar ion mill. The light-absorbing area is covered with a dielectric passivation. For a small-area device, 5×5 μm^2, a pulse response of 5.4 ps full-width-half-maximum (FWHM) or >100 GHz 3-dB frequency response has been demonstrated (Wang and Bloom, 1983).

Metal–semiconductor–metal (MSM) photodetectors commonly use interdigitated metal fingers to form the two electrical contacts for the device. These devices are attractive because of the low capacitance of the small active areas and the short transit time of the carriers between the electrodes. MSMs typically have lower responsivity or quantum efficiency than *p-i-n* devices because of the large amount of the incident light area covered by metal. Response can also be reduced by using thin *i* layers to try to minimize the transit-time effects of carriers needed to achieve high bandwidths. This can be a problem for *p-i-n* devices as well. The broad bandwidth possibilities and the ease and compatibility of processing with existing field-effect transistors (FETs) make MSMs a good choice for integrated optical devices. MSMs are being fabricated in GaAs and InGaAs material systems (Klingenstein *et al.*, 1992; Zirngibl *et al.*, 1989; Van Zeghbroeck *et al.*, 1988).

3.5 Avalanche Photodetectors

The avalanche photodetector (APD) operates under a strong reverse bias so that the electric field strength across the region between the p-type and n-type layers is large. When an incoming photon is absorbed, a cascading of carriers is created by a process known as impact ionization. This avalanche process of carriers produces carrier multiplication, or gain, in the device.

The process of impact ionization or multiplication that takes place in an APD is illustrated in Fig. 12 (Saleh and Teich, 1991). An incoming photon absorbed at point A creates an electron–hole pair, where the electron resides in the conduction band and the hole in the valence band. Under the strong electric field provided by the high reverse bias, the electrons are accelerated toward the n side of the device and the holes toward the p side. As the electron is accelerated, it gains energy with respect to the bottom of the conduction band and undergoes collisions with the semiconductor lattice, losing some of its energy. The electron reaches an average saturation velocity balancing the increase in velocity due to the acceleration in the electric field and decrease in velocity experienced in the random lattice collisions. An electron with energy greater than the band-gap energy E_g can generate another electron–hole pair as shown at point B in Fig. 12 by kicking an electron into the conduction band and leaving a hole in the valence band (Pearsall and Pollack, 1985), giving up energy in the process. The energy required is greater than E_g because of the energy used in the three-body collision (Capasso, 1985). This process can now continue with the two electrons each having the possibility of creating more electron–hole pairs and causing the cascading effect. The holes are likewise accelerated toward the p side of the device and can undergo impact ionization spawning more electron–hole pairs (see point C in Fig. 12).

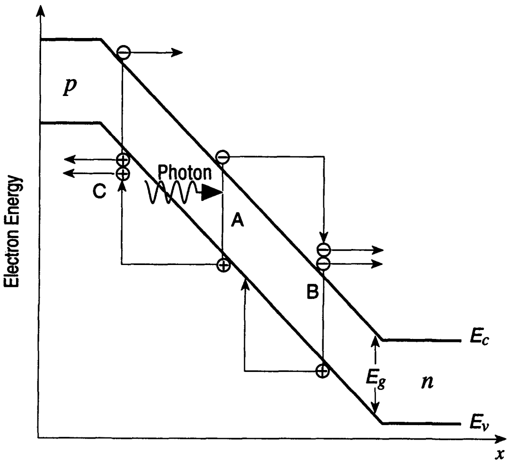

FIG. 12. The process of multiplication by impact ionization in an APD. A photon incident at point A creates an electron in the conduction band and a hole in the valence band. In a high electric field, the electron gains enough energy with respect to the bottom of the conduction band to generate another electron–hole pair at point B. Holes can likewise generate carrier pairs as shown at point C (Saleh and Teich, 1991).

Novel device designs are used to optimize APD performance. To increase quantum efficiency, the absorption layer of the APD needs to be thick enough to absorb the majority of the carriers incident, but to minimize the chance for the inclusion of an area of potential instability or area of uncontrolled avalanche (microplasmas), the multiplication region needs to be as small as possible. Various device structures have been designed in an attempt to reconcile these competing tendencies. The separate-absorption-multiplication (SAM) APD uses separate semiconductor layers to perform the necessary device functions and is able to optimize the features of each by maintaining spatially separate regions. Guard-ring structures are a way of lessening leakage currents, which can limit multiplication, by having a ring of low-doped, high-breakdown material around the active region of the device. Guard-ring structures are used in Si, Ge, and III-V devices.

For wavelengths from 0.8 to 1.0 μm, silicon is the material used for APDs. In the longer-wavelength range of 1.0–1.55 μm, germanium is used as well as III-V materials. In III-V semiconductors, because of the high leakage due to tunneling in homojunction APDs, heterojunction devices are used. Gain-bandwidth products of 100–130 GHz have been reported for various configurations.

Response times in APDs are limited by the same factors affecting *p-i-n*'s—transit times in the depletion region, *RC* time constants, diffusion times of carriers in the nearby undepleted regions—and in addition by avalanche buildup time.

In addition to the noise contributions listed in Sec. 2.2.8 for shot noise and thermal noise, another parameter of interest for APDs is multiplication noise described by the excess noise factor.

3.6 Arrays

Photodetector arrays are used in imaging and in spectroscopy. Detectors are placed close together, and light strikes many of them simultaneously. In spectroscopy, the light is dispersed into its various wavelengths before it is incident on the detector array. A current resulting from illumination of a particular array element indicates that light of that wavelength is present corresponding to a chemical signature of a substance under test. Such arrays have been fabricated in the InGaAs material system having over 500 elements sensitive to wavelengths from 600 to 1700 nm. A type of two-dimensional array called a charge-coupled device (CCD) is formed using a series of Schottky photodiodes and can be used to do visible or infrared imaging (see CHARGE-COUPLED DEVICES).

3.7 Waveguide Photodetectors

Detectors where the input light is coupled to the edge of the device are known as waveguide photodetectors. In conventional top-illuminated *p-i-n* detectors, a tradeoff exists between the speed of response and the quantum efficiency of the device. The *i* layer is made thin to minimize transit time and maximize frequency response, but thinning the *i* layer means there may not be enough absorption depth for a large fraction of the light to be absorbed and the quantum efficiency or responsivity is not optimized. In an edge-illuminated device, the current flow and the light absorption occur in perpendicular directions and both the speed and quantum efficiency can be high (Bowers and Burrus, 1986). Internal quantum efficiencies are determined by the wavelength of light and the absorption coefficient, the *i*-layer thickness, and the length of the chip. External quantum efficiency takes the coupling efficiency into account. Careful light coupling and packaging schemes are needed to get the light focused into the *i* layer of the device. Waveguide devices with 3-dB electrical bandwidths of 50 GHz and quantum efficiencies of 68% for antireflection-coated devices have been fabricated and tested (Kato *et al.*, 1992).

Fabrication processes have used both n^+ and semi-insulating substrates. The epitaxial structure is similar to a laser structure in that it contains waveguiding layers on either side of the active layer, though here the active layer absorbs rather than emits light. A typical epitaxial structure for the InP/InGaAs material system consists of a contact layer (either the n^+ substrate or an InP *n*-type grown layer), an InGaAsP *n*-type cladding layer to aid in the guiding of the mode, an InGaAs absorbing layer, an InGaAsP top guiding layer (p^+ or undoped), and *p* contacting layers (InP *p* type with an InGaAs and/or InGaAsP contacting layer on top to lower the contact resistance). A mesa or ridge is etched down through the active layer, and the mesa is passivated with polyimide. After a via hole is etched to contact the *p* layer, *p* contacts are formed on the top of the device by liftoff techniques. The wafers are thinned by lapping to facilitate cleaving. On the semi-insulating substrate, devices are etched down to the *n* layer and the *n* metal is deposited, and on the n^+-substrate devices the *n* metal is placed all over the back side of the device. Devices are cleaved and antireflection coated.

3.8 Quantum-Well Photodetectors

Quantum-well photodetectors take advantage of band-gap engineering in order to control their wavelength detection range and response. They depend on precisely controlled, often thin, alternating epitaxial layers grown by solid-source MBE, organometallic vapor-phase epitaxy, or gas-source MBE (Ritter *et al.*, 1991). Rapid switching between materials in order to achieve abrupt interfaces on an atomic scale (layers on the order of tens of ångströms) with well-characterized composition and doping profiles is necessary in order to grow the quantum wells (Manasreh and Brown, 1993). Electron confinement in these thin layers, caused by the conduction- or valence-band offset due to the difference in band-gap energies at the heterojunction interfaces, shows quantum effects where continuous energy levels become discrete (Dingle, 1987). A thin layer of small–band-gap material is placed between layers of higher–band-gap material forming a potential well where the electron or hole energy states are quantized (particle in a box). These discrete energy levels can be varied by adjusting the thickness and depth (band discontinuity) of the wells. More bound states with closer energy levels are found in wider quantum wells. Multiple quantum-well (MQW) devices are formed by growing stacked wells with barrier layers between them on the wafer. As the barrier layers become thinner than about 50 Å, the structure is referred to as a superlattice. Materials that are grown lattice mismatched to change the band structure of the device purposely are known as strained layers (Manasreh and Brown, 1993).

Detection at the long infrared wavelengths (3–14 μm) is achieved by using such quantum-well devices. Applications at these long wavelengths are for imaging with linear arrays, medical imaging, global and space surveillance, and astronomy. Information on other types of infrared detectors can be found in the article SENSORS, INFRARED.

3.9 High-Speed Detectors

As optical data rates increase in both the data communications and telecommunications markets, high-speed detectors will be necessary for the transportation of that information. 10-Gbit and 20-Gbit systems are now being designed in research environments. 2.488-Gbit SONET (Synchronous Optical Network) systems are already being implemented. Detectors designed for high speed that trade off thin *i* layers for short transit times and thick *i* layers for low capacitance will be needed. Designs that involve low capacitance, low series resistance, and short transit times and still maintain reasonable responsivities will be needed (Bowers and Burrus, 1987). *p-i-n* detectors with bandwidths of 100 GHz have been made in the GaAs and InGaAs material systems (Wang and Bloom, 1983; Wey, 1993). APDs with gain-bandwidth products of 120 GHz have also been demonstrated (Watanabe *et al.*, 1993).

3.9.1 Device Types and Trends As systems push to higher data rates, detector areas are shrunk in an effort to reduce junction capacitance, eventually making the devices difficult to fabricate and illuminate. Parasitic capacitances and inductances become very important to the speed of response of the devices, influencing the flatness and rolloff of the frequency response. Mesa *p-i-n* devices as small as 5 × 5 μm^2 have been fabricated for research applications (Wey, 1993), but would be difficult to reproduce repeatably in a device manufacturing environment. The small mesa size formed by wet etching means that the undercutting would need to be carefully monitored and traded off against the surface etches necessary to achieve low dark currents. Back-side–illuminated devices that can be attached by a solder bump technique known as flip-chip (Katsura *et al.*, 1990; Makiuchi *et al.*, 1993; see also ELECTRONIC COMPONENTS AND ASSEMBLIES: RELIABILITY AND TESTING) are a means of lowering device capacitance by removing the need for a front-side bondpad and lowering parasitics since bond wires are replaced with solder interconnects. In addition to the rf response increase, dc responsivity also increases for the back-side–illuminated flip-chip device over the front-side–illuminated device, where the benefit comes from using a double pass of the light through the *i* layer of the device, thus absorbing a larger fraction of the incident photons and converting them into usable photocurrent.

Optoelectronic integrated circuits (OEICs) are another way of forming interconnections between the devices by fabricating them on a single substrate, often using multiple material regrowths to achieve the layer structures necessary for the varied devices. OEICs using photodiodes as one of their elements have also been fabricated. Performance of the OEICs has not yet met the performance of the individual optical and electrical components, but improvements have been made and performance is beginning to approach that of the hybrid circuits, making OEICs useful for high-speed applications and lower-cost alternatives.

4. APPLICATIONS IN OPTICAL RECEIVERS

An optical receiver converts incoming optical information into an electrical signal that can then be analyzed by conventional electronic means. In long-haul communications systems, the optical signal incident on the photodetector may be weak and distorted, and so many receivers involve the photodetector, or optical-to-electrical converter (O/E), followed by an amplifier to boost the electrical signal to levels where it can be processed by the subsequent electronics. Some applications for receivers, however, involve looking at the source characteristics in the time domain on an oscilloscope where cleanly reproduced pulse response is a major concern. For these applications and those where the optical and electrical signals are at an adequate level, unamplified receivers are the choice (King *et al.*, 1993). Figure 13 shows a photograph of two such *p-i-n*–only photoreceivers attached to the test set of a high-speed oscilloscope. Desired characteristics of optical receivers are high sensitivity, low noise, wide dynamic range [ratio of maximum to minimum input signals (Senior, 1992)], and adequate bandwidth. These are necessary for long-haul systems where long repeater spacing and high capacity are important and, along with low cost, for local-area networks, local loops, cable TV, and data links (Williams, 1991).

In a digital system, a stream of data, or bits, is sent electrically as a series of ones and zeros. An electric pulse is applied to a laser or light-emitting diode (LED), and a series of optical pulses is transmitted down an optical fiber where it is attenuated and distorted somewhat before it impinges upon the pho-

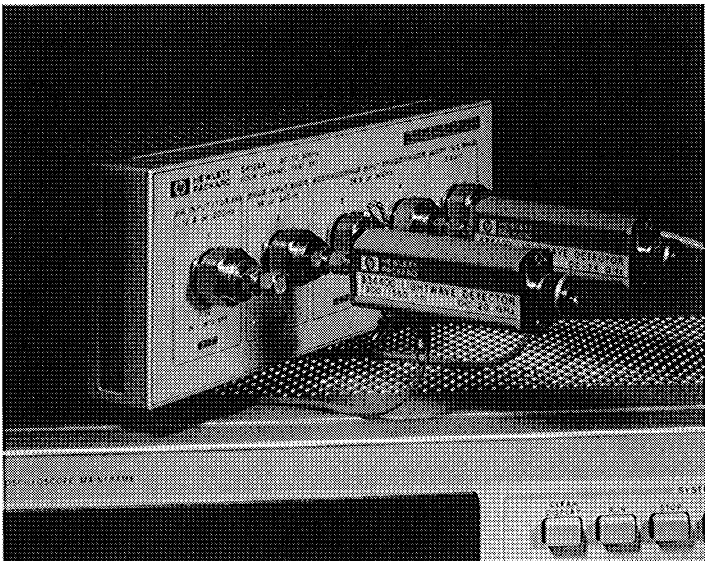

FIG. 13. Photograph of Hewlett-Packard 83440 series lightwave receivers.

todetector. An electrical wave form results that contains the fiber distortions plus any noise due to the photodetector. This is amplified and picks up any noise associated with the amplifier, and the pulses pass to a decision circuit where the ones and zeros must be discerned (Keiser, 1983). If the voltage is greater than some threshold voltage, then the conclusion is that a light pulse was present and a one is sensed. If the voltage falls below that threshold, than no light was present and a zero is detected. Detection can be done by asynchronous or synchronous methods. The bit error rate (BER) of the digital system is defined as the number of errors occurring in a given time interval N_e by the number of pulses transmitted during that time interval N_t (Keiser, 1983)

$$\mathrm{BER} = N_e/N_t. \tag{34}$$

Typical BERs for optical communications systems are 10^{-6}–10^{-10} (Keiser, 1983). Most systems now require BERs of 10^{-9} (Williams, 1991).

Noise, variable or undesirable components of the electrical signal, limits receiver performance. Noise can arise from several sources. Random fluctuation of currents in resistors is called Johnson or thermal noise, and in diodes it is called shot noise. Shot noise comes from photodiode dark current from both the semiconductor bulk and surface. APDs have additional noise due to the random nature of the gain process. Quantum noise is associated with the random process of converting light into electrical current. Interference of adjacent signals is noise referred to as cross talk or intersymbol interference. In a *p-n* or *p-i-n* photoreceiver, the thermal noise tends to dominate, and in an APD receiver, the random noise of the multiplication process adds additional shot noise (due to fluctuations in dark current and quantum noise) and this is the limiting factor (Senior, 1992).

Optical-receiver amplifier designs are usually of two types—high-impedance and transimpedance designs (Hullett and Muoi, 1976; Kasper, 1988). The high–input-impedance amplifier provides good sensitivity, but does not have wide bandwidth characteristics because of the effective integration of the detector output over a large time constant (Senior, 1992; Personick, 1973). The transimpedance amplifier uses a low-noise, high-impedance design where the high impedance is reduced by negative feedback provided by the feedback resistor (Senior, 1992). It has higher bandwidth performance than the high-impedance case. Transimpedance amplifiers are less sensitive than high-impedance designs (Williams, 1991). Transimpedance amplifier designs are being used in hybrid schemes and also in monolithic versions where an APD is integrated with an amplifier or a *p-i-n* diode is integrated with a FET to form a *p-i-n*-FET (Akahori *et al.*, 1991; Uchida *et al.*, 1991). *p-i-n*'s are generally used when speed is the major concern, and APDs can provide increased sensitivity as a result of their gain (Forrest, 1985).

Monolithic integration of photodetectors and amplifiers has been demonstrated using *p-i-n*'s and HBTs (heterojunction bipolar transistors) (Chandrasekhar *et al.*, 1990), MSMs and HEMTs (high–electron-mobility transistors) (Sasaki *et al.*, 1989; Yano *et al.*, 1990). These OEICs have been grown using InP/InGaAs heterostructures or InAIAs/InGaAs and fabricated on a single substrate. Photoreceivers that will respond to data rates of 1–4 Gbit/s have been made (Chandrasekhar *et al.*, 1990; Yano *et al.*, 1990).

As data rates increase, photodetector speeds will increase and OEICs will become necessary to overcome the parasitics associated with hybrid designs and interconnections. Photodetectors will continue to evolve as even lower-capacitance, lower–transit-time, high-response designs are in demand.

9.1
Introduction

9.1.1
History

Photoemission, that is, the emission of electrons by photons, was discovered as an unwanted side effect in the study of electromagnetic waves by Hertz (1887). At that time, neither the electron nor the photon was known as *particles*. Einstein (1905) explained the photoelectric effect as a quantum phenomenon and derived the correlation

$$E_{\max} = h\nu - \Phi \tag{9.1}$$

between the maximum kinetic energy $E_{\max}$ of the photoelectrons, the photon energy $h\nu$, and the work function Φ of the emitting solid (compare Figure 9.1). Many of the following decades were spent in finding clear experimental evidence for or against the Einstein formula (Millikan, 1916). The time was not ripe for photoelectron spectroscopy as we know it today, because photoemission turned out to be a rather surface-sensitive effect. The mean free path of photoelectrons in a solid limits the probing depth to a few atomic layers. The prerequisites for the preparation of reproducible, clean, and well-ordered surfaces were not in place until the sixties, when the necessary ultrahigh vacuum could be produced and measured on a routine basis. At a residual gas pressure of 10^{-6} torr (1.3×10^{-4} Pa), a surface atom is being hit by a residual gas molecule about once in every second, thus requiring pressures in the 10^{-10} torr range for controlled photoemission studies. When surface characterization techniques, such as low-energy electron diffraction (LEED) and Auger spectroscopy became generally available, photoelectron spectroscopy took a big leap forward. Photoelectron spectroscopy is now an indispensable technique for the determination of the electronic structure of solids, surfaces, and gas-phase species. Tunable and polarized synchrotron radiation became the light source of choice in the 1970s, and gave rise to the construction of a series of storage rings dedicated to the production of light from the ultraviolet to the X-ray regime. In the 1980s, the measurement of a complete set of quantum numbers became feasible for electrons in solids, which involves measuring the momentum and spin polarization of photoelectrons as a function of the photon energy and photon polarization. In the 1990s, measurements with an energy resolution

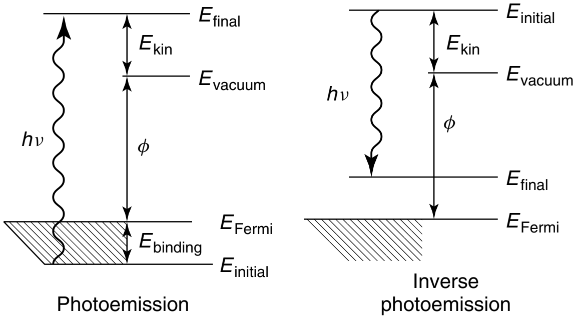

Fig. 9.1 Energy diagram for photoemission (photon in, electron out) and inverse photoemission (electron in, photon out). The energy of the lower state is determined by subtracting the photon energy $h\nu$ from the energy of the upper state. The latter corresponds to the kinetic energy of the emitted or the incoming electron.

better than the thermal energy became practical, which provided an opportunity to examine the electronic states that are relevant to magnetism, superconductivity, and other transport properties. Most recently, temporal resolution was introduced with pump–probe experiments for observing dynamics down to tens of femtoseconds, and spatial resolution down to tens of nanometers was achieved in photoelectron microscopes.

9.1.2
Phenomena

The basic energy diagram of the photoemission process is given in Figure 9.1. An electron is lifted from an occupied initial state into an unoccupied final state. Energy conservation allows it to obtain the desired energy E_{initial} of the initial state from the measured energy E_{final} of the photoelectron in the final state by simply subtracting the photon energy $h\nu$. As reference energies, one can use either the vacuum level E_{vacuum}, corresponding to a photoelectron with zero velocity, or the Fermi level E_{Fermi}, corresponding to the highest occupied state. From there one obtains energy differences, such as the kinetic energy E_{kin}, the work function Φ, and the binding energy E_{binding}. The Einstein relation for the maximum kinetic energy $E_{\max} = \text{h}\nu - \Phi$ follows directly for photoemission from the highest occupied state at E_{Fermi}.

Figure 9.1 also shows the energy diagram for the time-reversed process, that is, an incident electron dropping down into a lower unoccupied state by emission of a photon. This process is equivalent to the quantum description of bremsstrahlung, but in the low-energy regime of typically 10-eV kinetic energy, it is known today as *inverse photoemission*. It characterizes unoccupied states in a fashion complementary to the information provided by photoemission about occupied states. The counterpart to the Einstein relation is the Duane–Hunt equation

$$h\nu_{\max} = E_{\text{kin}} + \Phi \tag{9.2}$$

for the highest photon energy of the bremsstrahlung emitted by electrons with kinetic energy E_{kin}. Inverse photoemission as a surface technique got a late start compared to photoemission because its cross section is down by 4–5 orders of magnitude, requiring extremely sensitive photon detectors.

There are other electron and photon emission phenomena related to photoemission. As shown in Figure 9.2, a core hole created in the photoemission process can decay by an Auger process (a), which is most likely for shallow core levels, or by fluorescence (b), which is prevalent for deep core levels (Keski-Rahkonen and Krause, 1974). In addition, the photoelectron can lose energy by creating electron–hole pairs or plasmons during its escape. These processes actually limit the escape depth. The end result is a spectrum of emitted photoelectrons that contains several secondary features in addition to the directly emitted photoelectrons (Figure 9.3). For valence spectroscopy (often labeled as ultraviolet photoelectron spectroscopy (UPS)), the main disturbance is a tail of secondary electrons at low kinetic energies, caused by energy losses to electron hole pairs (Figure 9.3a). For core-level spectroscopy (often labeled as X-ray photoelectron spectroscopy (XPS), or electron spectroscopy for chemical analysis (ESCA)), there are additional Auger peaks and plasmon loss satellites complicating the spectra (Figure 9.3b). With tunable synchrotron radiation, it is straightforward to separate out the Auger peaks, because they do not change their kinetic energy with increasing photon energy, in contrast to elastic core lines and their plasmon loss satellites.

An important consideration in photoemission experiments is the probing depth, which is governed by the mean free path of the photoelectrons (Figure 9.4). Electrons penetrate solids farther at high kinetic energies, but their mean free path increases again at very low energies, because they do not have enough energy to excite plasmons (in metals) or electron–hole pairs (in insulators). In the 30- to 70-eV range, the mean free path reaches a minimum of only a few atomic distances, making it possible to separate surface

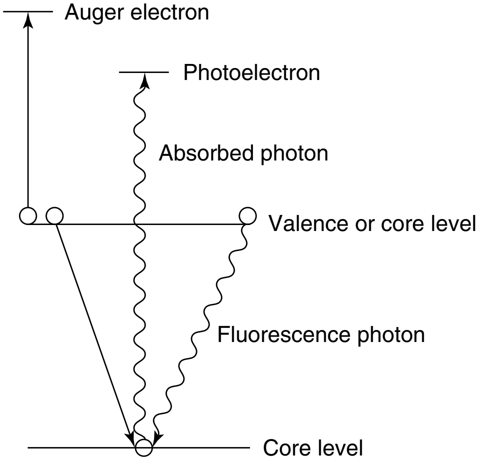

Fig. 9.2 Energy diagram for core-level photoemission, including the decay of the core hole by an Auger process (a) or by fluorescence (b).

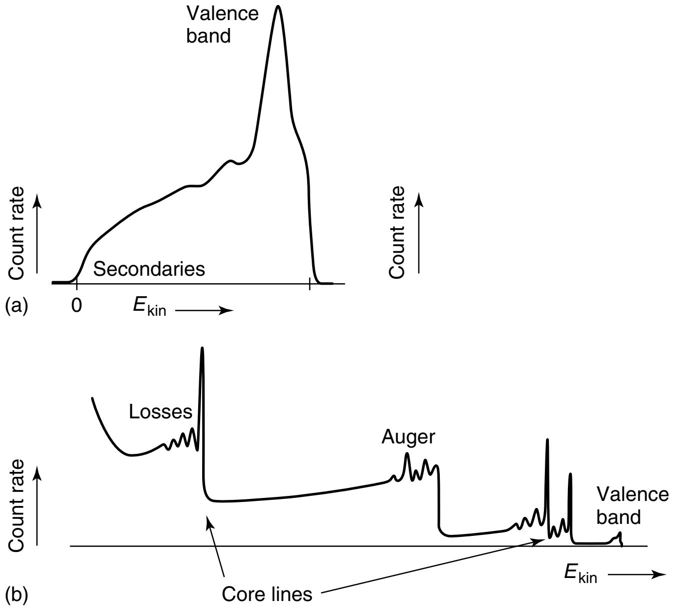

Fig. 9.3 (a) Typical valence photoelectron spectrum, showing photoelectrons directly emitted from the valence band and secondary electrons emitted after electron–hole pair production. The two energy cutoffs are determined by the vacuum level (zero kinetic energy E_{kin}) and the Fermi level (i.e., excitation of the highest occupied state). (b) Typical core-level photoelectron spectrum, showing core-level peaks, their plasmon loss satellites, and Auger electron features (Feuerbacher, Fitton and Willis, 1978).

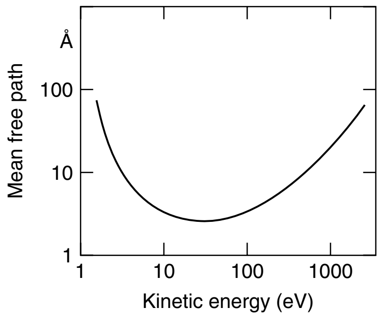

Fig. 9.4 Schematic dependence of the mean free path of photoelectron on their kinetic energy. The minimum at 30–70 eV can be used to probe surface or interface layers.

atoms from the bulk. The tunability of synchrotron radiation provides the ability of producing photoelectrons with the desired kinetic energy, which has spawned the field of surface core-level spectroscopy.

9.1.3
Theory

Photoemission is unique in providing the complete set of quantum numbers that characterize electrons in solids.

This made photoemission the preferred technique for investigating electrons in a solid and led to Philip Anderson's famous characterization of photoemission as "smoking gun" that might give away the secrets of electrons in high-temperature superconductors (Anderson and Schrieffer, 1991). For electrons in a periodic crystal lattice, these quantum numbers are energy E, momentum $\mathbf{p} = \hbar\mathbf{k}$, spin, and angular symmetry (represented by the point group in a solid). Polycrystalline solids can be characterized by the same quantum numbers, because each crystallite typically contains thousands to millions of unit cells. However, when the size of a crystallite reaches dimensions in the single digit nanometer regime (tens of atom diameters), the situation changes: instead of a continuum of energies, one obtains quantized states with discrete energies. This alters the fundamental electronic properties of a material, such as the band gap of a semiconductor, and leads to the capability of tailoring the electronic properties of materials in nanotechnology (Himpsel *et al.*, 1998).

The quantum numbers are obtained by using conservation laws during the photoemission process (see the general reviews Himpsel (1983), Kevan (1992) and Hüfner (2007)). We have already depicted the energy conservation law in Figure 9.1. A similar conservation law holds for the momentum parallel to the surface $\hbar k_{||}$, where $k_{||}$ is the corresponding wave vector. The wave vector of the photon is usually negligible compared to that of the electron for the energy range in question, because its wavelength is very much longer. The wavelength λ and wave vector $k = 2\pi/\lambda$ of the photon are given by the photon energy $h\nu$ via

$$\left(\frac{\lambda}{\text{Å}}\right) = \frac{12399}{(h\nu/\text{eV})} \tag{9.3}$$

and the parallel wave vector of the electron by its kinetic energy E_{kin} and polar escape angle ϑ via

$$\left(\frac{k_{||}}{\text{Å}^{-1}}\right) = 0.51 \times \left(\frac{E_{\text{kin}}}{\text{eV}}\right)^{1/2} \sin\vartheta \tag{9.4}$$

(1 Å = 0.1 nm). The momentum component perpendicular to the surface is not conserved during the passage of the photoelectron across the surface energy barrier, but it can be varied by tuning the photon energy. Angular symmetry can be inferred from polarization selection rules for the point group at a particular point in momentum space. Spin is conserved.

The complete set of quantum numbers is usually displayed in the form of energy-versus-momentum band dispersion, labeled with the appropriate symmetry and spin symbols (see Figure 9.17 in Section 9.5.3). Another way to represent the quantum numbers is in the form of constant energy surfaces with two momentum components as variables (see Figure 9.18 in Section 9.5.3). The Fermi surface is particularly important, because electrons near the Fermi level determine most electronic properties of a solid, such as conductivity, superconductivity, magnetism, and electronic phase transitions. The relevant electron energies are within a thermal energy range around the Fermi level, which is given by the width 3.5 $k_{\text{B}}T$ of the Fermi–Dirac distribution (k_B = Boltzmann constant, T = absolute temperature, $k_BT \approx 25$ meV at room temperature).

The theoretical description of photoemission is provided by an expression similar to Fermi's Golden Rule for a differential cross section (for details see Schattke *et al.* (2003)). It contains the absolute square of a matrix element M_{if} for the optical transition between the initial state $|\psi_i\rangle$ and the final state $\langle\psi_f|$ of the photoelectron, an average over all possible initial states, and a sum over all final states that are detected. The matrix element takes the following form:

$$M_{\mathrm{if}} \propto \langle\psi_{\mathrm{f}}|\boldsymbol{A}(\mathbf{r}) \cdot \mathbf{p}|\psi_{\mathrm{i}}\rangle \tag{9.5}$$

$\mathbf{A}(\mathbf{r})$ is the vector potential of the photon, which becomes a constant in the widely used dipole approximation.

The initial state is $|\psi_i\rangle$ is a Bloch function in a solid or at a surface. For core levels and gas-phase photoemission, the initial state simply becomes an atomic/molecular wave function. In many-body theory, the initial state is not an electron but a hole. This seems to be at odds with the fact that the initial state was occupied by an electron before the photoemission process. However, to measure the binding energy of this electron, one needs to eject it by photoemission. That leaves a hole in the solid. In the following, we keep using the notion of electrons for both initial and final states with the understanding that initial state electrons should really be considered as holes.

The final state $\langle\psi_f|$ is often called *a time-reversed LEED state* (LEED is low energy electron diffraction), because an energy- and angle-resolving detector accepts only photoelectrons with well-defined momentum. Those are similar to the incident electrons in a diffraction experiment, except for the fact that the $\langle\psi_f|$ is a complex conjugate with an inverted propagation direction. The diffracted waves in LEED correspond to incoming electron waves in the final state of photoemission, which is somewhat counterintuitive but mathematically correct. Codes for such "single-step" photoemission calculations are now widely available (see Section 2.10 in Schattke *et al.* (2003)). The earlier "three-step" model separates the Golden Rule expression into three simpler but approximate steps, that is, optical excitation, scattering on the way out, and transmission/refraction at the surface.

For a quick interpretation of photoemission spectra, one has to mainly consider the various selection rules inherent in the optical matrix element M_{if}, such as the conservation laws for energy and momentum parallel to the surface (modulo a reciprocal surface lattice vector, see Himpsel (1983) and Kevan (1992)). The momentum perpendicular to the surface is not conserved, because the periodicity of a solid is destroyed in this direction. In the three-step model, one can keep perpendicular momentum conservation for the first step, which takes place completely inside the solid. However, transitions from bulk states to evanescent final states are not covered by this approximation. Another useful selection rule holds for parity of the wave functions with respect to a mirror plane. The product of the parities of the initial, the operator $\mathbf{A} \cdot \mathbf{p}$, and the final state has to be even.

Although selection rules provide clear yes–no decisions, there are also more subtle effects due to the wave functions of the electronic states involved in the matrix element. The atomic symmetry character determines the energy dependence of the cross section (Yeh and Lindau, 1985), allowing a selection of specific orbitals by varying the photon energy. For example, the s, p-states in transition and noble metals dominate the spectra near the photoelectric threshold, while the d-states turn on at 10 eV above threshold. It takes photon energies of 30 eV above threshold to make the f-states in rare earths visible. Resonance effects at a threshold for a core-level excitation can also enhance particular orbitals. Conversely, the cross section for states with a radial node exhibits so-called Cooper minima, where they become almost invisible.

The wave functions of the electronic states in solids and at surfaces are usually approximated by the ground state wave functions obtained from a variety of schemes, for example, tight binding, local density approximation (LDA), or Hartree–Fock. Strictly speaking, one should use the excited-state wave functions and energies that represent the hole created in the photoemission process, or the extra electron added to the solid in the case of inverse photoemission. Such excited-state quasiparticle calculations have now become feasible, and provide the most accurate band dispersions to date. Particularly in the case of semiconductors, the traditional ground state methods are unable to determine the fundamental band gap from first principles, with Hartree–Fock overestimating it and LDA underestimating it, typically by a factor of 2.

Photoemission is able to provide even more information than the complete set of quantum numbers. In many-body theory, an electron is described by the Green's function G(A, B), which describes the propagation of the electron from point A to point B – obviously a very fundamental description of an electron. Photoemission essentially measures the imaginary part of the Green's function in momentum space. From the Greens function, one can extract the self-energy Σ of an electron, whose imaginary part quantifies the scattering of electrons in a solid. The real part of Σ describes an energy shift due to many-body interactions, which is not contained in single-electron band calculations. The real and imaginary parts of Σ are related to each other by an integral transform, the Kramers–Kronig relation.

Experimentally, the information about the Green's function is contained in the lineshape of the transitions observed in angle-resolved photoemission. Measuring the intrinsic lineshape requires high energy and momentum resolution together with high-quality samples. This has become possible in recent years (see Figures 9.5 and 9.6 and Hüfner (2007)). The energy width ΔE of a spectral peak determines the scattering time τ and the momentum width Δp determines the scattering length l:

$$\tau = \frac{\hbar}{\Delta E} \qquad l = \frac{\hbar}{\Delta p} \tag{9.6}$$

For example, one can alloy 20% Fe into the Ni crystal to form permalloy, a key material for magnetoelectronics. Taking spectra similar to those in Figure 9.7, one finds that the momentum width greatly increases for the spin-down electrons but not for the spin-up electrons (not shown; see Altmann *et al.* (2001)). This leads to a scattering length l of 0.6 nm for spin-down electrons, which agrees with the result of magnetoresistance measurements.

The real part of the self-energy manifests itself in a transition from "dressed" electrons close to the Fermi level to "bare" electrons farther away from it. For example, an electron can be "dressed" by a phonon cloud due to electron–phonon interaction (Plummer *et al.*, 2003). If the

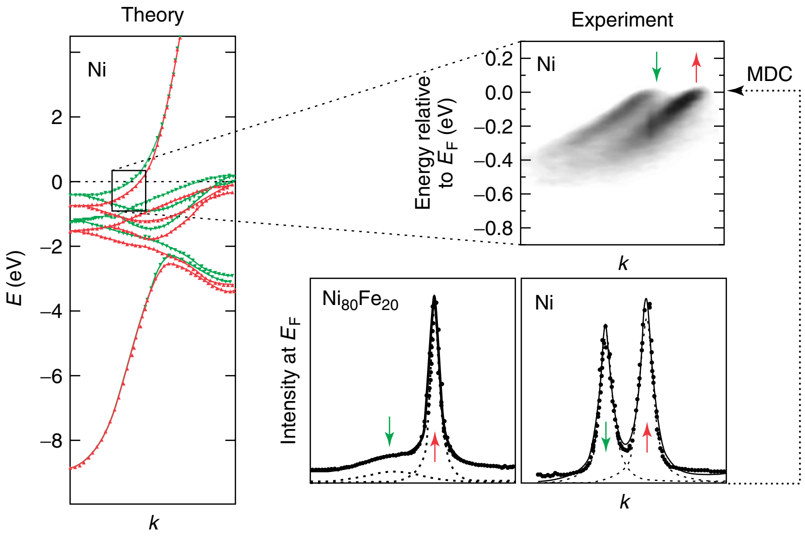

Fig. 9.5 Energy-versus-momentum band dispersions of ferromagnetic nickel, showing two sets of bands for the two spin directions (calculations on the left, data on the right). Modern electron spectrometers with energy and angle multidetection can zoom into the bands close to the Fermi level and image the band dispersion (upper right, with high photoemission intensity shown in dark shade). A momentum distribution curve (MDC) reveals the momentum broadening due to the finite scattering length (lower right). After Altmann *et al.* (2001).

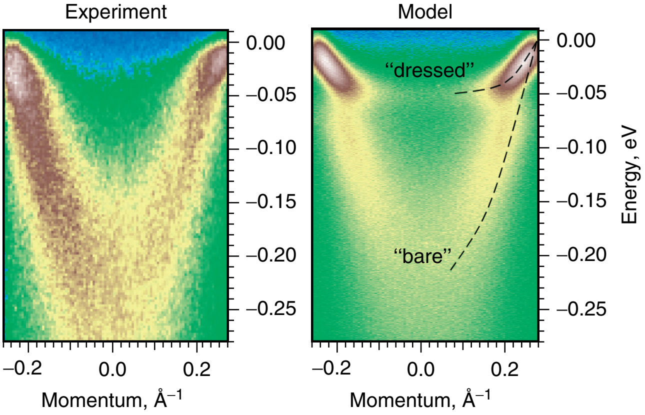

Fig. 9.6 Experimental and calculated plots of the photoemission intensity versus E and k for a high-temperature superconductor. There is a kink at about −0.04 eV, which indicates the transition from "dressed" to "bare" electrons. From Inosov *et al.* (2007).

electron moves too fast, the phonon cloud cannot follow and leaves a bare electron. This transition from dressed to bare electrons happens about one phonon energy away from the Fermi level. It manifests itself as a kink in the

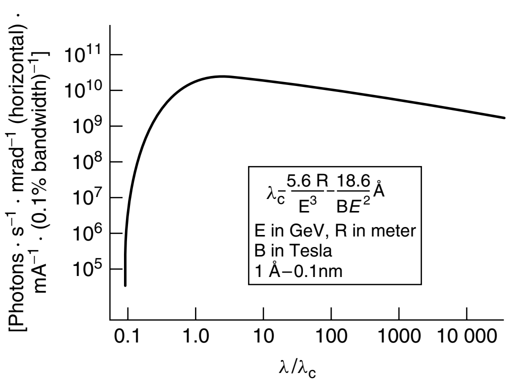

Fig. 9.7 The universal curve for the synchrotron radiation flux, plotted with λ/λ_c on the horizontal axis. λ_c is the critical wavelength, given by the electron energy E, the radius R of the electron orbit, or the magnetic field of the bending magnet.

$E(k)$ band dispersion where band curvature changes. The curvature is related to the inverse effective mass, and the mass changes from heavy for dressed electrons to light for bare electrons. An example is shown in Figure 9.6. This effect is particularly interesting for superconductors. Electrons are paired by exchanging phonons in conventional superconductors. The big question in high-temperature superconductors is the pairing mechanism, that is, the nature of the particle exchanged between pairs. The search for this particle has led to an intense study of kinks in the bandstructure of high-temperature superconductors. The example in Figure 9.6 shows how to model such a kink self-consistently in terms of the real and imaginary parts of the self-energy (Inosov *et al.*, 2007).

9.2
Instrumentation

9.2.1
Light Sources

To excite photoelectrons, a minimum photon energy of 5–10 eV is required. This is one of the reasons why conventional lasers have been of limited applicability in photoelectron spectroscopy. A detailed discussion of the possible sources for photoelectron excitation is given in Siegbahn and Karlsson (1982). In the ultraviolet radiation region, the most common source is based on a capillary glow discharge. The most convenient line is the so-called He I, which provides monochromatic radiation with a narrow line-width at 21.2 eV. This radiation originates from the 2p to 1s transition in neutral He atoms. Emission can also be produced from the He ions, the primary emission line being He II at an energy of 40.8 eV. Similarly, emission lines of Ne I at 16.8 eV and Ne II at 26.9 eV have frequently been used in photoelectron spectroscopy. Recent designs produce very efficient and highly monochromatic radiation by electron cyclotron resonance (ECR) in low-pressure He gas.

When a target is bombarded with an electron beam of sufficient energy and intensity, X-rays will be emitted via core-level fluorescence or bremsstrahlung. In principle, a vast amount of X-ray emitting materials should be available, but there are very few practical X-ray sources with high intensity, narrow energy width, and without satellite structures. The dominant radiation sources are Mg K_α at 1253.6 eV and Al K_α at 1486.7 eV. Because both magnesium and aluminum are easy to handle and their inherent line-width is as narrow as 1 eV, most commercial X-ray anodes are based on Al and/or Mg as the target material. It is also possible to produce monochromatized Al K_α and Mg K_α radiation by using, for instance, a quartz crystal monochromator. An excitation line-width of a few tenths of an electronvolt can be achieved, but with considerable loss of intensity. These technical approaches of achieving higher resolution have found their way into commercial instruments.

During the last two decades, synchrotron radiation has emerged both as a powerful and convenient excitation source in photoelectron spectroscopy (Winick and Doniach 1980; Koch, 1983; Winick *et al.*, 1989). The term *synchrotron radiation* is usually associated with the radiation emitted by relativistic electrons accelerated in a circular orbit. The basic properties of synchrotron radiation were first presented in an elegant paper by Schwinger (1949), although they had been treated much earlier by Schott (1912). With E being the electron energy and R the radius of the circular orbit, the total synchrotron radiation energy emitted per revolution by one electron is given by

$$\Delta E(R, E) = \frac{4\pi}{3} \times \frac{e^2}{R} \times \left(\frac{E}{m_0 c^2}\right)^4 \quad (9.7)$$

The spectral radiation distribution is characterized by a critical energy ε_c, given by

$$\varepsilon_c = \frac{3hc}{2R} \times \left(\frac{E}{m_0 c^2}\right)^3 \quad (9.8)$$

The physical significance of this equation is that half of the total power is radiated above the critical energy and half below. The photon intensity rapidly decreases for photon energies above the critical energy ε_c. A universal curve for the synchrotron radiation photon flux is shown in Figure 9.7. Synchrotron radiation has a number of desirable properties. It provides (i) a continuous spectral distribution from the infrared region into the X-ray region, (ii) high intensity, (iii) high degree of collimation, (iv) high degree of polarization (completely linearly polarized in the plane of the orbital and elliptically out of the plane), and (v) a pulsed time structure given by the orbital frequency of the circulating electron beam. An important development occurred with the realization that magnetic structures inserted in straight sections of the storage ring, so-called undulators and wigglers, could drastically improve the radiation characteristics of conventional bending magnets. Presently, severalz facilities are in operation and under construction that are optimized for these insertion devices, so-called third-generation sources. Figure 9.8 (Winick, 1994) shows the brightness of X-ray sources as a function of time since the X-ray tube was first introduced in 1895. Synchrotron radiation provides a few orders of magnitude higher brightness than conventional sources. Intense efforts are presently under way for the next step of source developments, that is, vacuum ultraviolet (VUV) and X-ray free-electron lasers (XFEL), also based on undulators but using linear accelerators instead of storage rings and using seed lasers. In addition to the properties listed above, such sources will provide femtosecond time resolution, full transverse coherence, and about ten orders of

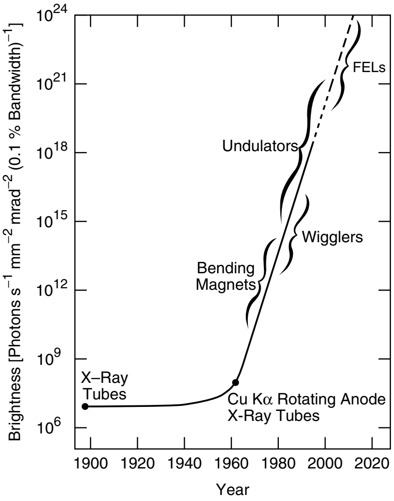

Fig. 9.8 Spectral brightness of X-ray sources as a function of time. From Winick (1994).

magnitude increase in peak brightness. Coupled with the rapid developments of conventional lasers toward even shorter wavelengths, the next decade will undoubtedly see spectacular improvements in light sources for photoemission (Chattopadhyay *et al.*, 2001).

An important advancement in laser-based sources for photoelectron spectroscopy has recently been achieved by developing a UV laser that can reach a photon energy of 6.994 eV while producing 10^{15} photons per second (Kiss *et al.*, 2005). It operates in a quasi-continuous-wave (quasi-CW) mode at a repetition frequency of 80 MHz. The high photon energy of 6.994 eV is achieved via the second harmonic of a frequency-tripled Nd : YVO_3 laser by using an optically contacted prism-coupled KBBF ($KBe_2BO_3F_2$) crystal (Togashi *et al.*, 2003). The setup is shown schematically in Figure 9.9(a). The electrons emitted from the sample have low kinetic energies, typically a few electron volts, and their energy and angle distributions are determined with a high-precision hemispherical electron analyzer. The laser source with unprecedented performance characteristics in combination with a high-resolution spectrometer has made it possible to measure spectra with a total resolution down to 360 μeV for electrons plus photons (Figure 9.9b). This points to the importance of developing novel sources in parallel with improvements in detector technology (as discussed in Section 9.2.2). The impact of these new laser sources is also related to the basic photoemission phenomena discussed in Section 9.1.2. The mean free path of photoelectrons increases with the decrease in kinetic energy, with the implication that the laser source discussed here makes it possible to study bulk phenomena. This is of particular importance for materials with large unit cells. The combination of ultrahigh energy resolution and bulk sensitivity has opened up new avenues to study complex phenomena, such as high-temperature superconductivity.

9.2.2
Detectors

The most common type of photoelectron spectrometers has been the hemispherical analyzer, which is of the electrostatic type. A key feature of efficient spectrometers is parallel detection. Energy

multidetection in hemispherical analyzers has been widely used for core-level spectroscopy (Section 9.4). There exist custom designs with more than one variable being detected simultaneously, such as energy and one angle in toroidal analyzers and two angles in display spectrometers. Simultaneous energy and angle multidetection has become available commercially with hemispherical spectrometers (Martensson *et al.*, 1994), which has led to a renaissance of angle-resolved photoemission from valence states. The states very close to the Fermi level E_{Fermi} can now be mapped with an energy resolution comparable to the thermal energy and a momentum resolution comparable to the inverse mean free path. This is illustrated in Figure 9.5 for ferromagnetic nickel, in which the energy-versus-momentum band dispersion is plotted (Altmann *et al.*, 2001). The $E(k)$ relation can be viewed directly on a television monitor, and the data in Figure 9.5 (upper right) are simply the time average of such a screen image. Currently, a third dimension is added to the multidetection method by incorporating time-of-flight energy detection into a spectrometer that displays both in-plane momentum components. Combined with short laser pulses, one can achieve very high energy resolution.

ZEKE (zero kinetic energy spectroscopy) was invented about 25 years ago (Schlag, 1998) and has developed rapidly since then (Cockett, 2005). Its main impact has been on high-resolution studies of molecular ions where it has yielded information on transition states in chemical reactions. ZEKE can provide energy resolutions 2–3 orders of magnitude higher than conventional photoelectron spectroscopy. The ZEKE technique is based on laser ionization of the molecule followed by a delayed

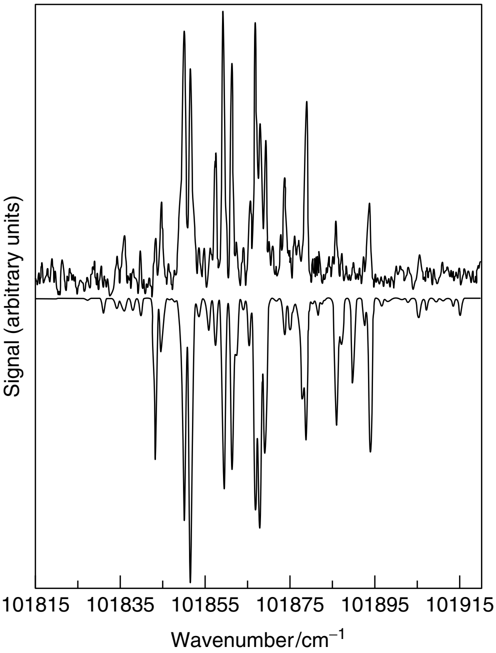

Fig. 9.10 Top: Rotationally resolved ZEKE photoelectron spectrum of a single vibrational structure in deuterated methane (CD_2H_2). Bottom: A simulated spectrum (inverted), broadened by a Gaussian line shape (0.7 cm^{-1} = 87 μeV full width half maximum). From Signorell and Merkt (2000).

electric pulse. In this way, electrons with zero kinetic energy can be separated out from the rest of the emitted electrons. Thus in a time-of-flight arrangement, the zero kinetic energy electrons can be collected separately. The physics behind ZEKE is intimately connected to Rydberg states. Rydberg states have hydrogenic characteristics with a very large principal quantum number n. The electrons in Rydberg states reside in very large orbitals and thus are much less sensitive to decay processes. This is the key for achieving high resolution. The ZEKE method is based on field ionization from the large-n Rydberg states. Even though conventional photoelectron spectroscopy with HeI radiation has been used routinely to study the vibrational fine structure of molecular energy levels, ZEKE makes it possible to resolve the entire set of vibrational levels, not only for the electronic ground state but also for the first excited state (Signorell and Merkt, 2000). It has also been demonstrated that fully resolved rotational spectra provide unprecedented information on the structure of molecular ions, for example, in a number of isotopomers of the methane ion (Keski-Rahkonen and Krause, 1974) (see Figure 9.10). Most of them exhibited such a small Jahn–Teller effect that structural changes can be ascribed to tunneling phenomena. For a normal Jahn–Teller effect, by contrast, the structure will be frozen to a specific minimum.

For detecting the spin of photoelectrons, one typically measures the right/left asymmetry in the electron scattering cross section at heavy nuclei (Mott scattering), after accelerating photoelectrons to 100 keV. A less bulky detector uses scattering at the electron cloud surrounding a heavy nucleus, typically at 150-eV electron energy. It lacks the absolute calibration of a Mott detector, however. In general, spin detection costs 3–4 orders of magnitude in detection efficiency.

9.3
Photoelectric Yield and Absorption Spectroscopy

9.3.1
Mechanism

This section starts with the simplest measurement in photoemission, which consists of determining the total photocurrent versus photon energy. Subsequent sections will deal with energy- and angle-resolved differential cross sections.

Before sophisticated measurements became routine, the determination of the quantum yield near the photoelectric threshold dominated the field. Such measurements were used to confirm the Einstein formula (Millikan, 1916), and to obtain the work function Φ of various materials by finding the photon energy for the onset of photoemission. Accurate determinations involved various extrapolation schemes, predicting certain power laws for the photoelectric yield near threshold (Fowler, 1931; Cardona and Ley, 1978). The photoelectric yield increases roughly like the square of the excess energy, because photoemission is dominated near threshold by the narrowing of an "escape cone" in momentum space that contains the electronic states with sufficient momentum perpendicular to the surface to overcome the surface potential step. Quantum yield measurements had technological consequences in the development of photocathodes for photomultipliers and night vision goggles.

The bulk of today's yield measurements is performed in a regime far above the photoelectric threshold, that is, at core-level absorption edges. In this case, the total electron yield (TEY) is closely related to the absorption coefficient, as long as the escape depth of the photoelectrons is short compared to the absorption length of the photons (Gudat and Kunz, 1972). Essentially, the number of photoelectrons is proportional to the number of core holes generated, which in turn is proportional to the absorption coefficient in the linear absorption regime near the surface. In the following, we will discuss applications of near edge X-ray absorption fine structure (NEXAFS) measurements. They involve transitions from a core level to the lowest unoccupied states. These are typically atomic/molecular orbitals that characterize the local chemical bonding and the magnetism at a specific atom. In semiconductors one observes the lowest conduction bands. Electron yield measurements over a wider photon energy range (hundreds of electronvolts) are usually labeled as EXAFS (extended X-ray absorption fine structure). The related technique of photoelectron diffraction is discussed in Section 9.6.1.

9.3.2
Unoccupied Atomic and Molecular Orbitals

Many molecules or polymers have characteristic unoccupied orbitals that dominate the absorption fine structure within the first tens of electron volts above a core-level threshold, most notably the lowest unoccupied orbital (LUMO), which serves as the electron acceptor in chemical reactions. (Its occupied counterpart, the highest occupied molecular

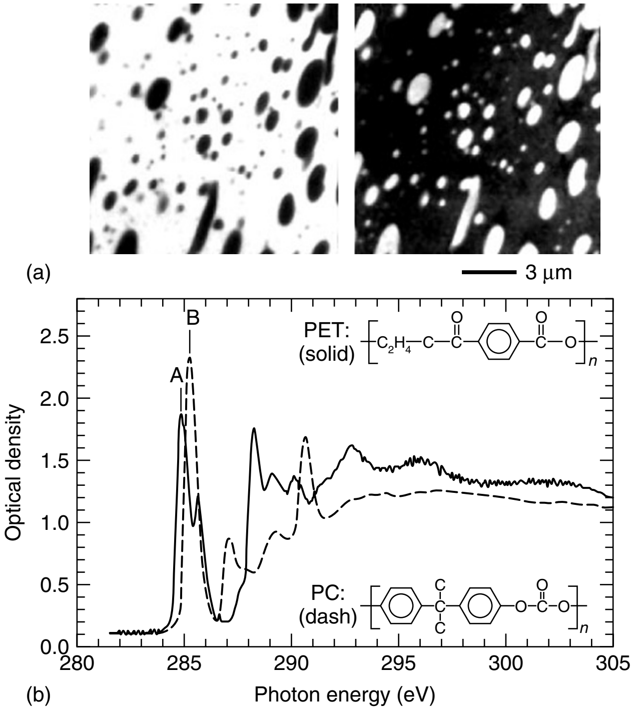

Fig. 9.11 Identification of different polymers in a blend by their π^* orbitals. The carbon 1s core-level absorption spectra (a) are used to identify the C1s to π^* transition energies of two polymers. By tuning into the respective π^* resonances, the two components can be distinguished in the micrograph (b). From Ade *et al.* (1992).

orbital (HOMO), can be measured by valence electron spectroscopy, which is discussed in Section 9.5.1.) The pattern of antibonding π^* and σ^* orbitals often serves as a fingerprint of a molecule. A large database of gas-phase spectra (Hitchcock and Mancini, 1994) helps in identifying surface species in NEXAFS (Stöhr, 1992). The polarization dependence of the absorption from different orbitals provides the orientation of adsorbed molecules. Similar applications exist with polymers. Figure 9.11 shows that two different polymers in a blend can easily be distinguished by their π^* orbitals (Ade *et al.*, 1992).

9.3.3
Solids

Absorption spectroscopy in solids provides information about the unoccupied states, like in the gas phase. In contrast to molecular systems, in which the Coulomb interaction between the excited electron and the core hole significantly distorts the energy scale, there is enough screening in many solid state systems to use the absorption spectrum directly as a measure of the density of unoccupied states. By using different core levels, it is possible to project the density of states onto a particular atomic species and to select states with

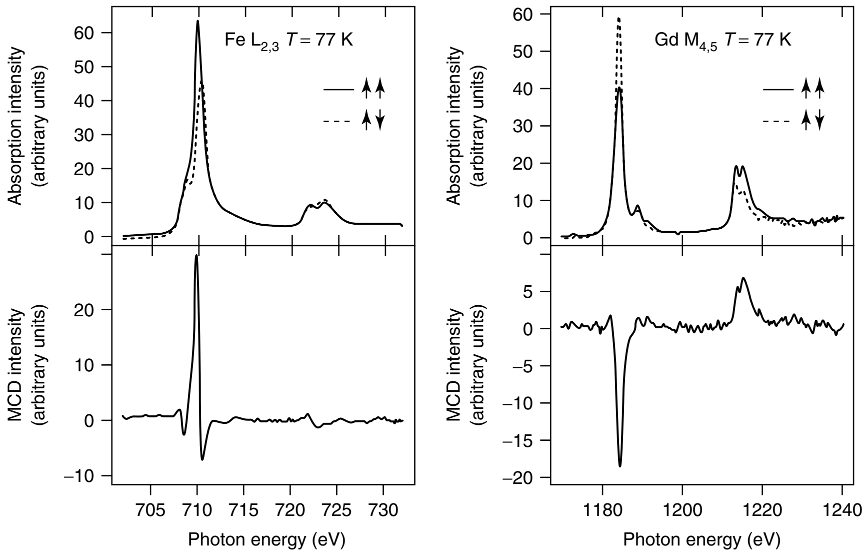

Fig. 9.12 Use of magnetic circular dichroism for determining the magnetization of the elemental species Fe (a) and Gd (b) in a garnet. Two absorption spectra for opposite magnetization directions are shown on top, and their difference at the bottom. From Rudolf *et al.* (1992).

a specific angular momentum l, using the $l \rightarrow (l \pm 1)$ selection rule. A more thorough analysis has to include the electron–hole interaction, which lowers the transition energy and leads to a characteristic multiplet structure, particularly for the localized 2p → 3d and 3d, 4d → 4f transitions.

9.3.4
Magnetic Dichroism

Using circularly polarized light with magnetic samples, it is possible to determine magnetic properties of specific atoms in magnetic alloys, at surfaces, and in molecules. Atomic sum rules produce an estimate of both the spin and the orbital contribution to the local magnetic moment. The two pieces of independent information come from the dichroism of the two spin-orbit partner lines of a core level, that is, the change in absorption induced by flipping the helicity of the light relative to the magnetization of the sample. In addition, one can play all the other selection rules, such as projecting the magnetic moment onto an atomic species or separating magnetism of d-electrons from that of f- and s-, p-electrons. Figure 9.12 gives an example, in which the magnetization of different constituents in a gadolinium iron garnet is determined (Rudolf *et al.*, 1992). This ability of separating the magnetism of different elements is very helpful for tailoring magnetic materials in magnetic nanostructures (Himpsel *et al.*, 1998).

9.3.5
Microspectroscopy

The recent development of third-generation synchrotron light sources with high brilliance makes it possible to perform absorption measurements with a spatial resolution down to tens of nanometers. The two pictures of a polymer blend in Figure 9.8 were taken at two different photon energies, where the two components absorb differently because of their different π^* orbital energies (Ade *et al.*, 1992). In this case, the absorption coefficient was measured directly in a scanning transmission X-ray microscope (STXM). Such experiments are frequently performed with an imaging photoemission electron microscope (PEEM). Microspectroscopy promises to become a versatile method that identifies not only the elemental species in a sample by the choice of the core-level absorption edge but also their chemical state by selecting transitions into individual unoccupied valence states. There are many applications in magnetism, biology, geology, tribology, and environmental science.

9.4
Core-Level Spectroscopy

9.4.1
Origin of Core-Level Shifts

The photoelectric effect shown in Figures 9.1 and 9.2 applies not only to valence electrons but also to the deeper core levels, provided the incoming photons have sufficient energy to overcome the core-level binding energy. Analogous to Eq. (9.1), it is possible to obtain the binding energy of a core electron from the photon energy and the kinetic energy. In a simplified picture, the electrons will thus appear at discrete energies characteristic for each element. XPS is thus element-specific. The binding energy is also sensitive to the chemical environment of an atom, which led to the acronym ESCA.

Quantitative calculations of core-level shifts need to take into account both the initial state electronic structure (the chemical shift) and the relaxation in the final state (which is caused by the removal of an electron) (Fadley, 1978). In the most simplified picture, the magnitude of the chemical shift is correlated with the amount of charge transfer in the initial state. For instance, the binding energy of a core level increases with the oxidation state of an element, because the increasing positive charge on the atom binds a core electron more strongly. This is demonstrated for the oxidation states of silicon in Figure 9.13 (Himpsel, 1990). All oxidation states of silicon are resolvable, with the three peaks between Si and SiO_2 originating from intermediate oxidation states, Si^{1+}, Si^{2+}, and Si^{3+}. An electropositive ligand gives up electrons to silicon, causing a chemical shift in the opposite direction, as shown on the right side of Figure 9.13 for calcium. It is interesting to note that the chemical shift in SiO_2 increases slightly with increasing oxide thickness (not shown), a manifestation of decreased screening in the final state. The intensity of the different oxidation state peaks in Figure 9.13 can be used to estimate the amount of suboxides in the interfacial $Si-SiO_2$ region (Himpsel *et al.*, 1988). This information has been quite valuable as a diagnostic tool for improving the gate oxide in silicon-base field-effect transistors and for developing high-k dielectrics to replace SiO_2 in the most recent generation of silicon microchips.

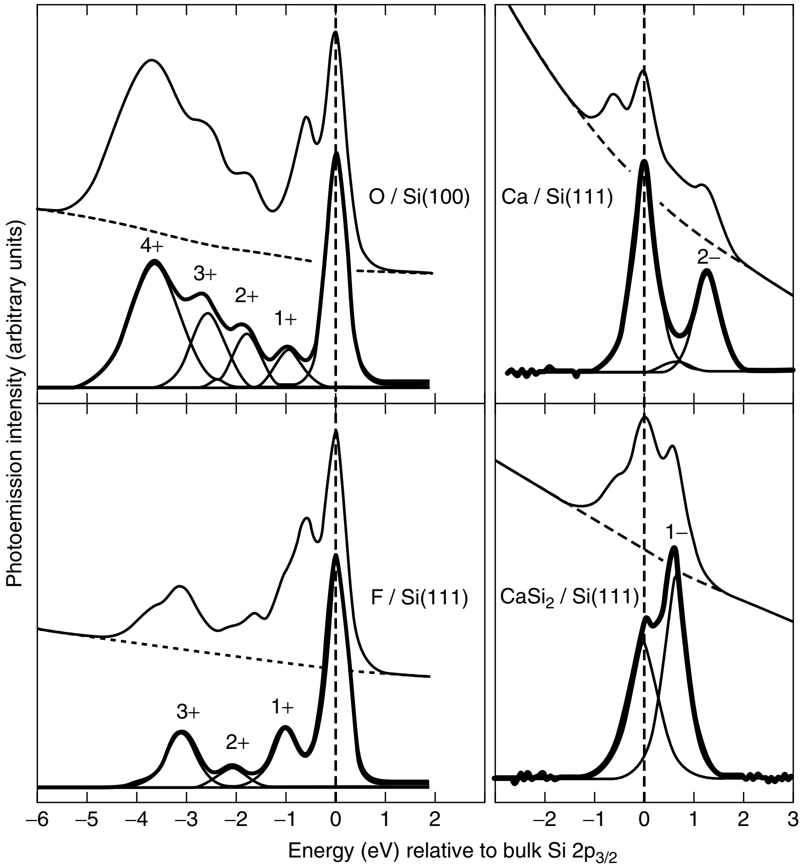

Fig. 9.13 Discrete chemical shifts, observed for different oxidation and reduction states of silicon. Electronegative ligands (O, F) give rise to chemical shifts toward higher binding energy and electropositive ligands (Ca) induce shifts to lower binding energy. Raw data are given on top of each panel. At the bottom, the secondary electron background has been subtracted and the Si $2p_{1/2}$ component removed. After Himpsel *et al.* (1988).

9.4.2
Atoms, Shake-Up, and Shake-Off Satellites

The core-level spectra from a closed-shell noble gas atom should in principle be very simple with discrete peaks corresponding to the different atomic subshells. However, final-state effects give rise to multielectron excitations, and atomic core-level spectra are characterized by a complex satellite structure, first discussed in Carlson (1967). The most likely multielectron process is a two-electron transition. However, higher order transitions and configuration interactions also contribute to the satellite spectra. It is common to distinguish between shake-up states and shake-off states, in which the second electron is excited to a higher bound state or an unbound continuum, respectively. The

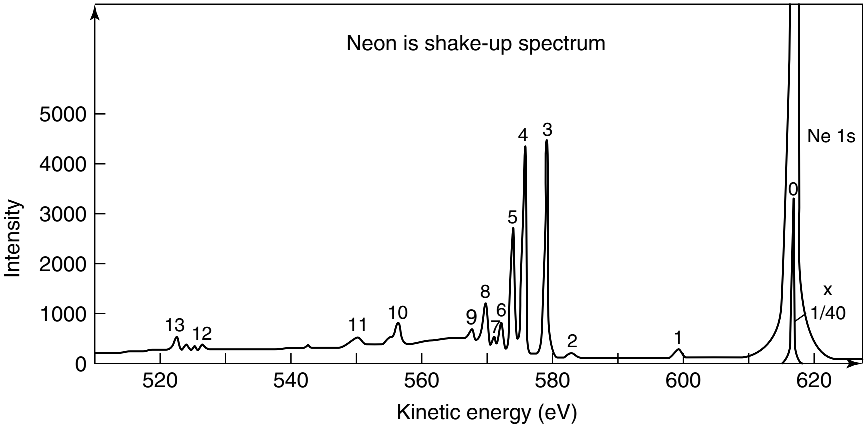

Fig. 9.14 The Ne 1s core-level photoelectron spectrum with accompanying satellites, labeled 1 through 13. From Gelius (1974).

Ne 1s core-level spectrum and the magnified satellite structure of the one-electron 1s line are shown in Figure 9.14. A detailed discussion and compilation of atomic core-level spectra and satellites can be found in Siegbahn and Karlsson (1982) and Sonntag and Zimmermann (1992).

9.4.3
Adsorbates and Surfaces

The chemical core-level shift of molecules adsorbed at surfaces provides information about the nature of chemisorption, dissociative or non-dissociative, as well as structural information. Figure 9.15 illustrates the results for carbon monoxide on Pt(111) (Björneholm *et al.*, 1993) by showing spectra for all relevant core levels (O 1s, C 1s, and Pt 4f). The clean Pt 4f spectrum contains two components, one for the topmost atomic layer, and the other for the underlying bulk Pt (Johansson and Mårtensson, 1980). CO forms a number of ordered phases on Pt (111), depending on the coverage. All of these have distinct arrangements of the CO molecule at the surface (on top, bridge site, and so on), and each of these structures leads to a characteristic chemical shift of the O 1s and C 1s levels. Chemically shifted peaks can thus provide information about both the bonding and the structure of adsorbed systems (Andersen *et al.*, 1991). They are used extensively by companies involved in semiconductor materials processing, developing catalysts, tribology, and surface coating. Tunable synchrotron radiation makes it possible to optimize the surface sensitivity of core-level spectroscopy by detecting photelectrons near the escape depth minimum (Figure 9.4).

Third-generation synchrotron radiation sources have opened up new avenues in core-level studies thanks to higher brightness and improved energy resolution. Time-resolved core-level spectroscopy is now feasible, as demonstrated for CO overlayers on Mo(110) in Figure 9.16 (Jaworowski *et al.*, 2001). As the exposure to CO is increased, the C 1s level first shifts toward higher

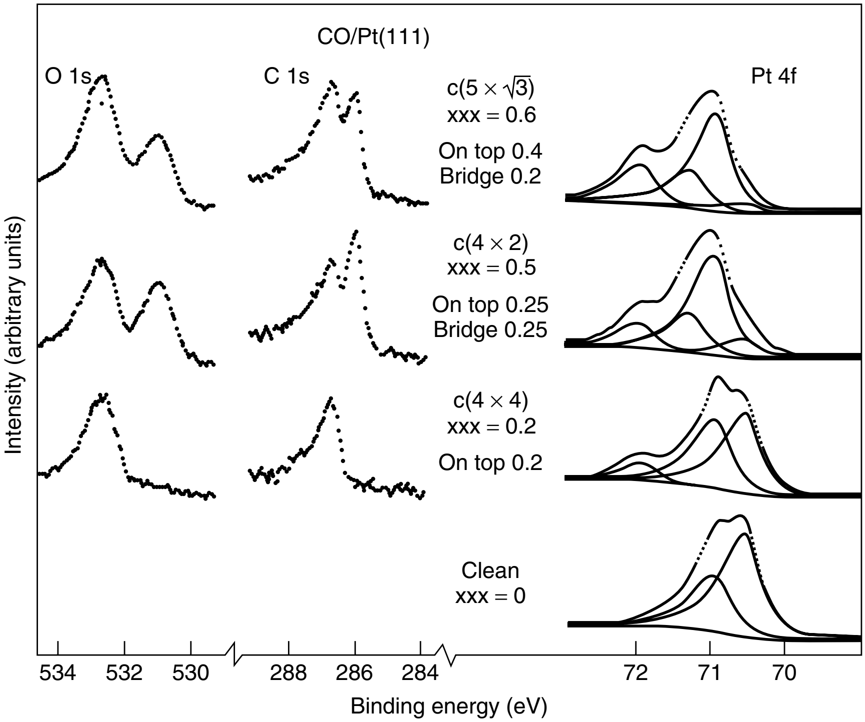

Fig. 9.15 The O 1s, C 1s, and Pt 4f core-level photoelectron spectra for various structures of CO chemisorbed on Pt(111). Adsorbate and substrate core-level shifts provide bonding site information. From Björneholm *et al.*, (1993).

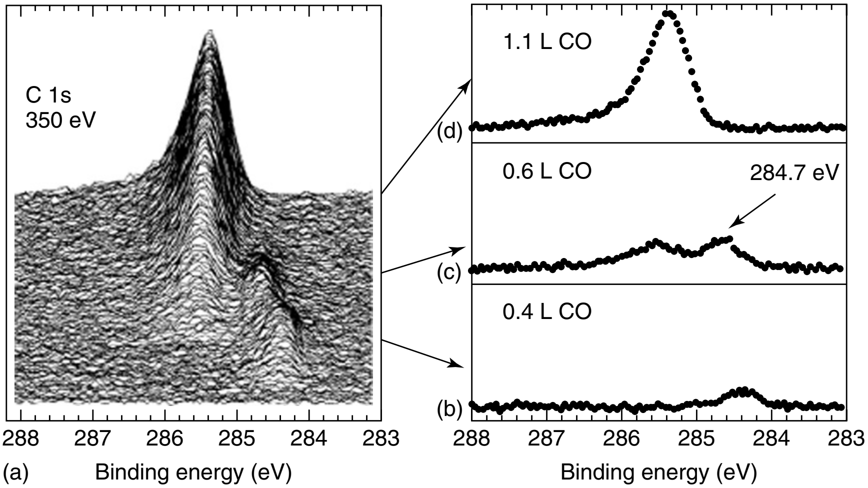

Fig. 9.16 Time-resolved core-level spectra from the C 1s region as a Mo(110) surface is exposed to CO. The recording time for each spectrum is 16 s. From Jaworowski *et al.* (2001).

binding energy and then develops a second component. A further increase of the CO coverage reduces the first component until it eventually disappears at saturation coverage. This evolution can be understood by a change in the tilt angle of the CO molecules at the surface. Such studies are valuable for understanding the precursor state before the molecular dissociates at higher temperature.

9.4.4
Solids

In Section 9.4.1, it was pointed out how core-level spectroscopy can be used for both qualitative (elemental and chemical specific) and quantitative analysis. Here, two other aspects of studies of solids are illustrated. The first example relates to the growth of thin films and their interfaces, a topic of particular importance for semiconductor structures (for an overview, see Weaver (1988)). The growth of a II-VI compound on a III-V semiconductor, that is, CdTe on InSb(100) is characterized by quantitative core-level spectroscopy using synchrotron radiation in Figure 9.17 (Mackey *et al.*, 1986). Two different growth conditions are shown, that is, room temperature (a) and 500 K (b). The core-level spectra show the evolution of the intensity of the 4d levels of In and Sb (substrate), and Cd and Te (overlayers) with increasing CdTe deposition. At room temperature, the overlayer appears to be stoichiometric (no relative change in the Cd and Te core- level intensities), and the In–Sb 4d core levels are attenuated monotonically. The interface is obviously quite abrupt because the substrate core levels are covered up by 7–15 Å of CdTe. The situation is dramatically different for deposition at 500 K. The In 4 d signal does not decrease as much as Sb 4d, the Te 4d is broadened, and the Cd signal is barely detectable. In this case, chemical reactions take place at the interface and an interfacial layer with indium telluride forms with segregated Sb. It can be concluded that the interface is neither abrupt nor stoichiometric on an atomic scale.

A second example deals with core-level spectra, which are completely dominated by atomic final-state effects and are very insensitive to the chemical environment. The most prominent representatives can be found among rare-earth compounds. The 4f core-level spectra for a few rare-earth antimonides are shown in Figure 9.18 (Campagna, Wertheim and Bucher, 1976). All the three spectra can be described very well with final-state multiplets without any consideration of the effects from differences in the chemical environment. From the multiplet structure, one can directly read off the valence of the rare-earth atoms.

9.5
Valence Electron Spectroscopy

Valence states are more complex than core levels, because their wave functions extend out to neighbor atoms and interact with them. Consequently, the set of quantum numbers characterizing valence states is richer, containing the three momentum components as additional quantum numbers (in solids) and forming bonding–antibonding orbital combinations (in molecules). The extra quantum numbers are determined by using additional variables, such as the angular pattern of the photoelectron

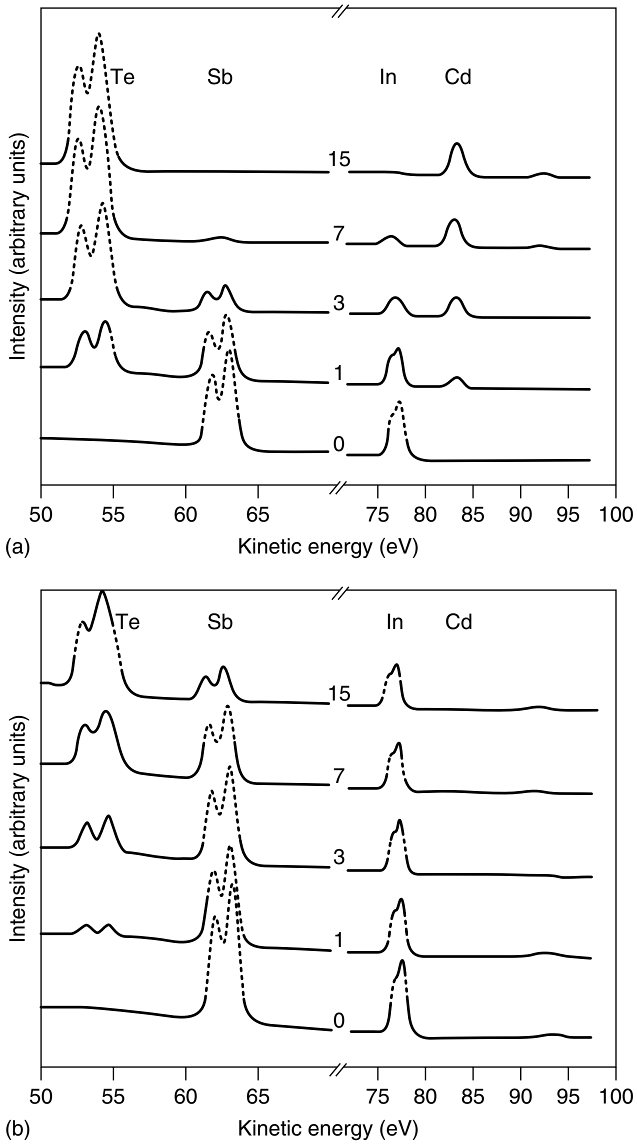

Fig. 9.17 Growth of CdTe on InSb(100), studied via the intensities of the 4d core levels (film thickness given in angstroms). At room temperature (a) the overlayer is stochiometric with a sharp interface. At 500 K (b) an interfacial layer of InTe is formed, together with segregated Sb. From Mackey *et al.* (1986).

and the photon polarization. The optimum energy range for mapping valence states has an upper limit of about 50 eV, because the cross section of valence states decays rapidly at higher photon energies.

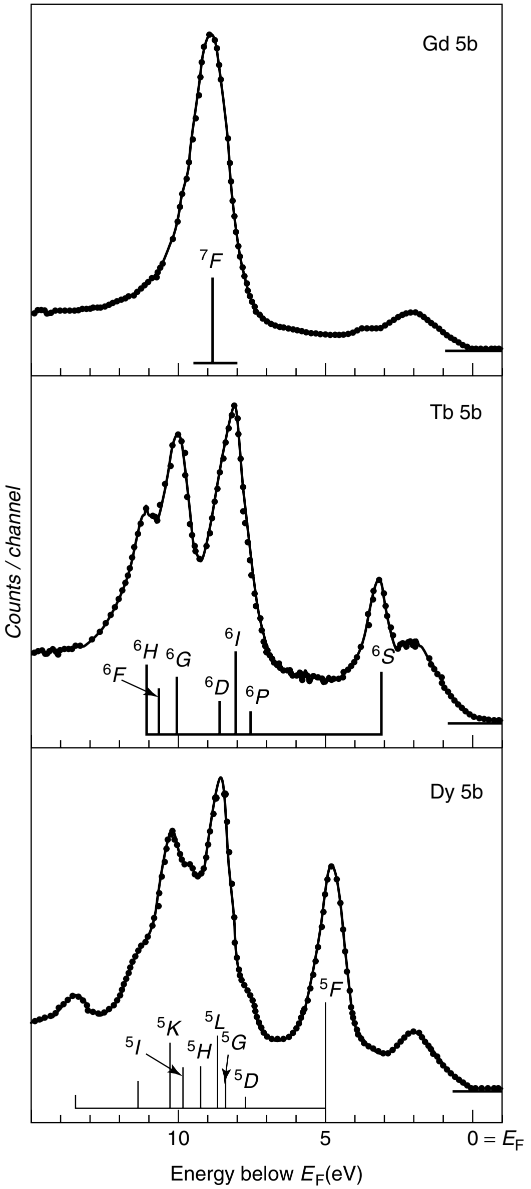

Fig. 9.18 Core-level spectra of the 4f levels for rare-earth antimonides. The agreement with calculated $4f^{n-1}$ multiplets shows that the multiplet structure reflects the number of 4f electrons in the final state. From Campagna, Wertheim and Bucher (1976).

9.5.1
Occupied Atomic and Molecular Orbitals

The valence orbitals of free molecules can be resolved in great detail by UPS (Turner *et al.*, 1970), including vibrational and rotational fine structure. During adsorption at a surface, for example, in catalysis-oriented studies, the molecular orbitals can be used for fingerprinting the adsorbate (Figure 9.19 (Demuth and Eastman, 1974)). Orbitals

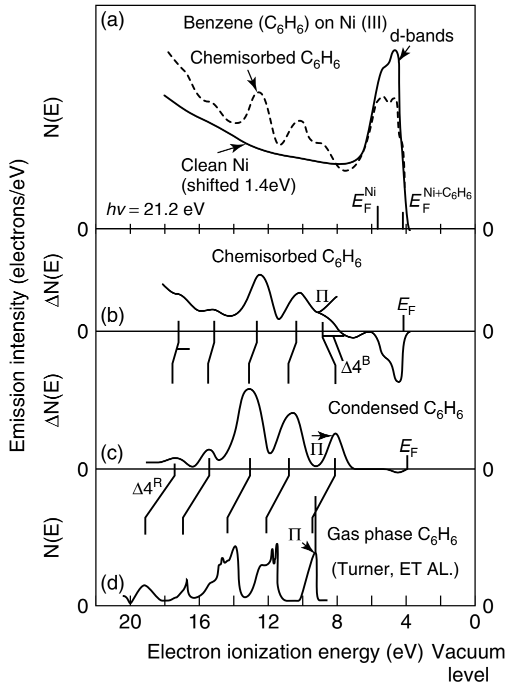

Fig. 9.19 Fingerprinting of adsorbed molecules by photoelectron spectroscopy. Benzene in the gas phase exhibits a characteristic pattern of valence orbitals (Turner *et al.*, 1970), which is shifted rigidly in energy after condensing it at a surface. The stronger chemisorption bond on a nickel surface causes the uppermost bonding orbital to fall out of place. From Demuth and Eastman (1974).

not involved in the surface-to-adsorbate bond experience only a rigid, upward energy shift, which is due to dielectric screening at the surface. Therefore, the pattern of orbital energies at a surface is often sufficient to identify the adsorbate, to decide whether or not a molecule has decomposed, and to pinpoint the orbitals that are involved in the surface bond by their additional energy shift.

Angular effects are averaged out in randomly oriented molecules except for only a single parameter β, which determines the angular distribution $d\sigma/d\Omega$ of photoelectrons in terms of the polar emission angle θ relative to the polarization of the light:

$$\frac{d\sigma}{d\Omega} = \left(\frac{\sigma}{4\pi}\right) \times (1 + \beta P_2(\cos\vartheta)) \qquad (9.9)$$

$P_2(x) = (3x^2 - 1)/2$ is the $l = 2$ Legendre polynomial. The asymmetry parameter β can take values between -1 and 2. At the magic angle $\vartheta = 54°$ the emission intensity is independent of β, making this a useful geometry for quantitative measurements of the cross section σ of a given orbital.

Molecules adsorbed at surfaces can be oriented by a crystalline substrate. In such a case, it becomes possible to determine their orientation by changing the polarization of the light and using dipole selection rules. For example, a p_z orbital is excited with the electric field vector along the z-direction, and a $p_{x,y}$ orbital with the component along the x, y- direction.

9.5.2
Surfaces and Quantum Wells

The surface disrupts the potential for electrons in a solid enough to give rise to separate surface states. They can have localized, broken-bond character, such as in semiconductors, or delocalized, evanescent wave character, such as s, p-states in metals. The d-states at metal surfaces lie somewhere in between. Surface states can be ideally probed with photoelectron spectroscopy when working at kinetic energies of 20–70 eV for the photoelectrons, where their escape depth goes through a minimum that is only a few atomic layers deep. Another way to become more sensitive to surface states is by placing the momentum and the kinetic energy of the photoelectrons in a band gap of bulk states. Both methods require tunable synchrotron radiation.

There are several criteria that help in distinguishing surface states from bulk states. The "crud" test is based on the assumption that a surface state is quenched by an adsorbate, which is true in most, but not all, cases. A cleaner method utilizes the two-dimensional nature of surface states, which implies that the energy of a surface state does not vary with the momentum perpendicular to the surface. This is tested by varying the photon energy at fixed parallel momentum. The most thorough test for a surface state consists of mapping all the bulk bands and ensuring that the state falls into a symmetry gap of the band structure. There are many surface resonances, however, that do not pass this last test but still exhibit strong localization in the outermost layer.

Quantum well states are two-dimensional, like surface states, but they are confined on both sides. Typically they are observed in highly perfect thin films where they are confined on the outer side by vacuum and on the inner side by a step in the inner potential. These films may be viewed as electron interferometers similar to a Fabry–Perot interferometer in optics. The standing electron waves inside the inerferometer correspond to quantum well states. Magnetic quantum well states play a role in magnetoelectronics, for example in the effect of giant magnetoresistance (GMR) that is used in reading heads for magnetically-stored data (compare Himpsel *et al.* (1998) for electronic states in magnetic nanostructures).

Quantum well states can be confined laterally in quantum wires and quantum dots, leading to one- and zero-dimensional electronic states. Currently, it is only possible to measure an ensemble of wires and dots where size inhomogeneities lead to an inhomogeneous broadening of the electronic states. Instruments for angle-resolved photoemission with a spatial resolution in submicrometer regime are under development that eventually will make it possible to study the sharp levels of a single nano object.

9.5.3
Band Mapping

The electronic structure of a crystalline solid is characterized mainly by the quantum numbers E and $\mathbf{p} = \hbar\mathbf{k}$, plus spin and point group symmetry (see Section 9.1.3). This information is traditionally compounded into $E(\mathbf{k})$ band dispersion plots with the appropriate symmetry labels for each band (Figures 9.5 and 9.20). The experimental techniques that can probe the complete set of quantum numbers are photoemission and inverse photoemission, with photoemission probing occupied states and inverse photoemission unoccupied states (see Figure 9.1). There are just

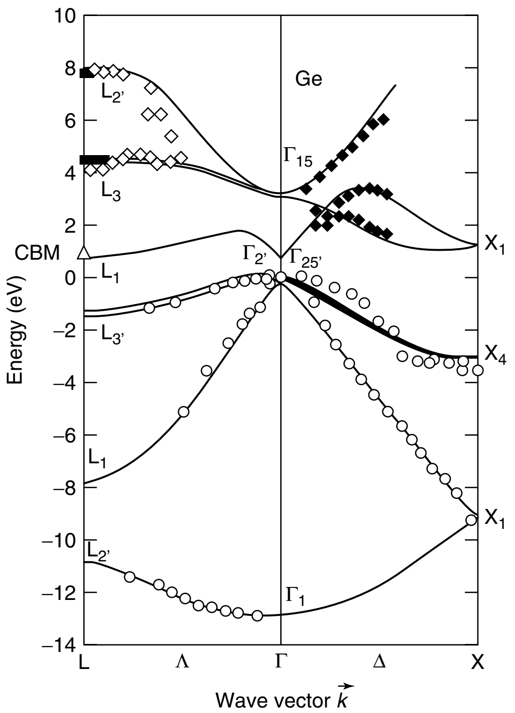

Fig. 9.20 Energy-versus-momentum band dispersions for germanium obtained from angle-resolved photoemission, inverse photoemission, and quasiparticle band calculations. Such band dispersions provide the complete information about electrons in solids. The labels denote the point group symmetry. From Wachs *et al.* (1985), Ortega and Himpsel (1994), and Hybertsen and Louie (1986).

enough variables in these experiments to cover all the unknowns. Roughly speaking, E is determined from the kinetic energy of the electrons, the two momentum components parallel to the surface, $k_{||}$, from the polar and azimuthal angles of the electrons, the perpendicular momentum from the photon energy, spin from the spin of the electrons, and the point group symmetry from the photon polarization. A more thorough analysis, particularly concerning the perpendicular momentum, can be found in various reviews (Himpsel, 1983; Kevan, 1992). Figure 9.20 shows the results from band mapping for germanium, both experimentally and theoretically. Angle-resolved photoemission and inverse photoemission results are compared with state-of-the-art quasiparticle calculations (Wachs *et al.*, 1985; Ortega and Himpsel, 1994; Hybertsen and Louie, 1986). Traditional local density calculations would not give the correct band gap for germanium, and in fact predict it to be metallic. A substantial body of experimental and theoretical band dispersions has been accumulated, and is being compiled as the basic set of electronic structure data for solids (Goldmann and Koch, 1989).

Multidetection allows it to determine the photoemission intensity versus E and $\mathbf{k}$ in quasi-continuous fashion and thereby make a connection to the imaginary part of the Greens function that describes electronic states in the presence of many-electron interactions (see Section 9.1.3). The photoemission intensity $I(E, \mathbf{k})$ can be displayed versus E, k_x (as shown in Figures 9.5 and 9.20) or versus k_x, k_y (as shown in Figure 9.21;

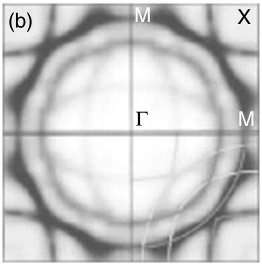

Fig. 9.21 Fermi surface of the two-dimensional material strontium ruthenate. From Damascelli *et al.* (2000).

(Damascelli *et al.*, 2000)). The former represents the $E(k_x)$ band dispersion, the latter the Fermi surface.

Current developments are directed toward high-energy resolution, to map the electronic states at the Fermi level that determine transport phenomena and phase transitions, such as superconductivity (Damascelli *et al.*, 2000; Inosov *et al.*, 2007) and magnetism (Altmann *et al.*, 2001).

9.5.4
Time-Resolved, Pump-Probe Measurements

The lifetime of electronic excitations and their decay mechanisms are at the heart of many technologies, such as optoelectronics and solar cells where long lifetimes are desirable. While optical experiments determine joint density of states, time-resolved photoemission is able to resolve the momentum of the states. The lifetime of electrons and holes strongly increases when approaching the Fermi momentum. It can also become quite long near local band minima in momentum space.

The experiments are typically performed with pulsed lasers in a pump–probe mode, which leads to the name two-photon photoemission (for an overview see Fauster (2003). Typically (but not exclusively), low-energy photons pump electrons from the valence band into long-lived intermediate states and higher energy ultraviolet photons ionize them from there (Höfer *et al.*, 1997; Fauster, 2003). These photons originate from the same laser, either directly or after frequency multiplication, and thus can be synchronized within tens of femtoseconds.

An example is provided in Figure 9.22, in which electrons are pumped into image states and then ionized by the probe pulse (Höfer *et al.*, 1997). Image states are electrons bound to a metal surface by their own image potential, which generates a hydrogen-like series of states converging to the vacuum level, but with 16 times smaller binding energies than in hydrogen. Coherent pumping of several image states with an ultrashort pulse causes quantum oscillations between different image states. These show the time dependence of the photoemission intensity as in Figure 9.19.

9.5.5
Inverse Photoemission

Inverse photoemission or bremsstrahlung isochromat spectroscopy (BIS) may be viewed as the time-reversed photoemission process (see Figure 9.1), with an incident electron and an emitted photon. It complements photoemission by probing unoccupied states, and in

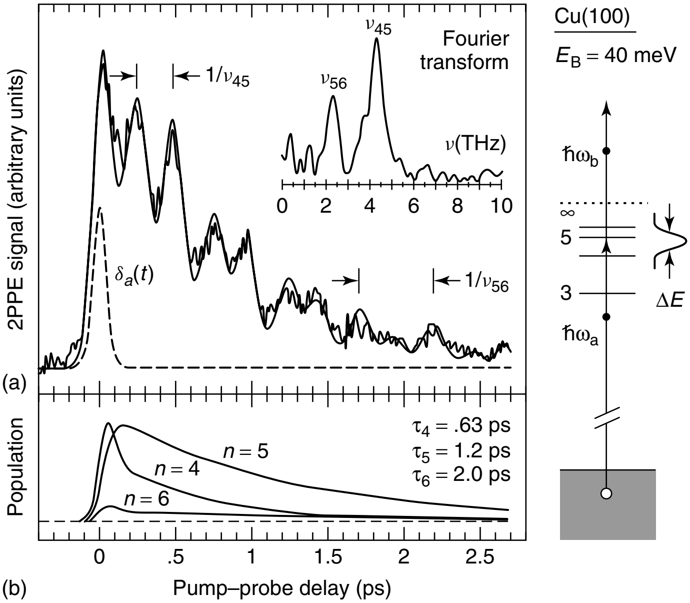

Fig. 9.22 Quantum beats in time-resolved photoemission. A femtosecond laser excites several quantum well states coherently, leading to an oscillatory population change between different states. From Höfer *et al.* (1997).

particular, the unoccupied states between the Fermi level and the vacuum level that are inaccessible to photoemission, neither as initial nor as final state. This gap contains many interesting states, for example, minority spin states in ferromagnets, broken-bond orbitals at semiconductor surfaces, and antibonding orbitals of adsorbed molecules. To visualize the territory covered by photoemission and inverse photoemission, one may examine the analogy between occupied and unoccupied states, bonding versus antibonding states, or donor versus acceptor states. Inverse photoemission poses experimental challenges, because its cross section is 4–5orders of magnitude lower than that for photoemission, due to a phase space factor in the cross section. Typical elastic photoelectron yields are in the range of 10^{-3} electrons per photon, while typical inverse photoemission yields are 10^{-8} photons per electron. Nevertheless, this technique has become a routine complement to photoemission work, as exemplified by the conduction band data in Figure 9.17. Results on semiconductors are reviewed by Himpsel (1990), results on metals and adsorbates by Dose (1985) and Smith (1988).

9.6
Structural Methods

9.6.1
EXAFS and Photoelectron Diffraction

As mentioned in Section 9.3.1, EXAFS provides structural information. The ejected photoelectron from an absorbing atom can be described as an outgoing spherical wave. The outgoing photoelectron wave will be backscattered by neighboring atoms, which thereby will create incoming waves, one from each atom. The interference between the outgoing and incoming waves gives rise to modulation of the absorption coefficient for photon energies above the threshold. The periodicity of this modulation contains information about the distance between the absorbing atom and its neighbors, and the amplitude of the modulation is a measure of the number of neighbors, that is, the coordination number. The EXAFS technique is used extensively for structural determinations of solids, liquids, and biomolecules (Prins and Koningsberger, 1985; Teo and Jay, 1981; Teo, 1986). A surface-sensitive version of EXAFS, with the acronym SEXAFS, surface extended X-ray absorption fine structure can be applied to determine the surface structure of monolayers of adsorbates on surfaces (Prins and Koningsberger, 1985). Experimentally, two parameters are measured: adsorbate-substrate bond lengths and absorption sites.

9.6.2
Photoelectron Diffraction

Although an EXAFS experiment integrates over all outgoing electron energies and emission angles, there is additional information to be gained from the energy and the angular distribution of the diffracted photoelectrons. The outgoing waves of photoelectrons emitted from a specific core-level scatter at nearby atoms and produce intricate diffraction patterns. This information is used in photoelectron diffraction (PhD) (Fadley, 1993; Fadley *et al.*, 1994; Woodruff, 2001). Experimentally, the intensity of a core level is measured either as function of the direction, or as the energy of the photoelectron, providing what is termed as *scanned-angle or scanned-energy data.* Considerable theoretical effort has been made into establishing accurate models relating photoelectron diffraction data to the surface structure (Fadley *et al.*, 1994). Compared to X-ray diffraction, the analysis is complicated by multiple scattering, which is inherent in the strong interaction of electrons with matter. That, on the other hand, provides high surface sensitivity. For photoelectrons with kinetic energies above 500 eV, it turns out that the scattering amplitude is highly peaked in the forward direction (forward focusing), which provides a direct determination of the bond directions for absorbed molecules and epitaxial relationships in thin films.

In addition to measure the momentum parallel to the surface via the angular distribution, it is also possible to vary the magnitude of the momentum by varying the photon energy, like in EXAFS. This requires the access to synchrotron radiation so that the photoelectron energy can be tuned continuously. This method is illustrated by a structure determination for the acetate species, CH_3COO-on the Cu (110) surface (Woodruff, 2001) (see Figure 9.23). Because the two carbon atoms are in different chemical environments, they can be distinguished by their chemical shift. The intensity modulations of the two chemically shifted peaks were measured in a well-defined emission direction as a function of the photoelectron kinetic energy. Such data can be analyzed by a multiple scattering model using trial structures (Woodruff, 2001), analogous to the determinaton of surface structures in LEED.

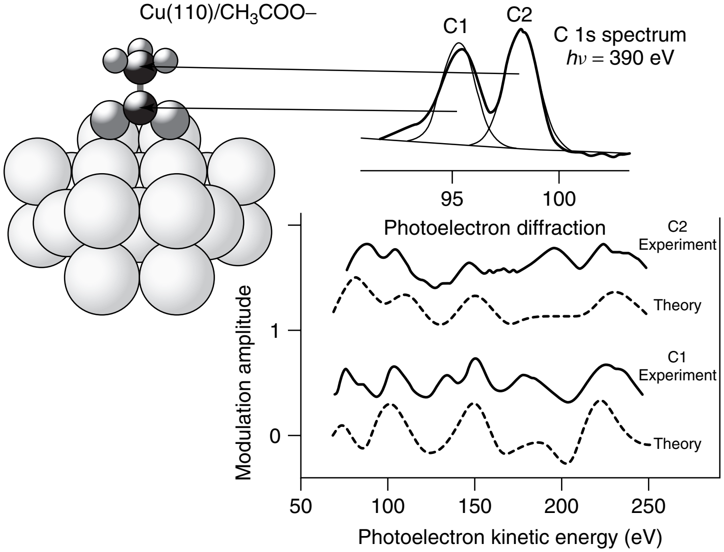

Fig. 9.23 Adsorption geometry of acetate (CH_3COO-) on the Cu(110) surface determined by photoelectron diffraction (PhD). From Woodruff (2001).

9.7
Summary and Outlook

Photoelectron spectroscopy has made significant contributions to the basic understanding of the electronic structure of atoms, molecules, solids, and surfaces. The technique has also been adopted into commercial instrumentation for routine qualitative and quantitative chemical analysis and materials characterization. Presently, thousands of research papers are published each year involving photoelectron spectroscopy in basic research or applications.

The development of the field of photoelectron spectroscopy, both for basic research and applications, has been closely tied to advancements in instrumentation, that is, better light sources and detectors. This trend will certainly continue in the foreseeable future. The third-generation synchrotron radiation sources are presently being implemented and will provide orders of magnitude improvements in brightness. It will be possible to study atoms, molecules, and solids with unprecedented spectral resolution. This will have a major impact for a better theoretical understanding of the complex photoelectron spectra of atoms and molecules. For solids and surfaces, major advances can be expected for studies of the electronic states around superconducting gaps in high-T_c materials, of charge density waves, surface transitions, and surface magnetism. Major breakthroughs should be anticipated in photoelectron microscopy in which all the assets of photoelectron spectroscopy will be applied with a spatial resolution down to a few tens of nanometers. Therefore, it is reasonable to predict that the tremendous growth of photoelectron spectroscopy during the last 40 years will continue well into the future.

Databases

Core-Level Binding Energies: Cardona and Ley (1978).

Atomic Core-Level Spectra: Siegbahn and Karlsson (1982).

Absorption and Core-Level Spectra of Metal Atoms: Sonntag and Zimmermann (1992).

Molecular Core-Level Absorption: Hitchcock and Mancini (1994). Avialable online at: http://unicorn.chemistry.mcmaster.ca/corex/cedb-title.html

Molecular Core-Level Energies: Bakke, Chen and Jolly (1980).

Molecular Valence Spectra: Turner *et al.* (1970).

Solid State Core and Valence Spectra: Goldmann and Koch (1989).

Cross sections: Yeh and Lindau (1985) and Keski-Rahkonen and Krause (1974).

Various databases are published regularly in Surface Science Spectra, published by the American Institute of Physics for the American Vacuum Society.

Glossary

Al K_α: X-ray line at 1.49-keV photon energy, emitted from the 1s level of aluminum. It is frequently used for core-level photoelectron spectroscopy (see Section 9.2.1).

ARPES: Angle-resolved photoelectron spectroscopy.

Auger Spectroscopy: Use of the Auger electrons emitted during the decay of core holes for elemental analysis at surfaces (see Figure 9.2).

BIS: Bremsstrahlung isochromat spectroscopy. A form of inverse photoemission with constant photon energy and variable electron energy, originally used in the X-ray regime (see Section 9.5.5).

ESCA: Electron spectroscopy for chemical analysis. Mapping of the core-level energies and their chemical shifts, typically using the K_α lines of Al or Mg at 1.49 keV and 1.25 keV, respectively (Siegbahn *et al.*, 1967). Synonym: XPS.

EXAFS: Extended X-ray absorption fine structure, determination of nearest-neighbor distances by interference effects in the core-level absorption spectrum (see Section 9.6.1).

GMR: Giant magnetoresistance, a strong variation of the electrical resistance in a magnetic field induced in sandwiches of magnetic and nonmagnetic metal layers.

GW: Calculation method for quasiparticles (see below), based on solving the Dyson equations with the full electron and photon propagators G and W (therefore the GW acronym), and a free particle approximation for the vertex. It goes beyond the LDA in determining the electronic structure for the excited state, which is measured in photoemission and inverse photoemission (see Section 9.1.3).

He I: Resonance line of helium gas at 21.2-eV photon energy, frequently used for photoelectron spectroscopy of valence states (see Section 9.2.1).

HOMO: Highest occupied molecular orbital in molecules. Together with the LUMO, the HOMO is responsible for most chemical reactions of a molecule, in particular charge transfer reactions, such as in a battery or in a solar cell.

LDA: Local density approximation, representing one of the most common methods for determining electronic states in solids and at surfaces (see Section 9.1.3).

LEED: Low-energy electron diffraction, often used in conjunction with photoelectron spectroscopy to characterize the ordering at surfaces.

LUMO: Lowest unoccupied molecular orbital in molecules. Together with the HOMO, the LUMO is responsible for most chemical reactions of a molecule.

Many-Body Theory: Many-body theory stands for a theory dealing with an infinite number of interacting particles. This is mathematically simpler than dealing with 10^{20} electrons in a macroscopic solid.

MCD: Magnetic circular dichroism, change of absorption between left- and right-handed, circularly polarized light, used for the determination of the magnetization at specific atomic sites (see Section 9.3.4).

NEXAFS: Near Edge X-ray absorption fine structure, mapping of unoccupied states via transitions from core levels (see Section 9.3). Synonyms: XANES, XAS, Partial Yield Spectroscopy.

PhD: Photoelectron diffraction, determination of the local atomic structure of surfaces (see Section 9.6.2).

Propagator: The propagator (or Green's function) describes the propagation of a particle from point A to point B in many-body theory. Mathematically, it is the expectation value of a particle creation operator at point A by an annihilation operator at point B.

Quasiparticle: In many-body theory, an electron loses its simple particle character by dragging other particles alon, such as phonons or other electrons in a solid. This whole particle cloud moves together and becomes a quasiparticle.

SEXAFS: Surface extended X-ray absorption fine structure, determination of nearest-neighbor distances at surfaces by interference effects in the core-level absorption spectrum (see Section 9.6.1).

Synchrotron Radiation: Versatile source of ultraviolet and X-ray light, emitted by high-energy electrons in a storage ring deflected by a magnetic field (see Section 9.2.1).

TEY: Total electron yield. One of the detection modes in XAS/NEXAFS/XANES spectroscopy where all electrons originating from the decay of the core hole are collected (see Section 9.3).

UPS: Ultraviolet photoelectron spectroscopy, mapping of the valence band structure of solids and surfaces with photon energies in the 5 to 50-eV range (see Figure 9.3).

XANES: X-ray absorption near edge structure, mapping of unoccupied states via transitions from core levels (see Section 9.3). Synonyms: NEXAFS, Partial Yield Spectroscopy.

XAS: X-ray absorption spectroscopy. Related terms: NEXAFS, XANES, Partial yield spectroscopy (see Section 9.3).

XPS: X-ray photoelectron spectroscopy. Mapping of the core-level energies and their chemical shifts, typically using the K_α lines of Al or Mg at 1.49 keV and 1.25 keV, respectively. See also ESCA.

XSW: X-ray standing wave, determination of the local atomic structure of surfaces (see Section 9.6.1).

ZEKE: Zero kinetic energy spectroscopy, a high-resolution spectroscopy for studies of molecular ions (see Section 9.2.2).

INTRODUCTION

Luminescence is described as light emitted by a *cold* excited body, in contrast with the light emitted by incandescent bodies. There is a variety of excitation processes: In photoluminescence, the excitation results from light absorption. Because of the quantum nature of light and considering only low excitation conditions, one absorbed photon can induce at best one luminescence photon whose energy is necessarily smaller than (or equal to) that of the exciting photon (Stokes's law). Historically, luminescence was restricted to the visible part of the spectrum, but nothing prevents an extension toward the ultraviolet or infrared regions. By comparison with other excitation processes like electron beam (see CATHODOLUMINESCENCE), electric field (see ELECTROLUMINESCENCE), injection in *p-n* junctions (see LIGHT-EMITTING DIODES), chemiluminescence, and bioluminescence, photoluminescence allows the best control over the excitation conditions and for that reason is the most useful process for studying the fundamental properties of luminescent materials. Development of luminescent materials for fluorescent tubes and cathode-ray

tubes took place in the 1940s. Study of photoluminescence in organic and semiconductor materials started at the end of the 1950s and developed very fast with the advent of lasers. The tremendous improvements of semiconductor quality linked to microelectronic applications, in terms of purity and doping control, allowed the identification of well-established luminescence mechanisms. Conversely, photoluminescence has become a very common nondestructive test of semiconductor structures.

1. PHYSICAL PRINCIPLES

1.1 General Scheme

Photoluminescence can be described as a three-step process:

1. absorption of one photon of the excitation source creating in the material a primary excitation;
2. evolution of this primary excitation by energy relaxation or energy transfer toward secondary excitation at lower energy; and
3. coupling of this secondary excitation to light, giving rise to the spontaneous emission of one luminescence photon.

Steps **1** and **3** require, as in the field of optical properties (see Optical Properties of Solids), the knowledge (a) of the electronic energy spectrum of the material and (b) of the strength of optical transition between any pair of energy levels. Traditionally, the energy spectrum of condensed matter is described in the framework of the *Born-Oppenheimer approximation*, which relies upon the fact that the movements of the nuclei are much slower than those of the electrons, because of the large mass ratio. Actually, electronic excitations and lattice vibrations are coupled with a strength depending on the material under consideration. Luminescence is linked mainly with electronic excitations; coupling between electronic and lattice excitations enters into play mainly in step **2** to allow for some energy relaxation. Let us note that Stokes's law is strictly valid only at temperature $T = 0$; at finite T, there is a finite probability to see the excitation jumping to a higher energy by phonon absorption: This leads to anti-Stokes emission.

1.2 Photoluminescence Quantum Efficiency

The photoluminescence quantum efficiency η is defined as the ratio of the number of photons emitted n_l to the number of excitation photons absorbed n_a: $\eta = n_l/n_a$. The fact that $\eta < 1$ is due to nonradiative processes that allow complete energy dissipation of the exciting photon. Among these are the multiphonon processes where an electronic excitation ΔE is dissipated into n lattice vibrations. Since the probability of such process decreases very fast with n, an energy gap large enough between the emitting state and the ground state is required in order to have a sizable quantum efficiency. This explains why metals, which exhibit a continuum of electronic excited states, are not luminescent materials.

1.3 Main Types of Luminescence Materials

To be more specific, we will consider three main types of luminescent materials:

1. Molecular organic materials (see Semiconductors, Organic—Electronic Properties). In that case, the building block is the isolated molecule (see Molecules), which is only weakly perturbed by its environment, e.g., a solvent or its inclusion in a molecular solid, tied by van der Waals interactions.
2. Luminescent centers in large-gap (hence transparent) insulators, like oxides, tungstates, silicates, or glasses (see Electron States, Localized). The most studied are transition-metal or rare-earth ions; the isolated ions have usually a rich spectrum of excitations linked to their partially filled d or f shell, providing opportunities to obtain luminescence in the visible. Perturbation of these ions by the crystalline matrix is usually treated in the crystal-field approximation. Another example is the F center in alkali halides, where an electron is trapped in an anion vacancy.
3. Semiconductors. They present an energy gap E_g between a filled valence band and an empty conduction band. In that case, luminescence takes place at an energy close to the band gap, which spans a range of values from near ultraviolet to infrared, depending on the material. The building blocks are now free electrons in the conduction band and free holes in the valence

band, characterized by their effective masses (see ELECTRONIC STRUCTURES OF SOLIDS). When Coulomb interaction between these particles and with impurities is taken into account, weakly bound states are built, which can be described in the effective-mass approximation: free excitons (see EXCITONS) or bound excitons; they dominate the luminescence spectrum in pure semiconductors at low temperature.

1.4 Specificity of Photoexcitation

Through the use of monochromatic excitation, very specific energy levels can be excited; this can be used either to optimize the luminescence quantum efficiency or for fundamental research in order to get a better understanding of step **2**. In addition, one can take advantage of light polarization, which allows additional selectivity in anisotropic materials and is at the roots of a technique known as "optical pumping" (see Sec. 3.1.5).

Depending upon the energy difference $E_a - E_l$ between excitation and luminescence, one can distinguish three cases (applicable mainly to semiconductors):

1. Resonance luminescence, when $E_a = E_l$. This is sometimes called Rayleigh scattering.
2. Hot luminescence, when E_l spans a region between E_a and the main luminescence band.
3. Thermalized luminescence corresponding to the main luminescence band, close to the band gap.

The relative importance of these three contributions is governed by a system of rate equations describing such an out-of-equilibrium situation.

2. METHODS AND EQUIPMENT

A typical experimental photoluminescence setup is shown in Fig. 1. It is composed of an excitation source, optical elements to focus excitation on the sample and collect the luminescence light, a spectrometer (or filter) to analyze the luminescence, and a detector followed by a data acquisition system.

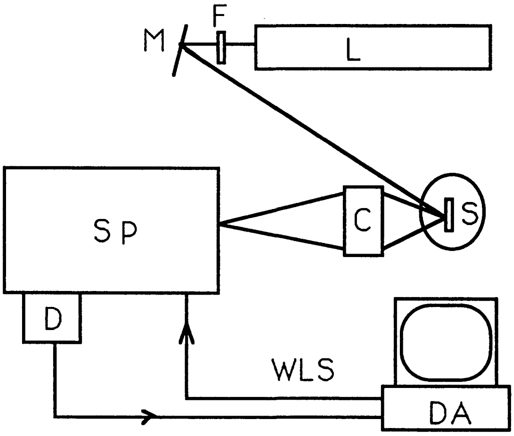

FIG. 1. Typical photoluminescence setup. *L*, laser; *F*, filter; *M*, mirror; *S*, sample; *C*, condenser; *SP*, spectrometer; *D*, detector; *DA*, data acquisition system; WLS, wavelength scanning.

2.1 Excitation Sources

Before the advent of lasers, the most useful sources were high-pressure mercury or xenon lamps. Both have a broad continuous spectrum extending from 300 nm to near infrared. Appropriate filters have to be inserted in order to cut source emission in the spectral region of sample luminescence. Lasers (see LASERS, GAS; LASERS, SOLID STATE) are excitation sources much more convenient for several reasons:

1. They are much more powerful.
2. Since they are well collimated, it is easy to use 100% of their power, as compared to 15% at best for conventional sources.
3. Their emission is essentially monochromatic.

Notice, however, that a filter may be required to suppress plasma emission lines in gas lasers. A wide range of wavelengths is now available from the infrared (CO_2 near 10 μm, CO near 5 μm, and Nd solid-state laser at 1.06 μm), through gas lasers in the visible (He-Ne, Ar, Kr), and recently gas lasers with intracavity second-harmonic generation for the 250-nm region.

2.2 Spectrometers and Detectors

If in some cases a filter could be enough to select a luminescence line, in most cases a spectrometer is needed to get the luminescence spectrum (see SPECTROMETERS, OPTICAL). The most widely used are grating spectrometers, either single or double. The light emitted by the sample should be focused on the entrance slit of the spectrometer by an objective or a combination of mirrors in the infrared to avoid absorption and dispersion.

In the ultraviolet, visible, and near infrared down to 1 μm, the most useful detectors are photomultipliers (see DETECTORS, RADIATION). Semiconductor detectors (photovoltaic, photoconductor, avalanche *p-n* junction) cover the visible and infrared range down to 10 μm (see DETECTORS, SEMICONDUCTOR). Chopping of the excitation at a frequency f followed by synchronous detection is common practice. Let us point out that this is mandatory only when using detectors exhibiting $1/f$ noise, since the detector contributes to the noise in a window δf around the frequency f. With photomultipliers, the best is to use a discriminator followed by a counter. Detector arrays, featuring up to 2048 (or even more) elements, provide a very efficient detection method, since wavelength scanning is suppressed. Fourier transform spectrometers (see INTERFEROMETERS AND INTERFEROMETRY; SPECTROMETERS, INFRARED) have also been used in the infrared; for a given spectral resolution, they can accommodate a luminescence beam of larger extension.

2.3 Control of Sample Temperature

Sample temperature is an important parameter in photoluminescence experiments, since, in general, line narrowing is expected on cooling. Moreover, new ground or excited states (see Sec. 3.2) can appear at low temperature, like some type of condensation (see Sec. 3.3.2). Optical cryostats (see CRYOGENICS) allow easy operation down to 1.5 K, the best cooling conditions being achieved by immersion of the sample in superfluid liquid helium. In peculiar cases, operation down to about 0.1 K has been obtained with a dilution refrigerator; in that case, excitation and luminescence light are transported through optical fibers, in order to minimize heat dissipation. Experiments between helium and room temperature are also easily performed—for example, using commercial closed-cycle refrigerators.

2.4 Photoluminescence Kinetics and Excitation Spectrum

It is often useful to study photoluminescence *kinetics*, i.e., how the luminescence intensity depends upon the excitation intensity, taking care of the fact that different luminescence lines may exhibit different kinetics. Another powerful way to obtain information about the photoluminescence process is the study of the dependence upon excitation wavelength of the luminescence spectrum. This is performed usually by recording the *photoluminescence excitation spectrum*, the excitation wavelength being scanned at fixed luminescence wavelength. A tunable source is required; this can be done either with a broad-band source and a monochromator or, more conveniently, with a tunable laser, like a dye laser (see ORGANIC DYE LASERS) or a solid-state tunable laser (titanium–sapphire or *F*-center). Often, the excitation spectrum is close to the absorption spectrum of the sample. Light *polarization* is an additional useful feature: by inserting a polarizer (either linear or circular) in the excitation and/or the luminescence beam, one can gain information about the symmetries of the primary excited state and the final emitting state, when the sample presents some kind of anisotropy, either natural or induced by external perturbations (see Sec. 2.7). Selection of the luminescence photon wave vector, realized by inserting a slit out of focus to limit the solid angle of the luminescence beam, can also be useful with anisotropic samples. Even with isotropic samples, a polarized excitation can induce some degree of polarization of the luminescence, a technique known as *optical pumping* (see Sec. 3.1.5).

2.5 Time Resolution

Time resolution adds new capabilities to directly measure characteristic times in the sample, like lifetime of states or transfer time between states. It requires first a pulsed excitation. For decay time longer than about 10 ns, modulation by electro-optical (see QUANTUM-OPTOELECTRONIC DEVICES) or acousto-optical (see MODULATORS AND DEMODULATORS, ACOUSTICAL) devices can be used. For shorter time scales down to 0.1 ns, mode-locked lasers can be used. Synchronously pumped dye (or titanium–sapphire) lasers can provide pulses reaching the subpicosecond range (see ULTRAFAST PULSE PHENOMENA), tunable in a substantial wavelength range.

Detection was done first using fast oscilloscopes or boxcar techniques, which require a scanning of the delay between excitation and gate defining the measurement window. A better method, in conjunction with photomultiplier detectors, is the so-called *single-photon counting* technique: the time delay between the excitation pulse and the first luminescence photon detected is measured with a time-to-amplitude converter, and the data are stored in the multichannel mode. This method is very efficient at low levels of excitation since essentially all luminescence photons are detected. With fast discriminators, time resolution below 50 ps is achievable. A second method relies upon *up-conversion* in a nonlinear medium (see OPTICS, NONLINEAR): Part of the excitation pulse is combined with the luminescence beam in a nonlinear crystal under phase-matching conditions; photons at an energy that is the sum of excitation and luminescence photon energies are detected. This method, less sensitive than the previous one, allows a time resolution down to the subpicosecond range; moreover, it can be used for infrared luminescence. A third method uses a *streak camera*: The luminescence light focused on a transparent photocathode creates electrons focused on a fluorescent screen after deflection by a sawtoothlike electric field synchronized with the excitation pulse. The bright trace on the screen, which is an image of the time-dependent luminescence, is read by an array of detectors. This method is fairly sensitive with a typical time resolution of about 10 ps and a spectral domain of wavelength below 850 nm. In all cases where the expected time resolution is below 10 ps, time broadening due to the passage on one grating has to be suppressed with the use of a double-grating spectrometer in the substractive mode.

Detection of *quantum beats* occurs when two nearby energy states separated by ΔE have been both excited by a short pulse; during their coherent decay, beats with a period $\Delta t = \hbar/\Delta E$ can be detected on the luminescence signal, under appropriate polarization conditions, thus allowing measurement in the time domain of small energy splitting.

2.6 Spatial Resolution

Using well-focused excitation in a spot of a few microns, any extension of the luminescence spot gives information about the diffusion of the excitations. This can be done by inserting a slit in the plane of an enlarged image of the emitting region. Such measurements can be performed in the time-resolved mode, allowing the measurement of a signal $S(\Delta x,\Delta\tau)$, where Δx is the distance to the exciting spot and $\Delta\tau$ is the delay after the exciting pulse. Under typical conditions, the analysis of $S(\Delta x,\Delta\tau)$ provides access to the lifetime and the diffusion coefficient of the excitations.

Another more powerful technique is provided by *four-wave mixing* experiments (see OPTICS, NONLINEAR), but this is outside the scope of this article.

2.7 External Perturbations

The purpose of external perturbations applied to the sample is to induce shift or splitting (see ELECTRON LEVEL SPLITTING) of the energy levels in order to help their theoretical identification. On solid samples, *hydrostatic pressure* up to 10 GPa can be applied by use of a diamond anvil cell: This induces shifts and in some cases phase transitions. *Uniaxial stress* of much lower intensity can be applied; it can induce splitting associated with polarization effects. It can also be applied as a modulation, using piezoelectric elements.

Magnetic fields up to about 10 T can be applied by use of split-coil superconducting magnets to allow light propagation perpendicular or parallel to the field. Different effects are induced, like Zeeman splitting, diamagnetic shift, or Landau level splitting; they can be detected on the photoluminescence spectrum, mainly at low temperature. Photoluminescence and electron paramagnetic resonance (see ELECTRON PARAMAGNETIC RESONANCE) can be combined into a technique known as *optical detection of magnetic resonance* (Cavenett, 1981): The change in spin populations at resonance is detected through modification of the intensity of some polarized components of photoluminescence lines. This method is quite sensitive and provides a correlation between different magnetic resonance components (i.e., different g factors) and different luminescence components. A related method, *level-crossing spectroscopy*, does not require microwaves: When two magnetic sublevels happen to cross, transfer between these two levels is enhanced and changes in polarized photoluminescence intensity can be recorded as bump or dip as a function of the field strength.

To conclude this section, let us point out that several extensions of photoluminescence as described in Secs. 2.3 to 2.7 can be combined in a given experiment, provided they are not mutually exclusive.

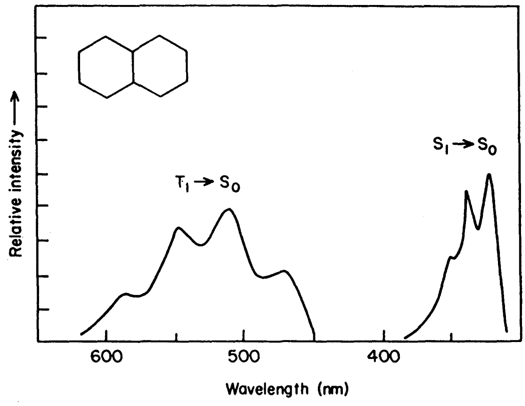

FIG. 2. Fluorescence ($S_1 \rightarrow S_0$) and phosphorescence ($T_1 \rightarrow S_0$) spectra of naphthalene at room temperature. The $T_1 \rightarrow S_0$ spectrum was obtained using a rigid polystyrene solution of naphthalene. The two spectra are plotted on different intensity scales.

3. APPLICATIONS

3.1 Fundamental Applications

In general, photoluminescence spectroscopy provides information about energy levels, as do other kinds of optical spectroscopy (see SPECTROSCOPY OF SOLIDS), but with special emphasis upon the lowest excited states. In addition, increasing the excitation level may induce new collective states (see Sec. 3.3.2). We give first examples of low-level photoluminescence in the three kinds of luminescence materials defined in Sec. 1.3. Particular emphasis is put on semiconductors.

3.1.1 Organic Crystals As an example, we will consider solid naphthalene or anthracene. Looking first into the lowest energy states of the isolated molecule, one finds a singlet ground state denoted S_0, and a first excited singlet state S_1 with a corresponding triplet state T_1 more than 0.5 eV below. These states are coupled to vibrational modes of the molecule. The optical transition $S_0 \rightarrow S_1$ is allowed whereas $S_0 \rightarrow T_1$ is forbidden. So the luminescence is dominated by the $S_1 \rightarrow S_0$ transition, accompanied on its low-energy side by several molecular vibration sidebands: This is called "prompt" fluorescence. The T_1 state is also populated from S_1 by intersystem crossing; it gives rise to slow phosphorescence (Fig. 2).

In the molecular crystal, where binding is due to van der Waals forces, the prompt fluorescence is not very different from that of the molecule; there is a moderate red shift due to the binding. The main difference is the possibility of rapid *energy transfer* to neighbors: At low temperature, this takes place through the formation of Frenkel excitons (see EXCITONS), which are delocalized excitations characterized by a wave vector **k**. When the temperature increases, the mean free path of the Frenkel exciton can decrease below the intermolecular distance. Then one has an incoherent hopping regime for these excitations. That rather fast energy transfer has several consequences: If the crystal is doped with a parent molecule, like naphthacene in anthracene, S_1 excitons can be trapped by the impurities; then the matrix prompt fluorescence is quenched at the benefit of naphthacene emission at lower energy. Another effect comes from collisions between two triplet excitons resulting in regeneration of a singlet S_1 (called also triplet fusion); this is the origin of "delayed" fluorescence.

Let us add that more complicated molecules, the organic dyes, are used in liquid solution to achieve tunable lasers (see ORGANIC DYE LASERS).

3.1.2 Luminescent Centers in Transparent Solids Most of the examples concern rare-earth or transition-metal ions in large-gap matrices (see SOLID, LIQUID, AND GASEOUS INSULATOR MATERIALS). Going from rare-earth elements to transition metals, as a result of the smaller diameter of *f* orbitals as compared with *d* orbitals, rare-earth ions are less perturbed by the crystal field and less coupled to lattice vibrations. Thus, emission and absorption lines of rare-earth ions are quite narrow. Some inhomogeneous broadening occurs in glasses (Er^{3+} in silica glass fiber, Nd^{3+} in glass). Strong coupling with lattice vibrations can lead to broad absorption and emission bands, like in the case of titanium-doped sapphire. Usually, ion concentration is in the few percent range so that samples of length in the centimeter range are required for laser emission. Concentration quenching is observed mainly for transition-metal ions (above 0.3% in ruby: Cr^{3+} in Al_2O_3). For rare-earth ions, stoichiometric material like $PrCl_3$ exhibits no luminescence quenching. Such material can give a micron-size optically pumped laser.

Another type of defect in ionic crystals has been widely studied: the *F* center, which corresponds to an electron trapped in an anion vacancy. Since the electron wave function extends toward the neighboring cations, strong electron–phonon coupling induces a large Stokes shift between absorption and emission (Fig. 3).

A nonlinear effect giving rise to "up-conversion" occurs in some transparent crystals doped with two types of luminescent ions, the first emitting at an energy E and the second at an energy E' smaller than but close to $2E$. If a lot of ions of the first type are excited, an energy transfer from two such ions to one of the second kind may occur, followed by the emission of a photon at energy E'. If E is in the near infrared, then an IR–visible conversion results.

3.1.3 Bulk Semiconductors

3.1.3.1 Intrinsic Luminescence. High-temperature photoluminescence in pure semiconductors is dominated by the band-to-band process: Free electrons recombine with free holes. This is a typical case of thermalized luminescence where electrons and holes are in thermal equilibrium with the lattice. However, since their densities n and p exceed the values of their densities n_0 and p_0 at thermal equilibrium in the unexcited semiconductor, their statistical distributions are described by separate *quasi-Fermi* levels, one for the electrons F_e and one for the holes F_h, with $F_e > F_h$. At vanishing excitation intensity, F_e and F_h both coincide with the Fermi level at equilibrium.

Another approach is given by the use of the principle of *detailed balance*, to get a relationship between light absorption and emission in a semiconductor at temperature T (Van Roosbroeck and Shockley, 1954). At thermodynamic equilibrium, at every photon energy, the number of photons emitted (through spontaneous and stimulated emission) is equal to the number of blackbody photons absorbed. Thus, a luminescence spectrum at temperature T can be deduced from the absorption spectrum, as well as a radiative lifetime (i.e., the lifetime if the only existing recombination process were the radiative one).

In fact, the effect of electron–hole Coulomb interaction is already present in the ex-

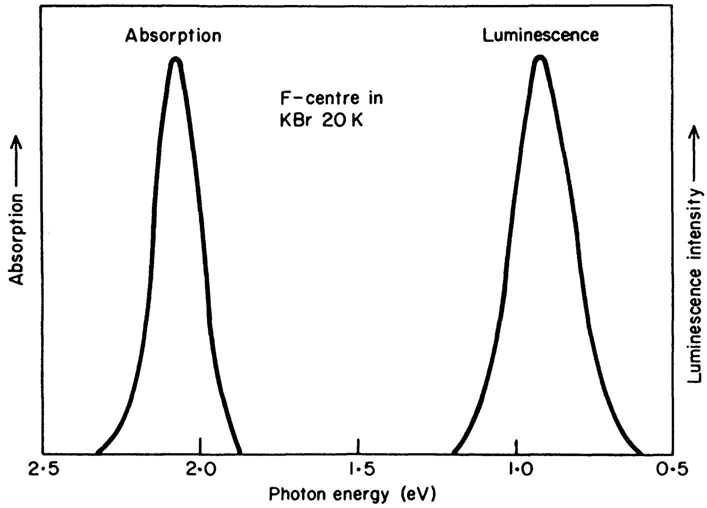

FIG. 3. Absorption and luminescence transitions between the ground state and the lowest electronic excited state of the *F* center in KBr.

perimental absorption spectrum and, thus, also in the luminescence. This interaction between an electron and a hole induces the formation of bound states, analogous to those of the hydrogen atom, called *Wannier excitons* (see EXCITONS). Their binding energy $\mathfrak{R}^*$ is scaled from the hydrogen Rydberg $\mathfrak{R}$ by the electron-hole reduced mass μ and the relative permittivity ϵ according to $\mathfrak{R}^* = (\mu/\epsilon^2)\mathfrak{R}$.

On the other hand, the optical band gap of a semiconductor can be either direct or indirect in reciprocal space. Since the photon wave vector is very small at the Brillouin-zone scale, first-order optical transitions take place vertically in **k** space. In direct-gap semiconductors, the extrema of conduction and valence bands are at the same point in the Brillouin zone; so first-order optical transitions are in general allowed (except in special cases). In indirect-gap semiconductors, band extrema are at different points $\mathbf{k}_v$ and $\mathbf{k}_c$ in the Brillouin zone; in that case, first-order optical transitions near the extrema are always forbidden. The next higher-order process, in pure semiconductors, has to involve the absorption or emission of a phonon of wave vector $\mathbf{k}_c - \mathbf{k}_v$. As a consequence, optical absorption near threshold for indirect-gap material is weak, and the radiative lifetime of the lowest exciton is large (in the millisecond range for Ge). In contrast, in direct-gap material, the optical absorption near threshold is strong; it exhibits well-resolved exciton lines, and the photoluminescence spectrum is in a region of strong optical absorption. This has several consequences. At high temperature, when electron–hole recombination dominates, once a photon has been emitted in the material, it has a good probability to be reabsorbed, creating again an electron–hole pair before escaping the material: Such a process, called *photon recycling*, enhances the diffusion of the electron–hole pairs and modifies the radiative lifetime, especially if the quantum efficiency is good. At lower temperature, when free excitons dominate the luminescence spectrum, a free exciton of small wave vector **k** will be absorbed, creating a photon with the same **k** that later on will create an exciton **k**, and so on, unless it makes a collision with a phonon or a lattice defect. This occurs if the exciton–photon coupling is strong enough; the result of this coupling is a mixed exciton–photon excitation that has been called *polariton*. Under such conditions, a luminescence photon has a chance to be created when a polariton hits the sample surface. In fact, photoluminescence is not the best method to study polaritons; resonant Brillouin scattering is the best way to determine the polariton dispersion relation.

The tendency of low-temperature photoluminescence to accumulate the excitations in the lowest possible excited state is also valuable to detect weak transitions related to *triplet* states, which are only weakly coupled to light; this allows the measurement of electron–hole *exchange* interaction. As an example, consider the case of exciton–polaritons in CdS, a crystal of uniaxial symmetry; the exciton is built from a spin-$\frac{1}{2}$ electron and a spin-$\frac{3}{2}$ hole, quantized along the *c* axis of the crystal. So excitons of total angular momentum $J = 1$ or $J = 2$ are obtained. The first are strongly coupled to light of polarization $\perp c$ and show a strong polariton effect; the second, our triplet, are weakly coupled to light. By using polarization and wave-vector selection in a photoluminescence experiment on pure CdS platelets, it was possible to measure accurately the energy difference between the $J = 2$ excitons and the longitudinal $J = 1$ polariton (see Fig. 4).

3.1.3.2 Effect of Impurities and Defects (see ELECTRON STATES, LOCALIZED). At 2 K, low-level photoluminescence in the near–band-gap spectral region is usually dominated by the effect of *shallow impurities*, donors and acceptors that are well-known dopants. Under typical conditions, unintentionally doped semiconductors present some compensation; under weak photocreation of electron–hole pairs, ionized donors and acceptors capture respectively free electrons and free holes. The first recombination process comes from pairs D^0-A^0 of neutral donor and acceptor (Dean, 1973). At somewhat higher temperature, a fraction of electrons may remain free, thus allowing electron-to-neutral acceptor transitions, noted e-A^0. When all donors and acceptors are neutral, additional electron–hole pairs can form free excitons, and these excitons can form bound states with different impurities or defects. Among these are an exciton bound to a neutral donor, denoted D^0X, or to a neutral acceptor, denoted A^0X (Bebb and Williams, 1972). Depending on the electron-to-hole mass ratio, binding to an ionized impurity is possible, e.g., D^+X in CdS. These

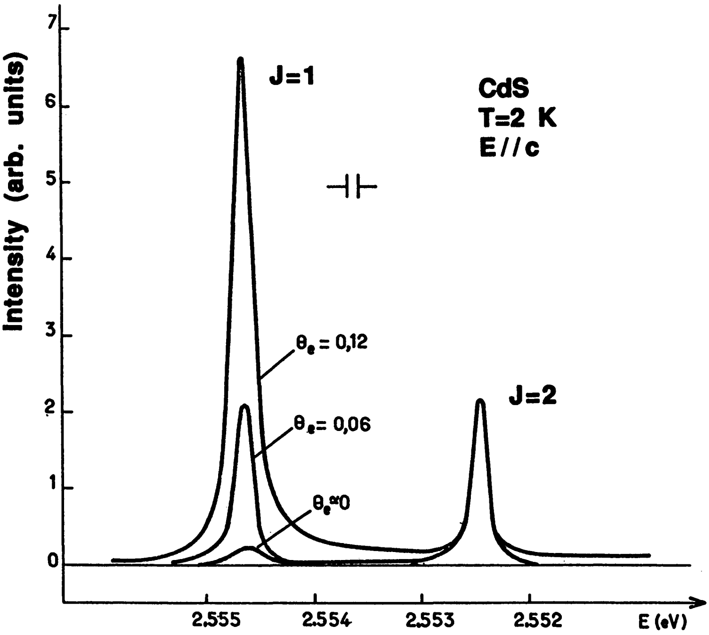

FIG. 4. Exchange splitting of free exciton in CdS. The photoluminescence spectrum is obtained at 2 K with polarization selection ($E \parallel c$) and photon wave-vector selection (**k** nearly normal to c), c being the axis of this hexagonal crystal: θ_e is the angle between **k** and a plane normal to c. For $\theta_e \to 0$, the $J = 1$ exciton becomes purely longitudinal, and the coupling with a photon $\parallel c$ vanishes.

complexes, in direct- as well as indirect-gap materials, give narrow luminescence lines that can be split in a magnetic field of a few tesla. If one considers the complex D^0X, its main decay process gives a photon and a neutral donor D^0 in its ground $1S$ state; however, there is less probable decay process, named *two-electron transition*, which leaves the neutral donor in its nS state (nP states are forbidden by symmetry considerations). So, from the energy difference between the two luminescence lines, the energy difference between the $1S$ and $2S$ states of the donor D^0 can be measured, which is very helpful for its identification. The same occurs for A^0X (Fig. 5).

When one atom of a semiconductor is replaced by an atom of the same column of the Mendeleev table, if they are not too different, an *alloy* can be obtained in the whole composition range. Examples of such behavior are $Ge_{1-x}Si_x$, $Ga_{1-x}Al_xAs$, and $GaAs_{1-x}P_x$. As a first approximation, they behave just like ordinary semiconductors whose parameters are now x dependent. However, specific features appear in the low-temperature photoluminescence spectra of these alloys. Since they are random alloys, statistical fluctuations of local concentration are unavoidable. They produce a tail of bound exciton states readily observable in the luminescence spectrum. In addition, time resolution shows the existence of energy transfer toward lower-energy states.

If the electronegativity of the impurity is too different from that of the host, in general, the solubility will be small. An impurity less electronegative can bind a hole; in contrast, it can bind an electron if it is more electronegative. Then, an additional carrier can neutralize the complex, which is called an *isoelectronic exciton*. This happens, for example, in GaP when Bi or N is substituted for P. Such complexes exhibit an electron–hole exchange splitting, readily observable

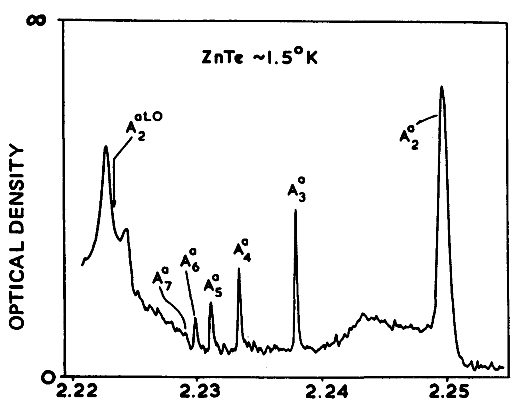

FIG. 5. Two-hole transitions in pure as-grown ZnTe at 1.5 K. The main line A_1^a, related to an exciton bound to a neutral acceptor, is at 2.375 eV; the lines A_n^a correspond to transitions starting from the ground state of A^0X, leaving A^0 in an nS excited state.

in low-temperature photoluminescence. Excitons can also be bound more strongly to pairs of isoelectronic impurities at different separation. Let us stress a strong apparent difference between GaAs and GaP. In GaAs at atmospheric pressure, it is impossible to detect any N-related luminescence signal. Under the action of a hydrostatic pressure larger than 2.2 GPa, photoluminescence lines related to N appear. This is because the energy levels of the N isoelectronic exciton are linked mainly to the conduction-band minima of X symmetry, at the Brillouin-zone edge, the lowest in GaP. In contrast, these minima are above the Γ minimum, at the Brillouin-zone center, in GaAs. The effect of pressure is to push up the Γ minimum and push down the X minima. With increasing pressure, GaAs becomes GaP-like, and the N-related lines appear.

Among the variety of *deep centers*, let us distinguish the *transition metals*. When they are incorporated in large-gap semiconductors, one recovers the situation encountered in Sec. 3.1.2. Mn in ZnS is such an example of a traditional luminescent material. In fact, Mn incorporated in most II-VI compounds with band gap larger than 2.2 eV produces an analogous yellow-orange luminescence band coming from the excitation of the ^5d shell of Mn^{2+}. Hybridization of transition-metal d orbitals with valence-band orbitals of the host crystal is somewhat larger in semiconductors. Another feature of interest is the magnetic moment carried by some of these transition-metal ions; consequences for the luminescence are examined in Sec. 3.2.2. Another class of deep centers may be called *lattice defects*, like vacancies, interstitials, antisites defects in compounds, and complex defects involving impurities and lattice defects. Photoluminescence is just a tool, among a lot of others, to help defect identification. Let us just mention the famous *EL*2 defect in GaAs; it is a native defect that exists in three charged states (0, +, and ++), giving energy levels near midgap and providing semi-insulating GaAs substrates. It involves likely an arsenic antisite As_{Ga} that might dissociate into a gallium vacancy V_{Ga} and an interstitial arsenic As_i in some of its possible charge states; this model is still under debate.

3.1.4 Low-Dimensional Semiconductor Structures With the advent in the seventies of refined growth methods [see CVD (CHEMICAL VAPOR DEPOSITION) and MOLECULAR BEAM EPITAXY], the growth of artificial layered structures became possible, with an accuracy approaching the atomic-layer limit. Other methods were developed later to obtain one-dimensional wires and zero-dimensional boxes (or dots) with somewhat poorer accuracy. Photoluminescence turned out to be a very efficient tool to study these structures since it requires no further preparation of the sample, in contrast with optical absorption measurements, which require substrate removal. A widely used substitute for absorption spectrum is the photoluminescence excitation spectrum. Figure 6 shows results for a GaAs quantum well; the photoluminescence excitation spectrum exhibits peaks that are related to the *quantization* of electron and hole movement along the growth axis (see ELECTRON STATES IN ZERO-, ONE-, AND TWO-DIMENSIONAL STRUCTURES). Excitonic effects are enhanced in two-dimensional structures, in agreement with theory. Another interesting feature is the Stokes shift between the lowest excitation peak and the photoluminescence peak. This shift, which depends on the well width and on the growth conditions, is related to the fact that it is impossible to grow perfect interfaces: There are always some steps or *interface roughness* and also some amount of interdiffusion. This specific kind of disorder induces a weak localization of the excitons, readily observed at 2 K.

Among the very large number of fundamental applications of photoluminescence in low-dimensional structures, let us single out the following, taken under extreme conditions: the study of a two-dimensional free-electron system in modulation-doped heterostructures in a transverse magnetic field. Through magnetotransport measurements, the integer quantum Hall effect and later the more unexpected fractional quantum Hall effect were discovered in such structures. Photoluminescence performed down to 0.1 K and in magnetic field up to 25 T did provide new insight into the nature of the ground state of this electron system: A plane of acceptors was introduced in GaAs at some distance from the interface; a weak photoexcitation neutralizes these acceptors, which can then recombine radiatively with the electrons, thus providing a precise measurement of the energy $E(H)$

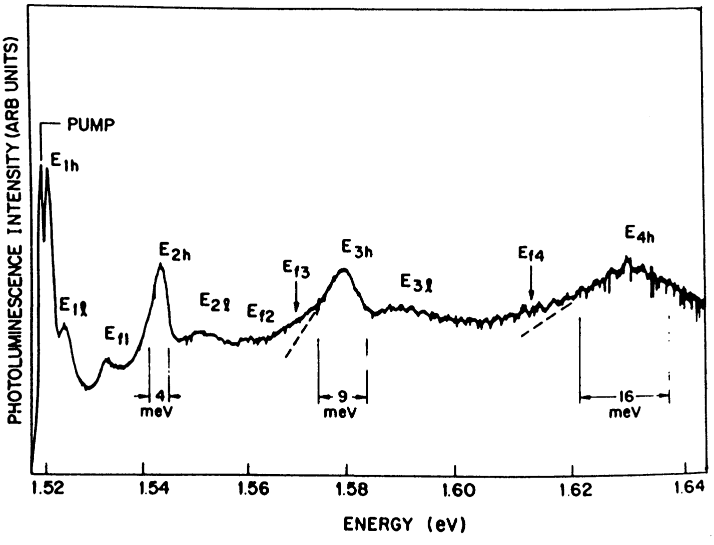

FIG. 6. Excitation spectrum of the exciton luminescence of a 26-nm GaAs quantum well in GaAlAs barriers. The strongest E_{nh} transitions ($n = 1$ to 4) are related to electron and heavy hole in their nth quantized states; transitions noted E_{nl} involve electron and light hole.

of the electron system as a function of the magnetic field H. Indeed, anomalies in the $E(H)$ curve were observed at the field values where the fractional quantum Hall effect is detected. This gives strong support to the theory, based on electron-electron Coulomb interaction, which predicts a new kind of condensation into an incompressible electron liquid for these particular fractional Landau level-filling factors. Experiments are still in progress to determine under what conditions the electron system could crystallize, as predicted by Wigner.

3.1.5 Optical Pumping and Hot Luminescence Absorption of circularly polarized light allows us to excite unequally sublevels in a degenerate set of levels. This *optical pumping* scheme, first developed on atoms, leads, through spin–orbit coupling, to *spin orientation.* The degree of spin orientation, $p_e = (n^+ - n^-)/(n^+ + n^-)$ where n^+ and n^- are the populations of the two spin states, can be monitored by measuring the polarization of the luminescence. This was done first in p-type GaSb (or GaAs). Because of spin–orbit effect near the top of the valence band, absorption of circular photons close to the band gap creates electrons with a degree of spin orientation $p_e = 0.5$; when they recombine with neutral acceptors, the degree of luminescence polarization, $p_L = (I^+ - I^-)/(I^+ + I^-)$ where I^+ and I^- are the intensities of plus or minus circular components of the luminescence, has a maximum value of 0.25. This value is obtained only if the electron lifetime τ is much shorter than the electron spin relaxation time τ_s. In general, one finds $p_L = 0.25/(1 + \tau/\tau_s)$. Then, using a magnetic field H perpendicular to the excitation beam, which is also the quantization axis for the spins, one can induce spin precession at the Larmor frequency $\Omega = g^* \mu_B H/\hbar$, where g^* is the effective gyromagnetic factor of the electron and μ_B is the Bohr magneton. This causes a depolarization of the luminescence known as the *Hanle effect*, the field-dependent polarization being given as

$$p_L(H) = p_L(0)/[1 + (\Omega T_s)^2]$$

where $1/T_s = 1/\tau + 1/\tau_s$. So, from these two measurements, the lifetime τ and the spin relaxation time τ_s can be determined, provided g^* is known (Parsons, 1969); in this way, fairly short times can be measured (down to the 10^{-11}-s range) with dc method; the trick was to use the Larmor frequency Ω as an internal clock.

Orientation of *excitons* is also possible: Under appropriate conditions, a polarized photon will be transmitted at the vacuum–crystal interface as an exciton (polariton) of the *same* polarization. In particular, one can create linearly polarized excitons; when submitted to a magnetic field parallel to their wave vector, the plane of their polarization will rotate, an effect that has been called resonant Faraday effect.

In a typical *hot photoluminescence* experiment, an excitation about 0.5 eV above the band gap is used; the very weak luminescence in the region between the excitation and the main near–band-gap luminescence was at the origin of a new effect: the *optical alignment of electron momenta*. For example, pumping between the heavy-hole band and the conduction band in GaAs with a linear photon of electric polarization along z creates preferentially electrons with wave vector perpendicular to z. Here again, alignment can be demonstrated by measuring the rate of polarization of hot luminescence; alignment can be relaxed by elastic collisions and destroyed by the action of a magnetic field, which induces a cyclotron motion in $\mathbf{k}$ space and introduces a new internal clock, the cyclotron frequency.

Let us add that analogous parameters can be measured in the time-resolved mode, but at the expense of more sophisticated equipment.

3.1.6 Exciton Transport Using a sharply focused pump beam, it is possible to detect the diffusion of the excitations by measuring the diameter of the luminescence spot, or even better using a time-resolved mode. For example, it was possible to show that excitons are indeed trapped at 2 K in type-II GaAs/AlAs superlattices, but become mobile at increasing temperature.

A new kind of exciton transport experiment occurs with the use of a nonuniform stress: Thus, a gradient of band gap is created so that an exciton experiences a force proportional to this gradient. With an excitation pulsed and localized, one can follow the movement of an exciton (or electron–hole) cloud by looking at the time- and space-resolved luminescence. The so-called "phonon wind" effect has been demonstrated (Wolfe, 1985).

3.2 Excitation–Medium Interaction

The excitation introduced into the semiconductor may interact with other (intrinsic) excitations of the medium; we consider two different cases.

3.2.1 Electron–Phonon Coupling, Polarons, Self-Trapping The excitation (electron–hole pair or exciton) can induce a lattice distortion, an effect described in terms of electron–phonon coupling. The strongest coupling occurs generally with longitudinal optical (LO) phonons in polar materials. Such an LO phonon carries with it an electric field to which any charge carrier couples. This coupling, known as Fröhlich interaction, increases in the series GaAs, ZnSe, CuBr. Such coupling has two effects on the luminescence: At moderate coupling strength, sidebands appear, separated from the no-phonon line by 1, 2, 3, . . . times the LO phonon energy; this occurs for bound states, like the D^0A^0 luminescence (e.g., the well-known "green edge" luminescence in CdS) as well as for free excitons. If the coupling is strong enough, self-trapping may occur: The exciton is localized in a strongly distorted region, which acts as a potential well for the exciton. This is observed in KI and NaI; in fact, free-running excitons and self-trapped excitons can coexist because these two states are separated by a potential barrier.

3.2.2 Electron–Magnetic-Ion Exchange Interaction, Magnetic Polaron Another type of interaction of the excitation with the medium is found in magnetic semiconductors: this is the carrier–ion exchange interaction. Starting from a paramagnetic medium, like a diluted magnetic semiconductor (see SEMICONDUCTORS, DILUTED MAGNETIC), a carrier (or an exciton) can lower its energy by the orientation of the ion spins with respect to the spin of the carrier. This can take place already in the ground state, e.g., for localized carriers like neutral donors or acceptors. For example, the increase of neutral acceptor binding energy due to exchange was determined by a shift of the D^0A^0 luminescence with temperature. Such shifts affect also the recombination of excitons weakly localized by disorder, either in bulk or in low-dimensional structures based on diluted magnetic semiconductors. Here again, as in Sec. 3.2.1, if the coupling between the exciton and the ions is strong enough, self-trapping (or free magnetic polaron) may occur. It should be favored in low-dimensional structures; experiments to detect true free magnetic polarons in low-dimensional structures are going on actively.

3.3 High-Excitation Effects

Increasing the excitation level induces two kinds of effects.

3.3.1 Saturation, Optical Gain, Laser We have already shown in Sec. 3.1.3.2 an example of luminescence saturation when all donors and acceptors are neutralized: the D^0A^0 luminescence is saturated. But another effect takes place when the population n_e of the excited state is larger than the population n_g of the ground state: Photons at the energy difference can be amplified rather than absorbed; absorption is proportional to $n_g - n_e$ and gain is just a negative absorption. With band-to-band transition, population inversion can be realized near the band gap because electrons and holes are fermions. When gain occurs, the luminescence is modified in a way that depends upon the geometry of the excited region and the existence of an optical cavity that provides feedback: Laser emission may result see (LASER PHYSICS).

3.3.2 Many-body Effects: Biexcitons, Electron–Hole Plasma or Liquid When the intensity of excitation increases, especially in semiconductors, the density of electrons, holes, and excitons may increase to a point where their mutual Coulomb interaction can shift the energy of the excited states, or even produce new kinds of excited states. At low temperature, with increasing exciton density in pure materials, two excitons can form a bound state, the *exciton molecule* (or *biexciton*), in close analogy with the hydrogen molecule. These have been detected as specific luminescence lines first in direct-gap material: CuCl and later CdS; then in indirect-gap materials like AgBr and Si. At a total density of electrons and holes exceeding the Mott density, the excited medium is described as an electron–hole plasma. In such a state, the mean energy of an electron–hole pair is modified, with respect to the band gap, by a positive term, the Fermi energy of the particles, and a negative one coming from the Coulomb interaction between the particles. As a consequence, the luminescence band due to an electron–hole plasma exhibits a broadening related to the Fermi energy and a shift related to the Coulomb term, both functions of the density. In direct-gap materials, a strong optical gain is also obtained; it may distort the luminescence band and lead to laser action. In indirect-gap materials, something special may occur: because one kind of carrier occupies several equivalent valleys, there is a reduction of the Fermi energy; then the mean energy of a pair exhibits, for some density n_0, a minimum that can stay below the free exciton energy. This phase at density n_0, which is the most stable one at $T = 0$, has been called *electron–hole liquid*; its existence was predicted by Keldysh and well studied mainly using photoluminescence in the 1970s, first in Ge and Si (Fig. 7), later in GaP and SiC. At finite temperature, thermal equilibrium between the electron–hole liquid and the free-exciton gas is nothing but a new example of liquid–gas coexistence. Another kind of condensation was considered in the case of free excitons, which are bosons, being made of two fermions: this is the Bose–Einstein condensation, which is likely occurring in Cu_2O.

3.3.3 Higher-Order Emission Processes A first kind may be called partial Auger process. For example, an exciton interacting with another particle (electron or exciton) can recombine with emission of a photon, some energy being transferred to the second particle. This was well studied in direct-gap materials like CdS. Such a process is likely playing a major role in the mechanism of blue laser emission in ZnSe-based heterostructures, a domain of intense activity.

In a second kind, two electron–hole pairs can recombine with emission of a single photon. For example, a weak green luminescence at about two times the band gap was detected from electron–hole liquid and biexcitons in Si.

3.4 Practical Applications

3.4.1 Nondestructive Material Testing Photoluminescence turns out to be an easy test of a class of materials since it requires

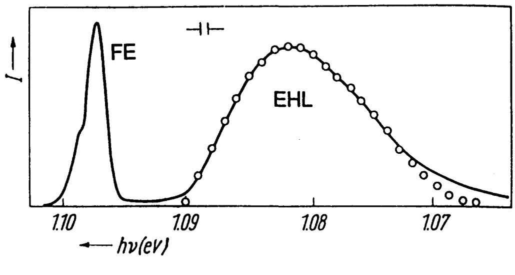

FIG. 7. Photoluminescence spectrum of pure Si at 4.2 K, showing the coexistence of free excitons (FE) and electron–hole liquid (EHL). Si being an indirect-gap material, both luminescence bands are phonon assisted with the same phonons. Open circles correspond to a theoretical fit of the EHL band.

generally no special treatment of the sample and is clearly nondestructive. It finds applications mainly with semiconductors.

In the case of bulk samples, it gives an indication about impurity content and crystalline perfection. It is especially useful for fairly pure samples, where some impurities can be identified from their specific narrow luminescence lines at low temperature. However, precise determination of impurity density is not possible, but comparison with calibrated samples may be useful. Indication about nonradiative centers may be obtained from luminescence decay.

Testing of low-dimensional structures is even more interesting. From the luminescence energy and the photoluminescence excitation spectrum, a precise determination of the energy spectrum of the structure is obtained, which is compared with a model using as inputs the nominal parameters of the growth process. Low-temperature line broadening and Stokes shift give also indications about the quality of the interfaces, to be correlated with the growth conditions.

3.4.2 Devices: Optically Pumped Solid-State Lasers and Amplifiers Whereas most practical luminescent sources use electrical excitation (e.g., semiconductor lamps or electroluminescent panels), optical excitation is used to produce optical gain in the medium, and this is applied to get light amplifiers and lasers. As an amplifier, one can cite Er^{3+}-doped silica fiber, which operates near 1.5 μm; the most efficient pump was found to be a GaAsP injection laser. Such an amplifier is now the best candidate for fiber-optics high-rate communications all around the world. Most solid-state lasers like Nd^{3+} in glass or crystals are optically pumped. Here again, the best overall efficiency is obtained using as a pump semiconductor injection lasers. In the case of a luminescent material like titanium-doped sapphire, the broad gain spectrum leads to a laser with wide tunability, from 680 to 1000 nm; in addition, since the broadening due to phonon coupling is homogeneous, very short laser pulses can be obtained, down to 100 fs.

GLOSSARY

Boxcar: Detection mode using a gate to select in a time window an electronic signal.

Brillouin Scattering: Light scattering by acoustical phonons in crystals.

Brillouin Zone: The polyhedron in reciprocal space over which the wave vector **k** is allowed to vary.

Effective Mass: In a crystal near a band extremum, the dispersion relation for an electron is a quadratic function of its wave vector **k**, written as $E = \hbar^2k^2/2m^*$. The effective mass m^* is the quantity governing the response of the electron in the crystal to an external perturbation, in the same way as m_0, the free electron mass, for an electron in vacuum.

Exchange Interaction: Interaction between particles that satisfy the Pauli exclusion principle, electrons among them.

Frenkel Exciton: In a crystal, coherent propagation of an excitation primarily localized on a molecule or an ion.

Landau Level: Orbital quantized state of a free electron in a magnetic field.

Mode-Locked Laser: By forcing all the longitudinal modes of a laser to be in phase near an end mirror, a pulsed operation is obtained, with a delay between pulses equal to the round-trip time of a photon in the laser cavity.

Modulation-Doped Heterostructure: By introducing donors in the barrier material (e.g., GaAlAs) at some distance from the interface with the well (e.g., GaAs), part of the donor electrons transfer to the well, creating a high-mobility two-dimensional electron gas.

Mott Density: At increasing electron density, a transition from a collection of isolated impurities (or exciton gas) to a metallic state (or an electron–hole plasma) takes place at the Mott density.

Phase Matching: In a nonlinear process, conditions upon the propagation angles of the different beams such that, inside the crystal, wave-vector conservation is insured.

Phonon Wind: In semiconductors, a cloud of acoustical phonons created, e.g., at the focus of an optical beam can push electrons, holes or excitons, thus contributing to an anomalous carrier diffusion.

Quantum Hall Effect: In a two-dimensional electron gas, a plateau in the Hall effect and a dip in the longitudinal resistance are observed at integer (or fractional) Landau-level filling factors.

Rayleigh Scattering: Elastic scattering of light by fixed defects or surface roughness.

Reciprocal Space (k Space): A mathematical space, with dimension of inverse length, over which wave vectors are defined.

Synchronous Detection: Detection of an electronic signal involving the product with a sinusoidal reference signal at frequency *f*. The component of the signal at frequency *f* is extracted.

Subtractive Mode: In a double-grating spectrometer, geometry that insures constant optical path length for any ray.

Wannier Exciton: In crystalline semiconductors, excitation made of an electron–hole pair tied by Coulomb interaction, free to move in the crystal.

INTRODUCTION

Photosynthesis is the physicochemical process by which plants, algae, and photosynthetic bacteria use light energy to drive the synthesis of organic compounds. In plants, algae, and certain types of bacteria, the photosynthetic process results in the release of molecular oxygen and the removal from the atmosphere of carbon dioxide, which is used to synthesize carbohydrates. Other types of bacteria use light energy to create organic compounds but do not produce oxygen. Photosynthesis provides the energy and reduced carbon required for the survival of virtually all life on our planet, as well as the molecular oxygen necessary for the survival of oxygen-consuming organisms. In addition, the fossil fuels currently being burned to provide energy for human activity were produced by ancient photosynthetic organisms. Although photosynthesis occurs in cells or organelles that are typically only a few microns across, the process has a profound impact on the earth's atmosphere and climate. Each year more than 10% of the total atmospheric carbon dioxide is reduced to carbohydrate by photosynthetic organisms. Most, if not all, of

the reduced carbon is returned to the atmosphere as carbon dioxide by microbial, plant, and animal metabolism, and by biomass combustion. In turn, the performance of photosynthetic organisms depends on the earth's atmosphere and climate. Over the next century, the large increase in the amount of atmospheric carbon dioxide created by human activity is certain to have a profound impact on the performance and competition of photosynthetic organisms. Knowledge of the physicochemical process of photosynthesis is essential for understanding the relationship between living organisms and the atmosphere and the balance of life on earth.

1. BRIEF HISTORY

In the 1770s, Joseph Priestley, an English chemist and clergyman, performed experiments showing that plants release a type of air that allows combustion. He demonstrated this by burning a candle in a closed vessel until the flame went out. He placed a sprig of mint in the chamber and after several days showed that the candle could burn again. Although Priestley did not know about molecular oxygen, his work showed that plants release oxygen into the atmosphere. It is noteworthy that over 200 years later, investigating the mechanism by which plants produce oxygen is one of the most active areas of photosynthetic research. Building on the work of Priestley, Jan Ingenhousz, a Dutch physician, demonstrated that sunlight was necessary for photosynthesis and that only the green parts of plants could release oxygen. During this period, Jean Senebier, a Swiss botanist and naturalist, discovered that CO_2 is required for photosynthetic growth, and Nicolas-Théodore de Saussure, a Swiss chemist and plant physiologist, showed that water is required. It was not until 1845 that Julius Robert von Mayer, a German physician and physicist, proposed that photosynthetic organisms convert light energy into chemical free energy.

By the middle of the nineteenth century, the key features of plant photosynthesis were known, namely, that plants could use light energy to make carbohydrates from CO_2 and water. The empirical equation representing the net reaction of photosynthesis for oxygen-evolving organisms is

$$CO_2 + 2H_2O + \text{light energy} \rightarrow [CH_2O] + O_2 + H_2O, \qquad (1)$$

where $[CH_2O]$ represents a carbohydrate (e.g., glucose, a six-carbon sugar). The synthesis of carbohydrate from carbon and water requires a large input of light energy. The standard free energy for the reduction of one mole of CO_2 to the level of glucose is +478 kJ/mol. Because glucose, a six-carbon sugar, is often an intermediate product of photosynthesis, the net equation of photosynthesis is frequently written as

$$6CO_2 + 12H_2O + \text{light energy} \rightarrow C_6H_{12}O_6 + 6O_2 + 6H_2O. \qquad (2)$$

The standard free energy for the synthesis of glucose is +2870 kJ/mol.

Not surprisingly, early scientists studying photosynthesis concluded that the O_2 released by plants came from CO_2, which was thought to be split by light energy. In the 1930s, comparison of bacterial and plant photosynthesis lead Cornelis van Niel to propose the general equation of photosynthesis that applies to plants, algae, and photosynthetic bacteria (discussed by Wraight, 1982). Van Niel was aware that some photosynthetic bacteria could use hydrogen sulfide (H_2S) instead of water for photosynthesis and that these organisms released sulfur instead of oxygen. Van Niel, among others, concluded that photosynthesis depends on electron donation and acceptor reactions and that the O_2 released during photosynthesis comes from the oxidation of water. Van Niel's generalized equation is

$$CO_2 + 2H_2A + \text{light energy} \rightarrow [CH_2O] + 2A + H_2O. \qquad (3)$$

In oxygenic photosynthesis, $2A$ is O_2, whereas in anoxygenic photosynthesis, which occurs in some photosynthetic bacteria, the electron donor can be an inorganic hydrogen donor, such as H_2S in which case A is elemental sulfur, or an organic hydrogen donor such as succinate in which case A is fumarate.

The biochemical conversion of CO_2 to carbohydrate is a reduction reaction that involves the rearrangement of covalent bonds between carbon, hydrogen, and oxygen. The energy for the reduction of carbon is provided by energy-rich molecules that are produced by the light-driven electron-transfer reactions. Carbon reduction can occur in the dark and involves a series of biochemical reactions that were elucidated by Melvin Calvin, Andrew Benson, and James Bassham in the late 1940s and 1950s. Using the radioisotope carbon-14, most of the intermediate steps that result in the production of carbohydrate were identified. Calvin was awarded the Nobel Prize for Chemistry in 1961 for this work.

In 1954, Daniel Arnon and co-workers discovered that plants, and A. Frenkel discovered that photosynthetic bacteria, use light energy to produce ATP, an organic molecule that serves as an energy source for many biochemical reactions. During the same period, L. N. M. Duysens showed that the primary photochemical reaction of photosynthesis is an oxidation/reduction reaction that occurs in a protein complex (the reaction center). Over the next few years, the work of several groups, including those of Robert Emerson, Bessel Kok, L. N. M. Duysens, Robert Hill, and Horst Witt, combined to prove that plant, algae, and cyanobacteria require two reaction centers, photosystem II and photosystem I, operating in series.

In 1961, Peter Mitchell suggested that cells can store energy by creating an electric field or a proton gradient across a membrane. Mitchell's proposal that energy is stored as an electrochemical gradient across a vesicular membrane opened the door for understanding energy transformation by membrane systems. He was awarded the Nobel Prize in Chemistry in 1978 for his theory of chemiosmotic energy transduction.

Most of the proteins required for the conversion of light energy and electron transfer reactions of photosynthesis are located in membranes. Despite decades of work, efforts to determine the structure of membrane-bound proteins had little success. This changed in the 1980s when Johann Deisenhofer, Hartmut Michel, and Robert Huber determined the structure of the reaction center of the purple bacterium *Rhodospeudomonas viridis*. They were awarded the Nobel Prize for Chemistry in 1988 for their work, which provided insight into the relationship between structure and function in membrane-bound proteins.

A key element in photosynthetic energy conversion is electron transfer within and between protein complexes and simple organic molecules. The electron-transfer reactions are rapid (as fast as a few picoseconds) and highly specific. Much of our current understanding of the physical principles that guide electron transfer is based on the pioneering work of Rudolph A. Marcus, who received the Nobel Prize in Chemistry in 1992 for his contributions to the theory of electron-transfer reaction in chemical systems.

The overall equation for photosynthesis is deceptively simple. In fact, a complex set of physical and chemical reactions must occur in a coordinated manner for the synthesis of carbohydrates. To produce a sugar molecule such as sucrose, plants require nearly 30 distinct proteins that work within a complicated membrane structure. Research into the mechanism of photosynthesis centers on understanding the structure of the photosynthetic components and the molecular processes that use radiant energy to drive carbohydrate synthesis. The research involves several disciplines, including physics, chemistry, structural biology, biochemistry, molecular biology, and physiology, and serves as an outstanding example of the success of multidisciplinary research. As such, photosynthesis presents a special challenge in understanding several interrelated molecular processes. From a physicist's viewpoint, the reactions that transform energy are of particular interest, and it is on these processes that this description will focus.

2. CLASSIFICATION OF PHOTOSYNTHETIC ORGANISMS

All life can be divided into three domains, Archaea, Bacteria, and Eucarya, which originated from a common ancestor (Woese *et al.*, 1990). Historically, the term photosynthesis has been applied to organisms that depend on chlorophyll (or bacteriochlorophyll) for the conversion of light energy into chemical free energy (Gest, 1993). These include organisms in the domains Bacteria (photosynthetic bacteria) and Eucarya (algae and higher plants). The most primitive domain, Archaea, includes organisms known as halobacteria, which convert light energy into chemical free energy. However, the mechanism by which halobacteria convert light is fundamentally different from that of higher organisms because there is no oxidation/reduction chemistry and halobacteria cannot use CO_2 as their carbon source. Consequently, some biologists do not consider halobacteria as photosynthetic (Gest, 1993). This article will follow the historical definition of photosynthesis and omit halobacteria.

2.1 Oxygenic Photosynthetic Organisms

The photosynthetic process in all plants and algae, as well as in certain types of photosynthetic bacteria, involves the reduction of CO_2 to carbohydrate and the removal of electrons from H_2O, which results in the release of O_2. In this process, known as oxygenic photosynthesis, water is oxidized by the photosystem II reaction center, a multisubunit protein located in the photosynthetic membrane. Years of research have shown that structure and function of photosystem II is similar in plants, algae, and certain bacteria, so that knowledge gained in one species can be applied to others. This homology is a common feature of proteins that perform the same reaction in different species. The importance of this homology at the molecular level is shown by the fact that there are an estimated 300 000–500 000 species of plants. If different species had evolved diverse mechanisms for oxidizing water, research aimed at a general understanding of photosynthetic water oxidation would be hopeless.

2.2 Anoxygenic Photosynthetic Organisms

Some photosynthetic bacteria can use light energy to extract electrons from molecules other than water. These organisms are of ancient origin, presumed to have evolved before oxygenic photosynthetic organisms. Anoxygenic photosynthetic organisms occur in the domain Bacteria and have representatives in four phyla: Purple Bacteria, Green Sulfur Bacteria, Green Gliding Bacteria, and Gram Positive Bacteria.

3. GENERAL PRINCIPLES OF PHOTOSYNTHETIC ENERGY TRANSFORMATION IN PLANTS

The energy that drives photosynthesis originates in the center of the sun, where mass is converted to heat by the fusion of hydrogen. Over time, the heat energy reaches the sun's surface, where some of it is converted to light by blackbody radiation that reaches the earth. A small fraction of the visible light incident on the earth is absorbed by plants. Through a series of energy-transducing reactions, plants are able to transform light energy into chemical free energy in a stable form that can last for hundreds of millions of years (e.g., fossil fuels). A simplified scheme describing how plants transform energy is presented in this section. The focus is on the structural and functional features essential for the energy-transforming reactions. For clarity, mechanistic and structural details are omitted. A more highly resolved description of oxygenic and anoxygenic photosynthesis is given in the remaining sections.

The photosynthetic process in plants and algae occurs in small organelles, known as chloroplasts, that are located inside cells. The photosynthetic reactions are traditionally divided into two types: the "light reactions," which consist of electron- and proton-transfer reactions, and the "dark reactions," which consist of the biosynthesis of carbohydrates from CO_2. The light reactions occur in a complex membrane system (the photosynthetic membrane) that is made up of protein complexes, electron carriers, and lipid molecules. The photosynthetic membrane is surrounded by water and can be thought of as a two-dimensional surface that defines a closed space, with an inner and an outer water phase. A molecule or ion must pass through the photosynthetic membrane to go from the inner space to the outer space. The protein complexes embedded in the photosynthetic membrane have a unique orientation with respect to the inner and outer phases. The asymmetrical arrangement of the protein complexes allows some of the energy released during electron transport to create an electrochemical gradient of protons across the photosynthetic membrane.

Photosynthetic electron transport consists of a series of individual electron-transfer steps from one electron carrier to another. The electron carriers are metal ion complexes and aromatic groups. The metal ion complexes and most of the aromatic groups are bound within proteins. Most of the proteins involved in photosynthetic electron transport are composed of numerous polypeptide chains that lace through the membrane, providing a scaffolding for metal ions and aromatic groups. An electron enters a protein complex at a specific site, is transferred within the protein from one carrier to another, and exits from the protein at a different site. The protein controls the pathway of electrons between the carriers by determining the location and environment of the metal ion complexes and aromatic groups. By setting the distance between electron carriers and controlling the electronic environment surrounding a metal ion complex or an aromatic group, the protein controls pairwise electron transfer reactions. Between proteins, electron transfer is controlled by distance and free energy, as for intraprotein transfer, and by the probability that the two proteins are in close contact. Protein association is controlled by a number of factors, including the structure of the two proteins, their surface electrical and chemical properties, and the probability that they collide with one another. Not all electron carriers are bound to proteins. The reduced forms of plastoquinone and nicotinamide adenine dinucleotide phosphate (NADPH) act as mobile electron carriers operating between protein complexes. For electron transfer to occur, these small molecules must bind to special pockets in the proteins known as binding sites. The binding sites are highly specific and are a critical factor in controlling the rate and pathway of electron transfer.

The light reactions convert energy into several forms (Fig. 1). The first step is the conversion of a photon to an excited electronic state of an antenna pigment molecule located in the antenna system. The antenna system consists of hundreds of pigment molecules (mainly chlorophyll and carotenoids) that are anchored to proteins within the photosynthetic membrane and serve a specialized protein complex known as a reaction center. The electronic excited state is transferred over the antenna molecules as an exciton. Some excitons are converted back into photons and emitted as fluorescence, some are converted to heat, and some are trapped by a reaction-center protein. Excitons trapped by a reaction center provide the energy for the primary photochemical reaction of photosynthesis—the transfer of an electron from a donor molecule to an acceptor molecule. Both the donor and acceptor molecules are attached to the reaction-center protein complex. Once primary charge separation occurs, the subsequent electron-transfer reactions are energetically downhill. In oxygenic photosynthetic organisms, two different reaction centers work in series: photosystem II and photosystem I. Electrons are transferred from photosystem II to the photosystem I reaction center by intermediate carriers. The net reaction is the transfer of electrons from a water molecule to NADP$^+$, producing the reduced form, NADPH. In the photosynthetic process, much of the energy initially provided by light energy is stored as redox free energy (a form of chemical free energy) in NADPH, to be used later in the reduction of carbon. In addition, the electron-transfer reactions concentrate protons inside the membrane vesicle and create an electric field across the photosynthetic membrane. In this process, the electron-transfer reactions convert redox free energy into an electrochemical po-

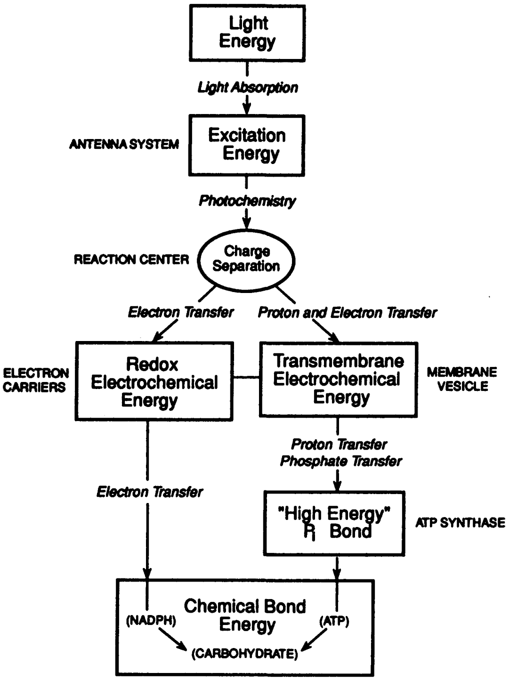

FIG. 1. Photosynthesis shown as a series of reactions that transform energy from one form to another. The different forms of energy are shown in boxes, and the direction of energy transformation is shown by the arrows. The energy-transforming reaction is shown by italics in the arrows. The site at which the energy is stored is shown in capital letters outside the boxes. The primary photochemical reaction, charge separation, is shown in the oval. Details of these reactions are given in the text.

tential of protons. The energy stored in the proton electrochemical potential is used by a membrane-bound protein complex (ATP synthase) to attach a phosphate group covalently to adenosine diphosphate (ADP), forming adenosine triphosphate (ATP). Protons pass through the ATP-synthase protein complex that transforms electrochemical free energy into a type of chemical free energy known as phosphate group-transfer potential (or a high-energy phosphate bond) (Klotz, 1967). The energy stored in ATP can be transferred to another molecule by transferring the phosphate group. The net effect of the light reactions is to convert radiant energy into redox free energy in the form of NADPH and phosphate group-transfer energy in the form of ATP. In the light reactions, the transfer of a single electron from water to $NADP^+$ involves about 30 metal ions and seven aromatic groups. The metal ions include 19 Fe, 5 Mg, 4 Mn, and 1 Cu. The aromatics include quinones, pheophytin, NADPH, tyrosine, and a flavoprotein.

The NADPH and ATP formed by the light reactions provide the energy for the dark reactions of photosynthesis, known as the Calvin cycle or the photosynthetic carbon reduction cycle. The reduction of atmospheric CO_2 to carbohydrate occurs in the aqueous phase of the chloroplast and involves a series of enzymatic reactions. The first step is catalyzed by the protein Rubisco (D-ribulose 1,5-bisphosphate carboxylase/oxygenase), which attaches CO_2 to a five-carbon compound. The reaction produces two molecules of a three-carbon compound. Subsequent biochemical reactions involve several enzymes that reduce carbon by hydrogen transfer and rearrange the carbon compounds to synthesize carbohydrates. The carbon reduction cycle involves the transfer and rearrangement of chemical bond energy.

4. OXYGENIC PHOTOSYNTHESIS IN PLANTS

4.1 Chloroplasts—Structure and Organization

Photosynthesis occurs inside chloroplasts, which are small organelles found in plant cells. Chloroplasts provide the energy and reduced carbon needed for plant growth and development, while the plant provides the chloroplast with CO_2, water, nitrogen, organic molecules, and minerals necessary for the chloroplast biogenesis. Most chloroplasts are located in specialized leaf cells, which often contain 50 or more chloroplasts per cell. Each chloroplast is defined by an inner and an outer envelope membrane and is shaped like a meniscus convex lens that is 5–10 μm in diameter (Fig. 2), although many different shapes and sizes can be found in plants. The inner envelope membrane acts as a barrier, controlling the flux of organic and charged molecules in and out of the chloroplast. Water passes freely through the envelope membranes, as do other small neutral molecules like CO_2 and O_2. There is convincing evidence that chloroplasts were once free-living bacteria that invaded a nonphotosynthetic cell long ago. They have retained some of the DNA necessary for their assembly, but much of the DNA necessary for their biosynthesis is located in the cell nucleus. This enables a cell to control the biosynthesis of chloroplasts within its domain.

Inside the chloroplast is a complicated membrane system, known as the photosynthetic membrane (or thylakoid membrane), that contains most of the proteins required for the light reactions. The proteins required for the fixation and reduction of CO_2 are located outside the photosynthetic membrane in the surrounding aqueous phase. The photosynthetic membrane is composed mainly of glycerol lipids and protein. The glycerol lipids are a family of molecules characterized by a polar head group that is hydrophilic and two fatty acid side chains that are hydrophobic. In membranes, the lipid mol-

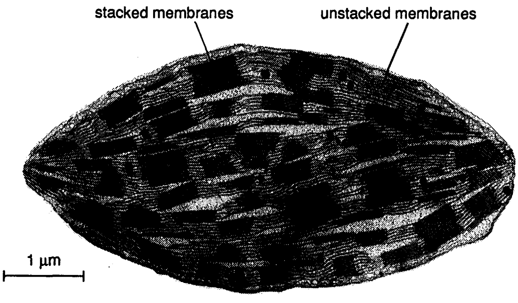

FIG. 2. An electron micrograph of a plant chloroplast. Micrograph by A. D. Greenwood, courtesy of J. Barber.

ecules arrange themselves in a bilayer, with the polar head toward the water phase and the fatty acid chains aligned inside the membrane forming a hydrophobic core (Fig. 3). The photosynthetic membrane is vesicular, defining a closed space with an outer water space (stroma) and an inner water space (lumen). The organization of the photosynthetic membrane can be described as groups of stacked membranes (like stacks of pita bread, with the inner pocket representing the inner aqueous space), interconnected by nonstacked membranes that protrude from the edges of the stacks (Staehelin, 1986). Experiments indicate that the inner aqueous space of the photosynthetic membrane is likely continuous inside of the chloroplast. It is not known why the photosynthetic membrane forms such a convoluted structure. To understand the energetics of photosynthesis, the complicated structure can be ignored and the photosynthetic membrane can be viewed as a simple vesicle.

4.2 Light Absorption—The Antenna System

Plant photosynthesis is driven primarily by visible light (wavelengths from 400 to 700 nm) that is absorbed by pigment molecules (mainly chlorophyll *a* and *b* and carotenoids). Plants appear green because of chlorophyll, which is so plentiful that regions of the earth appear green from space. The absorption spectra of chlorophyll *a* and *b* and of a chloroplast are shown in the article EXCITONS. Light is collected by 200–300 pigment molecules that are bound to light-harvesting protein complexes located in the photosynthetic membrane. The three-dimensional structure of the light-harvesting complex (Kühlbrandt *et al.*, 1994) shows that the protein determines the position and orientation of the antenna pigments. The light-harvesting complexes surround the reaction centers and serve as antennae. Photosynthesis is initiated by the absorption of a photon by an antenna molecule, which occurs in

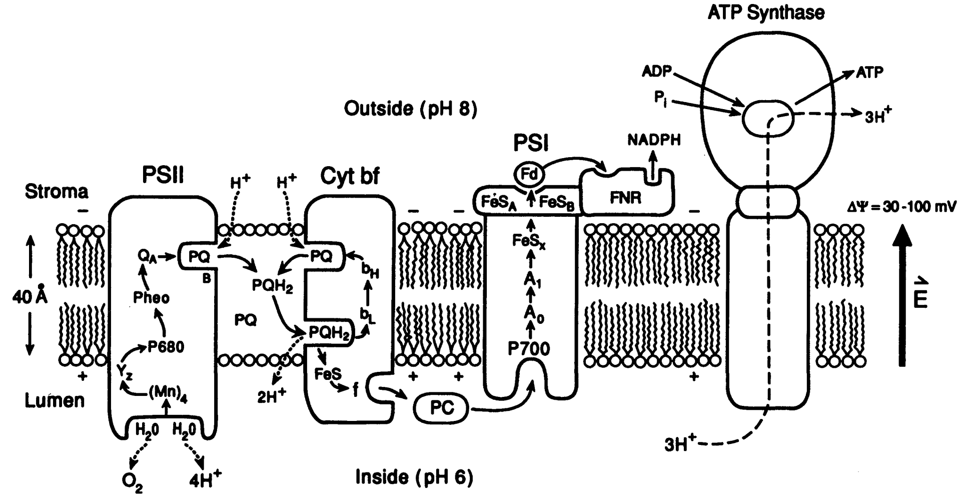

FIG. 3. Model of the photosynthetic membrane of plants showing the electron-transport components and the ATP-synthase enzyme (cross-sectional view). The complete membrane forms a vesicle. The pathways of electrons are shown by solid arrows. The membrane-bound electron-transport protein complexes involved in transferring electrons are the photosystem II and I reaction centers (PSII and PSI) and the cytochrome *bf* complex (Cyt *bf*). Abbreviations: Y_z, tyrosine; P680 and P700, the reaction-center chlorophyll of photosystem II and photosystem I, respectively; Pheo, pheophytin; Q_A, bound plastoquinone; PQ, free plastoquinone (oxidized form), PQH_2, free plastoquinone (reduced form); b_L and b_H, different forms of *b*-type cytochromes; FeS, iron-sulfur centers; *f*, cytochrome *f*; PC, plastocyanin; A_0, chlorophyll; A_1, phylloquinone; Fd, ferredoxin; FNR, ferredoxin/NADP$^+$ oxidoreductase; NADPH, nicotinomide adenine dinucleotide phosphate (reduced form); ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate; H^+, protons; $\Delta\Psi$, the light-induced electrical potential across the membrane. The light-harvesting protein complexes are not shown. Details are given in the text.

10^{-15} s and causes a transition from the electronic ground state to an excited state. Within 10^{-13} s, the excited state decays by vibrational relaxation to the first excited singlet state. The fate of the excited-state energy is guided by the structure of the protein. Because of the proximity of other antenna molecules with the same or similar energy states, the excited-state energy has a high probability of being transferred by resonance energy transfer to a near neighbor. Exciton energy transfer between antenna molecules is due to the interaction of the transition dipole moment of the molecules. The probability of transfer is dependent on the distance between the transition dipoles of the donor and acceptor molecules ($1/R^6$), the relative orientation of the transition dipoles, and the overlap of the emission spectrum of the donor molecule with the absorption spectrum of the acceptor molecule (for a discussion of resonance energy transfer, see EXCITONS). Photosynthetic antenna systems are very efficient at this process. Under optimum conditions, over 90% of the absorbed quanta are transferred within a few hundred picoseconds from the antenna system to the reaction center, which acts as a trap for the excitons.

4.3 Primary Photochemistry—Photosystem II and Photosystem I Reaction Centers

Photosystem II uses light energy to drive two chemical reactions: the oxidation of water and the reduction of plastoquinone. The photosystem II complex is composed of more than 15 polypeptides, and at least nine different redox components (chlorophyll, pheophytin, plastoquinone, tyrosine, Mn, Fe, cytochrome b559, carotenoid, and histidine) have been shown to undergo light-induced electron transfer (Debus, 1992). However, only five of these redox components are known to be involved in transferring electrons from H_2O to the plastoquinone pool—the water-oxidizing manganese cluster $(Mn)_4$, the amino acid tyrosine, the reaction center chlorophyll (P680), pheophytin, and the plastoquinone molecules, Q_A and Q_B. Of these essential redox components, tyrosine, P680, pheophytin, Q_A, and Q_B have been shown to be bound to two key polypeptides that form the heterodimeric reaction center core of photosystem II (*D*1 and *D*2). Recent work indicates that the *D*1 and *D*2 polypeptides also provide ligands for the $(Mn)_4$ cluster. The three-dimensional structure of photosystem II is not known. Our knowledge of its structure is guided by the known structure of the reaction center in purple bacteria and biochemical and spectroscopic data. Figure 4 shows a schematic view of photosystem II that is consistent with current data.

Photochemistry in photosystem II is initiated by charge separation between P680 and pheophytin, creating $P680^+/Pheo^-$. Primary charge separation takes about 3 ps (Fig. 5). Subsequent electron-transfer steps have been designed through evolution to prevent the primary charge separation from recombining. This is accomplished by transferring the electron within 200 ps from pheophytin to a plastoquinone molecule (Q_A) that is permanently bound to photosystem II. Although plastoquinone normally acts as a two-electron acceptor, it works as a one-electron acceptor at the Q_A site. The electron on Q_A- is then transferred to another plastoquinone molecule that is loosely bound at the Q_B site. Plastoquinone at the Q_B site differs from Q_A in that it works as a two-electron acceptor, becoming fully reduced and protonated after two photochemical turnovers of the reaction center. The full reduction of plastoquinone requires the addition of two electrons and two

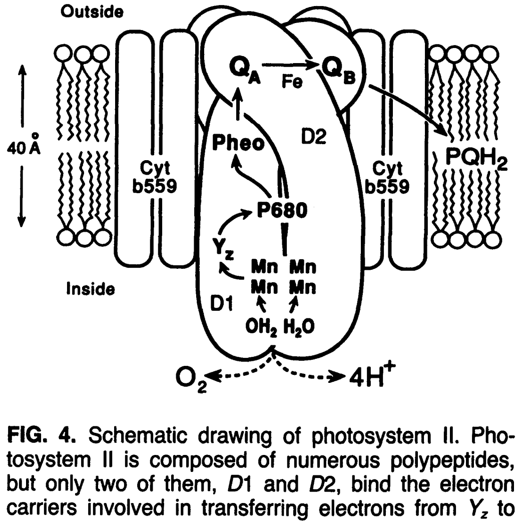

FIG. 4. Schematic drawing of photosystem II. Photosystem II is composed of numerous polypeptides, but only two of them, *D*1 and *D*2, bind the electron carriers involved in transferring electrons from Y_z to plastoquinone. Abbreviations: Y_z, tyrosine; P680, reaction-center chlorophyll (primary electron donor); Pheo, pheophytin; Q_A and Q_B, bound plastoquinone; PQH_2, reduced plastoquinone; Cyt *b*559, *b*-type cytochrome. Details are given in the text.

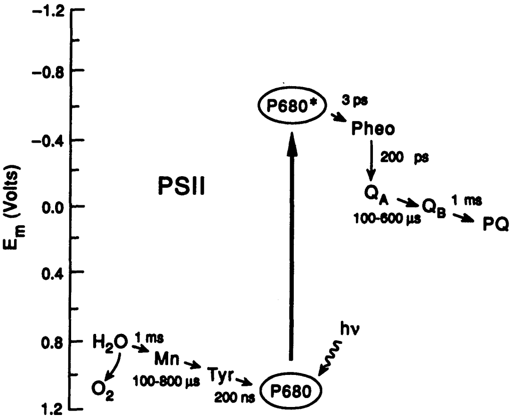

FIG. 5. Photosystem II electron-transport pathways and rates. The vertical axis shows the midpoint potential of the electron carriers. The heavy vertical arrow shows light absorption. P680* is the electronically excited state of P680. The abbreviations are given in the legend of Fig. 4.

protons, i.e., the addition of two hydrogen atoms (Fig. 6). The reduced plastoquinone then debinds from the reaction center and diffuses into the hydrophobic core of the membrane, then an oxidized plastoquinone molecule finds its way to the Q_B-binding site, and the process is repeated. Because the Q_B site is near the outer aqueous phase, the protons added to plastoquinone during its reduction are taken from the outside of the membrane.

Photosystem II is the only known protein complex that can oxidize water, resulting in the release of O_2 into the atmosphere. Despite years of research, little is known about the molecular events that lead to water oxidation. Energetically, water is a poor electron donor. The oxidation-reduction midpoint potential ($E_{m,7}$) of water is +0.82 V (pH 7). In photosystem II, this reaction is driven by the oxidized reaction center, P680$^+$ (the midpoint potential of P680/P680$^+$ is estimated to be +1.2 V at pH 7). How electrons are transferred from water to P680$^+$ remains a mystery (Govindjee and Coleman, 1990). It is known that P680$^+$ oxidizes a tyrosine on the $D1$ protein and that Mn plays a key role in water oxidation. Four Mn ions are present in the water-oxidizing complex. X-ray absorption spectroscopy shows that Mn undergoes light-induced oxidation. Water oxidation requires two molecules of water and involves four sequential turnovers of the reaction center. Each photochemical reaction creates an oxidant that removes one electron. The net reaction results in the release of one O_2 molecule, the deposition of four protons into the inner water phase, and the transfer of four electrons to the Q_B site (producing two reduced plastoquinone molecules).

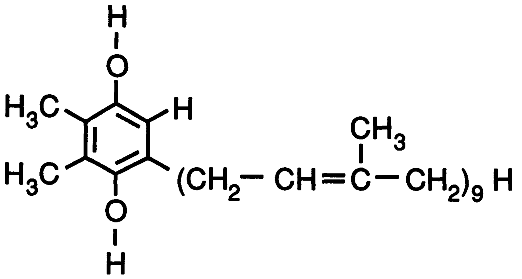

FIG. 6. Structure of plastoquinone (reduced form), an aromatic molecule that carries electrons and protons in photosynthetic electron transport.

The photosystem I complex catalyzes the oxidation of plastocyanin, a small soluble Cu protein, and the reduction of ferredoxin, a small FeS protein (Fig. 7). Photosystem I is

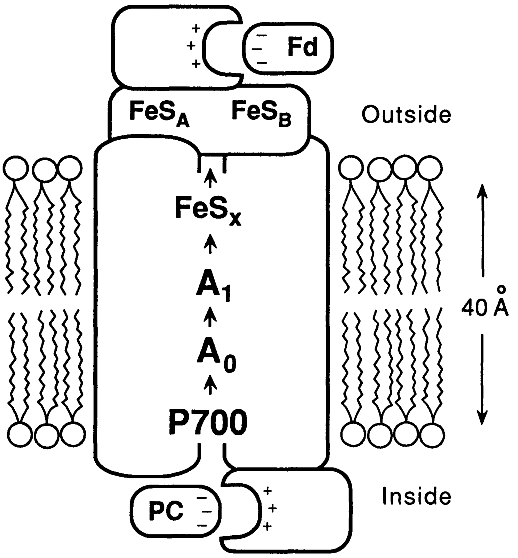

FIG. 7. Schematic drawing of photosystem I. Photosystem I is composed of numerous polypeptides, but only three of them bind the electron carriers. Abbreviations: PC, plastocyanin; P700, reaction-center chlorophyll (primary electron donor); A_0, chlorophyll; A_1, phylloquinone; FeS, FeS centers; Fd, ferredoxin. Details are given in the text.

composed of a heterodimer of proteins that act as ligands for most of the electron carriers (Krauss *et al.*, 1993). The reaction center is served by an antenna system that consists of about two hundred chlorophyll molecules (mainly chlorophyll *a*), and primary photochemistry is initiated by a chlorophyll *a* dimer, P700. In contrast to photosystem II, many of the antenna chlorophyll molecules in photosystem I are bound to the reaction-center proteins. Also, FeS centers serve as electron carriers in photosystem I, and so far as is known, photosystem I electron transfer is not coupled to proton translocation. Primary charge separation occurs between a primary donor, P700, a chlorophyll dimer, and a chlorophyll monomer (A_0). The subsequent electron transfer events and rates are shown in Fig. 8.

4.4 Electron Transport

Electron transport from water to NADP$^+$ requires three membrane-bound protein complexes operating in series: photosystem II, the cytochrome bf complex, and photosystem I (Fig. 3). Electrons are transferred between these large protein complexes by small mobile molecules. Because these small molecules carry electrons (or hydrogen atoms) over relatively long distances, they play a unique role in photosynthetic energy conversion. This is illustrated by plastoquinone (PQ), which serves two key functions. Plastoquinone transfers electrons from the photosystem II reaction center to the cytochrome *bf* complex and carries protons across the photosynthetic membrane. It does this by shuttling hydrogen atoms across the membrane from photosystem II to the cytochrome *bf* complex. Because plastoquinone is hydrophobic, its movement is restricted to the hydrophobic core of the photosynthetic membrane. Plastoquinone operates by diffusing through the membrane until, as a result of random collisions, it becomes bound to a specific site on the photosystem II complex. The photosystem II reaction center reduces plastoquinone at the Q_B site by adding two electrons and two protons, creating PQH_2. The reduced plastoqinone molecule debinds from photosystem II and diffuses randomly in the photosynthetic membrane until it encounters a specific binding site on the cytochrome *bf* complex. The cytochrome *bf* complex is a membrane-bound protein complex that contains four electron carriers, three cytochromes, and an FeS center. In a complicated reaction sequence that is not fully understood, the cytochrome *bf* complex removes the electrons from reduced plastoquinone and facilitates the release of the protons into the inner aqueous space. The electrons are eventually transferred to the photosystem I reaction center. The protons released into the inner aqueous space contribute to the proton chemical free energy across the membrane.

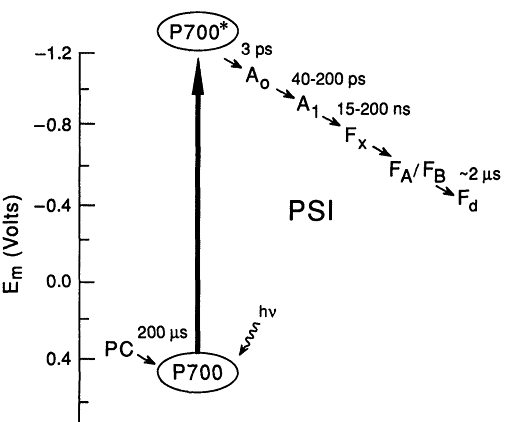

FIG. 8. Photosystem I electron transport pathways and rates. The vertical axis shows the midpoint potential of the electron carriers. Abbreviations are given in the legend of Fig. 7.

Electron transfer from the cytochrome *bf* complex to photosystem I is mediated by a small Cu protein, plastocyanin (PC). Plastocyanin is water soluble and operates in the inner water space of the photosynthetic membrane. Electron transfer from photosystem I to NADP$^+$ requires ferredoxin, a small FeS protein, and ferredoxin-NADP oxidoreductase, a peripheral flavoprotein that operates on the outer surface of the photosynthetic membrane. Ferredoxin and NADP$^+$ are water soluble and are found in the outer aqueous phase.

As discussed in Sec. 3, the pathway of electrons is largely determined by the energetics of the reaction and the distance between the carriers. The electron affinity of the carriers is represented in Fig. 9 by their midpoint potentials, which show the free energy available for electron-transfer reactions under equilibrium conditions. (It should be kept

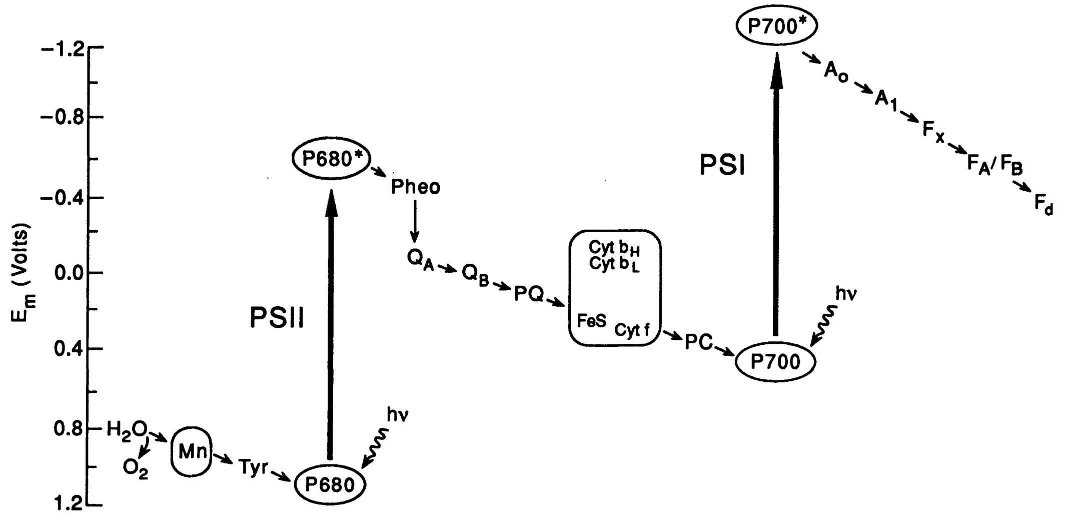

FIG. 9. The electron transport pathway of plants (oxygenic photosynthesis). Abbreviations are given the legend of Fig. 3. Details are given in the text.

in mind that reaction conditions during photosynthesis are not in equilibrium.) Subsequent to primary charge separation, electron transport is energetically downhill (from a lower to a higher redox potential). It is the downhill flow of electrons that provides free energy for the creation of a proton chemical gradient.

Photosynthetic membranes effectively limit electron transport to two dimensions. For mobile electron carriers, limiting diffusion to two dimensions increases the number of random encounters (Whitmarsh, 1986). Furthermore, because plastocyanin is mobile, any one cytochrome *bf* complex can interact with a number of photosystem I complexes. The same is true for plastoquinone, which commonly operates at a stoichiometry of about six molecules per photosystem II complex.

4.5 Creation of a Proton Electrochemical Potential

Electron transport creates the proton electrochemical potential of the photosynthetic membrane by two types of reactions.

1. The release of protons during the oxidation of water by photosystem II and the translocation of protons from the outer aqueous phase to the inner aqueous phase by the coupled reactions of photosystem II and the cytochrome *bf* complex in reducing and oxidizing plastoquinone on opposite sides of the membrane creates a concentration difference of protons across the membranes ($\Delta p\mathrm{H} = p\mathrm{H}_{\mathrm{in}} - p\mathrm{H}_{\mathrm{out}}$).
2. Primary charge separation at a reaction center drives an electron across the photosynthetic membrane, which creates an electric potential across the membrane ($\Delta\Psi = \Psi_{\mathrm{in}} - \Psi_{\mathrm{out}}$).

Together, these two forms of energy make up the proton electrochemical potential across the photosynthetic membrane ($\Delta\mu_{\mathrm{H}^+}$), which is related to the pH difference across the membrane and the electrical potential difference across the membrane by the following equation:

$$\Delta\mu_{\mathrm{H}^+} = F\Delta\Psi - 2.3\mathrm{R}T\,\Delta p\mathrm{H},$$

where F is the Faraday constant, R is the gas constant, and T is the temperature in kelvins. Although the value of $\Delta\Psi$ across the photosynthetic membrane in chloroplasts can be as large as 100 mV, under normal conditions the proton gradient dominates. For example, during photosynthesis, the outer pH is typically near 8 and the inner pH is typically near 6, giving a pH difference of 2 across the membrane that is equivalent to 120 mV. Under these conditions, the free energy for proton transfer from the inner to the outer aqueous phase is −12 kJ/mol of protons.

4.6 Synthesis of ATP by the ATP-Synthase Enzyme

The conversion of proton electrochemical energy into chemical free energy is accomplished by a single protein complex known as ATP synthase. This enzyme catalyzes a phosphorylation reaction, which is the formation of ATP by the addition of inorganic phosphate (P_i) to ADP:

$$ADP^{-3} + P_i^{-2} + H^+ \rightarrow ATP^{-4} + H_2O.$$

The reaction is energetically uphill (ΔG = +32 kJ/mol) and is driven by proton transfer through the ATP-synthase protein. The ATP-synthase complex is composed of two major subunits, CF_0 and CF_1 (Fig. 10). The CF_0 subunit spans the photosynthetic membrane and forms a proton channel through the membrane. The CF_1 subunit is attached to the top of the CF_0 on the outside of the membrane and is located in the aqueous space. The CF_1 subunit is composed of several different protein subunits, referred to as α, β, γ, δ, and ϵ. The top portion of the CF_1 subunit is composed of three $\alpha\beta$ dimers that contain the catalytic sites for ATP synthesis. The molecular processes that couple proton transfer through the protein to the chemical addition of phosphate to ADP are poorly understood. It is known that phosphorylation can be driven by a *p*H gradient, a transmembrane electric field, or a combination of the two. Experiments indicate that three protons must pass through the ATP-synthase complex for the synthesis of one molecule of ATP. However, the protons are not involved in the chemistry of adding phosphate to ADP. Paul Boyer and co-workers have proposed an alternating binding site mechanism for ATP synthesis (Boyer, 1993). One model based on their proposal is that there are three catalytic sites on each CF_1 that cycle among three different states. The states differ in their affinity for ADP, P_i, and ATP. At any one time, each site is in a different state. Initially, one catalytic site on CF_1 binds one ADP and one inorganic phosphate molecule relatively loosely. Through a conformational change of the protein, the site becomes a tight binding site, which stabilizes ATP. Next, proton transfer induces an alteration in protein conformation that causes the site to release the ATP molecule into the aqueous phase. In this model, the energy from the proton electrochemical gradient is used to lower the affinity of the site for ATP, allowing its release to the water phase. The three sites on CF_1 act cooperatively; i.e., the conformational states of the sites are linked. It has been proposed that protons affect the conformational change by driving the rotation of the top part (the three $\alpha\beta$ dimers) of CF_1. This revolving-site mechanism would require rates as high as 100 rev/s. It is worth noting that flagella that propel some bacteria are driven by a proton pump and can rotate at 60 rev/s.

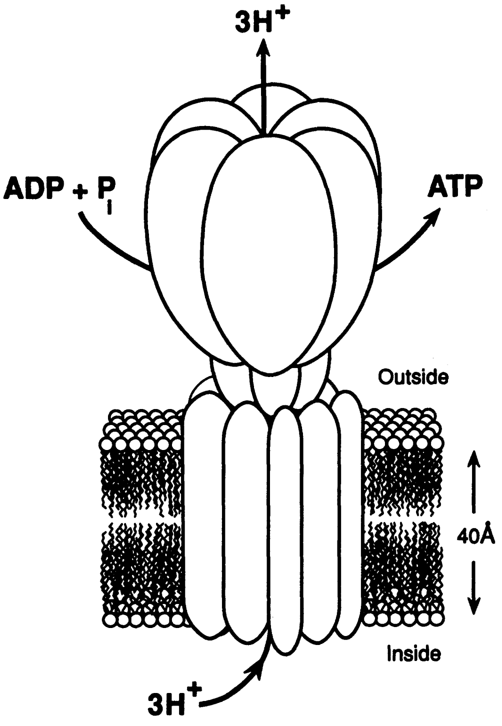

FIG. 10. Schematic drawing of the ATP-synthase enzyme embedded in the membrane. Proton transfer through the ATP synthase provides the energy for the creation of ATP from ADP and P_i. Abbreviations are given in the legend of Fig. 3. Details are given in the text.

4.7 Synthesis of Carbohydrates from Atmospheric CO_2 by the Calvin-Cycle Enzymes

All plants and algae remove CO_2 from the environment and reduce it to carbohydrate by the Calvin cycle. The process is a sequence of biochemical reactions that reduce carbon and rearrange bonds to produce carbohydrate from CO_2 molecules. The first step is the addition of CO_2 to a five-carbon compound (ribulose 1,5-bisphosphate) (Fig. 11). The six-carbon compound is split, giving two molecules of a three-carbon compound (3-phosphoglycerate). This key reaction is catalyzed by Rubisco, a large water-soluble protein complex. The carboxylation reaction is energetically downhill. The main energy input in the Calvin cycle is the phosphorylation by ATP and subsequent reduction by NADPH of the initial three-carbon compound forming a three-carbon sugar, triose phosphate. Some of the triose phosphate is exported from the chloroplast and provides the building block for synthesizing more complex molecules. In a process known as regeneration, the Calvin cycle uses some of the triose phosphate molecules to synthesize the energy-rich ribulose 1,5-bisphosphate needed for the initial carboxylation reaction. This reaction requires the input of energy in the form of one ATP. Overall, 13 enzymes are required to catalyze the reactions in the Calvin cycle. The energy-conversion efficiency of the Calvin cycle is approximately 90%. The reactions do not involve energy transduction but rather the rearrangement of chemical energy. Each molecule of CO_2 reduced to a sugar $[CH_2O]_n$ requires two molecules of NADPH and three molecules of ATP.

Rubisco is a bifunctional enzyme that, in addition to binding CO_2 to ribulose bisphosphate, can also bind O_2. This oxygenation reaction produces the 3-phosphoglycerate that is used in the Calvin cycle and a two-carbon compound (2-phosphoglycolate) that is not useful for the plant. In response, a complicated set of reactions (known as photorespiration) are initiated that serve to recover reduced carbon and to remove phosphoglycolate. The Rubisco oxygenation reaction appears to serve no useful purpose for the plant. Some plants have evolved specialized structures and biochemical pathways that concentrate CO_2 near Rubisco, which serves to decrease the fraction of oxygenation reactions.

4.8 Photosynthetic Quantum Yield and Energy Conversion Efficiency

The theoretical minimum quantum requirement for photosynthesis is eight quanta for each molecule of oxygen evolved (four quanta required by photosystem II and four by photosystem I). Measurements in leaves under optimal conditions (e.g., low light) give

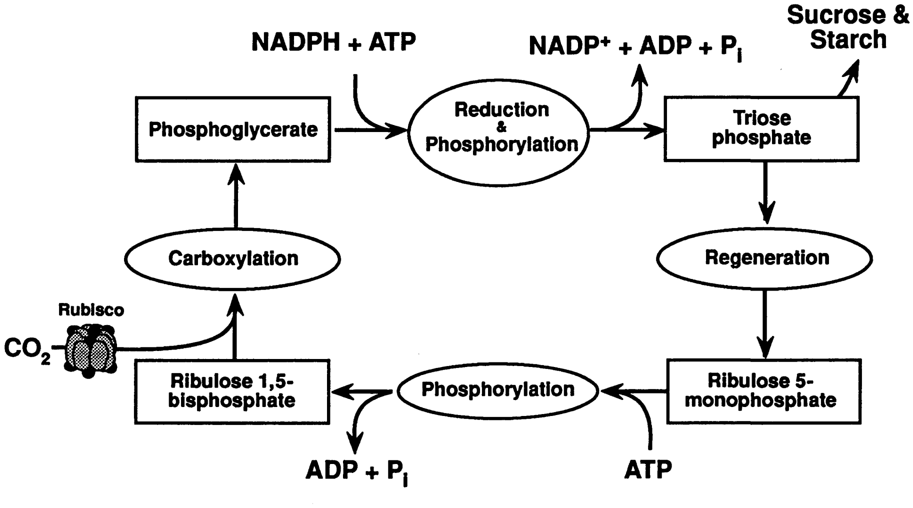

FIG. 11. An abbreviated scheme showing reduction of carbon dioxide by the Calvin cycle. The first step is carboxylation, in which ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) catalyzes the addition of CO_2 to the five-carbon compound ribulose 1,5-bisphosphate, which is subsequently split into two molecules of the three-carbon compound 3-phosphoglycerate. Next are reduction and phosphorylation reactions that form the carbohydrate triose phosphate. Some of the triose phosphate molecules are used to form the products of photosynthesis, sucrose and starch, while the rest is used to regenerate ribulose 1,5-bisphosphate needed for the continuation of the cycle. Details are given in the text.

quantum requirements of 8–10 photons per oxygen molecule released. These quantum yield measurements show that the quantum yields of photosystem II and photosystem I reaction centers under optimal conditions are near 100%. These values can be used to calculate the theoretical energy conversion efficiency of photosynthesis (free energy stored as carbohydrate/light energy absorbed). If eight red quanta are absorbed (8 mol of red photons are equivalent to 1400 kJ) for each CO_2 molecule reduced (480 kJ/mol), the theoretical maximum energy efficiency for carbon reduction is 34%. Under optimal conditions, plants can achieve energy conversion efficiencies within 90% of the theoretical maximum. However, under normal growing conditions, the actual performance of the plant is far below these theoretical values. The factors that conspire to lower the quantum yield of photosynthesis include limitations imposed by biochemical reactions in the plant and environmental conditions that limit photosynthetic performance. One of the most efficient crop plants is sugar cane, which has been shown to store up to 1% of the incident visible radiation over a period of 1 year. However, most crops are less productive. The annual conversion efficiency of corn, wheat, rice, potatoes, and soybeans typically ranges from 0.1% to 0.4% (Odum, 1971).

5. OXYGENIC PHOTOSYNTHESIS IN ALGAE

Algae are photosynthetic eukaryotic organisms that evolve O_2 and reduce CO_2. They represent a diverse group that include dinoflagellates, euglenoids, yellow-green algae, golden-brown algae, diatoms, red algae, brown algae, and green algae. The photosynthetic apparatus and biochemical pathways of carbon reduction of algae are similar to plants. Photosynthesis occurs in chloroplasts that contain photosystems II and I, the cytochrome bf complex, the Calvin-cycle enzymes, and pigment-protein complexes containing chlorophyll *a* and other antenna pigments (*e.g.*, chlorophyll *b* in green algae, chlorophyll *c* and fucoxanthol in brown algae and diatoms, and phycobilins in red algae). Green algae are thought to be the ancestral group from which land plants evolved. Algae are abundant and widespread on the earth, living mainly in fresh and sea water. Some algae live as single-celled organisms, while others form multicellular organisms, some of which can grow quite large, such as kelp and seaweed. Phytoplankton in the ocean is made up of algae and oxygenic photosynthetic bacteria. Most photosynthesis in the ocean is due to phytoplankton, which is an important source of food for marine life.

6. OXYGENIC PHOTOSYNTHESIS IN BACTERIA

6.1 Cyanobacteria

Cyanobacteria are photosynthetic prokaryotic organisms that evolve O_2. Fossil evidence indicates that cyanobacteria existed over 3 billion years ago, and it is thought that they were the first oxygen-evolving organisms on earth. Cyanobacteria are presumed to have evolved in water in an atmosphere that lacked O_2. Initially, the O_2 released by cyanobacteria reacted with ferrous iron in the oceans and was not released into the atmosphere. Geological evidence indicates that the ferrous Fe was depleted around 2 billion years ago, and earth's atmosphere became aerobic. The release of O_2 into the atmosphere by cyanobacteria has had a profound affect on how life evolved.

The photosynthetic apparatus of cyanobacteria is similar to that of chloroplasts. The main difference lies in the antenna system. Cyanobacteria depend on chlorophyll *a* and specialized protein complexes called phycobilisomes that gather light energy. They do not contain chlorophyll *b*. As in chloroplasts, the chlorophyll *a* is located in membrane-bound proteins. The phycobilisomes are bound to the outer side of the photosynthetic membrane and act to funnel exciton energy to the photosystem II reaction center. They are composed of phycobiliproteins, protein subunits that contain covalently attached open ring structures known as bilins that are the light-absorbing pigments. Primary photochemistry, electron transport, phosphorylation, and carbon reduction occur much as they do in chloroplasts. Cyanobacteria have a simpler genetic system than plants and algae, which enables them to be easily modified genetically. Because of this, cyanobacteria have been used as a model to understand photosynthesis in plants. By genetically altering photosynthetic proteins, researchers can investigate the relationship between molecular structure and function.

6.2 Prochlorophytes

Over the past three decades, several types of oxygenic bacteria known as prochlorophytes (or oxychlorobacteria) have been discovered that have light-harvesting protein complexes that contain chlorophyll *a* and *b* but do not contain phycobilisomes (Palenik and Haselkorn, 1992). Because prochlorophytes have chlorophyll *a*/*b* light-harvesting proteins like chloroplasts, they are being investigated as models for plant photosynthesis.

7. ANOXYGENIC PHOTOSYNTHESIS IN BACTERIA

Anoxygenic photosynthetic bacteria differ from oxygenic organisms in that each species has only one type of reaction center. In some photosynthetic bacteria, the reaction center is similar to photosystem II, and in others, it is similar to photosystem I. However, neither of these two types of bacterial reaction center is capable of extracting electrons from water, and so they do not evolve O_2. Many species can only survive in environments that have a low concentration of O_2. To provide electrons for the reduction of CO_2, anoxygenic photosynthetic bacteria must oxidize inorganic or organic molecules available in their environment. For example, the purple bacterium *Rhodobacter sphaeroides* can use succinate to reduce NAD^+ by a membrane-linked reverse electron transfer that is driven by a transmembrane electrochemical potential. Although many photosynthetic bacteria depend on Rubisco and the Calvin cycle for the reduction of CO_2, some are able to fix atmospheric CO_2 by other biochemical pathways.

Despite these differences, the general principles of energy transduction are the same in anoxygenic and oxygenic photosynthesis. Anoxygenic photosynthetic bacteria depend on bacteriochlorophyll, a family of molecules similar to chlorophyll that absorb strongly in the infrared between 700 and 1000 nm. The antenna system consists of bacteriochlorophyll and carotenoids that serve a reaction center where primary charge separation occurs. The electron carriers include quinones (e.g., ubiquinone, menaquinone) and the cytochrome *bc* complex, which is similar to the cytochrome *bf* complex of oxygenic photosynthetic apparatus. As in oxygenic photosynthesis, electron transfer is coupled to the generation of an electrochemical potential that drives phosphorylation by ATP synthase. The energy required for the reduction of CO_2 is provided by ATP and NADH, a molecule similar to NADPH.

7.1 Purple Bacteria

There are two divisions of photosynthetic purple bacteria: the nonsulfur purple bacteria (e.g., *Rhodobacter sphaeroides* and *Rhodospeudomonas viridis*) and the sulfur purple bacteria (e.g., *Chromatium vinosum*). Nonsulfur purple bacteria typically use an organic electron donor, such as succinate or malate, but they can also use hydrogen gas. The sulfur bacteria use an inorganic sulfur compound, such as hydrogen sulfide, as the electron donor. The only pathway for carbon fixation by purple bacteria is the Calvin cycle. Sulfur purple bacteria must fix CO_2 to live, whereas nonsulfur purple bacteria can grow aerobically in the dark by respiration on an organic carbon source.

The determination of the three-dimensional structures of the reaction center of the nonsulfur purple bacteria, *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides,* provides an unprecedented opportunity to understand the structure and function of photosynthetic reaction centers (Deisenhofer *et al.*, 1984, 1985; Feher *et al.*, 1989). The positions of the electron-transfer components in the reaction center of *Rhodobacter sphaeroides* are shown in Fig. 12 (Norris and van Brakel, 1986). The reaction center contains four bacteriochlorophyll and two bacteriopheophytin molecules. Two of the bacteriochlorophyll molecules form the primary donor (P870). At present, there is controversy over whether a bacteriochlorophyll molecule is an intermediate in electron transfer from the P870 to bacteriopheophytin. However, there is agreement that the remaining steps involve two quinone molecules (Q_A and Q_B) and that two turnovers of the reaction center result in the release of reduced quinone (QH_2)

into the photosynthetic membrane. Although there is a nonheme Fe between the two quinone molecules, there is convincing evidence that this Fe is not involved directly in transferring an electron from Q_A to Q_B. Because the primary donor (P870), bacteriopheophytin, and quinone acceptors of the purple bacterial reaction center are similar to the photosystem II reaction center, the bacterial reaction center is used as a guide to understand the structure and function of photosystem II.

Light-driven electron transfer is cyclic in *Rhodobacter sphaeroides* and other purple bacteria (Fig. 13). The reaction center produces reduced quinone, which is oxidized by the cytochrome *bc* complex. Electrons from the cytochrome *bc* complex are transferred to a soluble electron carrier, cytochrome c_2, which reduces the oxidized primary donor P870$^+$. The product of the light-driven electron transfer reactions is ATP. The electrons for the reduction of carbon are extracted from an organic donor, such as succinate or malate, or from hydrogen gas, but not by the reaction center. The energy needed to reduce NAD$^+$ is provided by light-driven cyclic electron transport in the form of ATP. The energy transformation pathway is complicated. Succinate is oxidized by the membrane-bound enzyme succinate dehydrogenase that transfers the electrons to quinone—the source of electrons for the reduction of NAD$^+$. However, electron transfer from reduced quinone to NAD$^+$ is energetically uphill. By a mech-

FIG. 13. Comparison of electron-transport pathways in oxygenic and anoxygenic organisms (from Blankenship, 1992). Abbreviations: Cyt bc_1, cytochrome *bc* complex; P840, reaction center bacteriochlorophyll; other abbreviations are given in the legends of Figs. 3 and 12.

anism that is poorly understood, a membrane-bound enzyme is able to use energy stored in the proton electrochemical potential to drive electrons from reduced quinone to NAD^+.

7.2 Green Sulfur Bacteria

Green sulfur bacteria (e.g., *Chlorobium thiosulfatophilum* and *Chlorobium vibrioforme)* can use sulfur compounds as the electron donor as well as organic hydrogen donors. As shown in Fig. 13, the reaction center of green sulfur bacteria is similar to the photosystem I reaction center of oxygenic organisms. The FeS centers in the reaction center can reduce NAD^+ (or $NADP^+$) by ferredoxin and the ferredoxin-$NAD(P)^+$ oxidoreductase enzyme; therefore green sulfur bacteria are not necessarily dependent on reverse electron flow for carbon reduction. The antenna system of the green sulfur bacteria is composed of bacteriochlorophyll and carotenoids and is contained in complexes known as chlorosomes that are attached to the surface of the photosynthetic membrane. This antenna arrangement is similar to the phycobilisomes of cyanobacteria. Green sulfur bacteria can fix CO_2 without Rubisco. It has been proposed that they accomplish this by using the respiratory chain that normally oxidizes carbon (known as the Krebs cycle), resulting in the release of CO_2. With the input of energy, this process can be run in the reverse direction, resulting in the uptake and reduction of CO_2.

7.3 Green Gliding Bacteria

Green gliding bacteria (e.g., *Chloroflexus aurantiacus*), also known as green filamentous bacteria, can grow photosynthetically under anaerobic conditions or in the dark by respiration under aerobic conditions. Like the green sulfur bacteria, green gliding bacteria harvest light using chlorosomes. The green gliding bacteria appear to have reaction centers similar to those of the purple bacteria (Fig. 13), but there are several notable differences. For example, instead of two monomer bacteriochlorophyll molecules, *C. aurantiacus* has one bacteriochlorophyll and one bacteriopheophytin, and the metal between the two quinones is Mn rather than Fe. *C. aurantiacus* appears to fix CO_2 by a scheme that does not involve the Calvin cycle or the reverse Krebs cycle (Ivanovsky *et al.*, 1993).

7.4 Heliobacteria

Heliobacteria (e.g., *Heliobacterium chlorum* and *Heliobacillus mobilis*) are in the phylum Gram Positive Bacteria that are strict anaerobes. Although the heliobacterial reaction center is similar to photosystem I in that it can reduce NAD^+ (or $NADP^+$), it contains a different type of chlorophyll known as bacteriochlorophyll *g*.

8. CONTROL OF INTRAPROTEIN ELECTRON TRANSFER

The three-dimensional structure of the reaction center of *Rhodopseudomonas viridis* and *Rhodobacter sphaeroides* reveals the distances between the electron donors and acceptors (Deisenhofer *et al.*, 1984,1985; Norris and van Brakel, 1986; Feher *et al.*, 1989) and has had an important influence on biophysical and molecular genetics studies designed to identify the factors that control the rate of electron transfer within proteins. There is currently a controversy concerning the importance of the amino acid composition of the protein on the rate of intraprotein electron transfer. In part, the disagreement centers on whether the protein between the donor and acceptor molecules can be treated as a uniform material or whether the specific amino acid composition of the protein significantly alters the rate. For example, it has been proposed that aromatic amino acids may provide a particular pathway that facilitates electron transfer between a donor and acceptor pair. This is the case in the photosystem II reaction center, where a tyrosine residue on one of the reaction center core proteins donates an electron to the primary donor chlorophyll, $P680^+$. However, in other cases, replacement of an aromatic residue by another nonaromatic residue results in relatively minor changes in the rate of electron transfer. L. Dutton and co-workers (Moser *et al.*, 1992) have analyzed electron-transfer reactions in biological and chemical systems in terms of electron tunneling theory developed by R. Marcus and others (DeVault, 1984). Dutton and co-workers argue that protein provides a uniform electronic barrier to electron tunneling and a uniform nuclear characteristic frequency. They suggest that the specific amino acid residues between an electron transfer pair are generally of less importance than the distance in determining the rate of pairwise electron transfer. In their view, protein controls the rate of electron transfer mainly through the distance between the donor and acceptor molecules, the free energy, and the reorganization energy of the reaction. The importance of distance is demonstrated by electron-transfer data from biological and synthetic systems showing that the dependence of the electron transport rate on the edge-to-edge distance is exponential over 12 orders of magnitude when the free energy is optimized (Moser *et al.*, 1992). Increasing the distance between two carriers by 1.7 Å slows the rate of electron transfer tenfold. The extent to which this view is generally applicable for intraprotein electron transfer remains to be established (Williams, 1992). One of the challenges in understanding pairwise electron-transfer rates from first principles is illustrated by the reaction center of *Rhodobacter sphaeroides*, in which the redox components are arranged along a twofold axis of symmetry that extends from the primary donor (P870) to the Fe. Despite the fact that the reaction center presents two spatially similar pathways for electron transfer from P870 to quinone, nearly all electrons are transferred down the right arm of the reaction center, as shown in Fig. 12. The same holds true for the reaction center of *Rhodopseudomonas viridis*, in which it is estimated that electron transfer down the left arm is less than 1:100 (Kellogg *et al.*, 1989). The challenge to theorists is to explain the surprisingly high probability of electron flow down the right arm. Since the distances are similar, it has been suggested that electron transfer down the left arm is less probable because of an endothermic free-energy change (Parson *et al.*, 1990) or to an unfavorable rearrangement energy for the reaction (Moser *et al.*, 1992).

9. GLOBAL PHOTOSYNTHESIS AND THE ATMOSPHERE

The amount of CO_2 removed from the atmosphere each year by oxygenic photosynthetic organisms is massive. It is estimated that photosynthetic organisms remove 100×10^{15} g/yr of carbon (Houghton and Woodwell, 1989). This is equivalent to 4×10^{18} kJ of free energy stored in reduced carbon, which is roughly 0.1% of the incident visible radiant energy incident on the earth per year. Each year the photosynthetically reduced carbon is oxidized, either by living organisms for their survival or by combustion. The result is that more CO_2 is released into the atmosphere from the biota than is taken up by photosynthesis. The amount of carbon released by the biota is estimated to be $(1–2) \times 10^{15}$ g/yr of carbon. Added to this amount is carbon released by the burning of fossil fuels, which amounts to 5×10^{15} g/yr of carbon. The oceans mitigate this increase by acting as a sink for atmospheric CO_2. It is estimated that the oceans remove about 2×10^{15} g/yr of carbon from the atmosphere. This carbon is eventually stored on the ocean floor. Although these estimates of sources and sinks are uncertain, the net global CO_2 concentration is increasing. Direct measurements show that each year the atmospheric carbon content is currently increasing by about 3×10^{15} grams. Over the past 200 years, CO_2 in the atmosphere has increased from about 280 parts per million (ppm) to its current level of 360 ppm. On the basis of predicted fossil fuel use and land management, it is estimated that the amount of CO_2 in the atmosphere will reach 700 ppm within the next century. The consequences of this rapid change in our atmosphere are unknown. Because CO_2 acts as a greenhouse gas, some climate models predict that the temperature of the earth's atmosphere may increase by 2–8 °C. Such a large temperature increase would lead to significant changes in rainfall patterns. Little is known about the impact of such drastic atmospheric and climatic changes on plant communities and crops. Current research is directed at understanding the interaction between global climate change and photosynthetic organisms.

GLOSSARY

ATP: Adenosine triphosphate, a small water-soluble molecule that acts as an energy currency in cells.

ATP Synthase: A membrane-bound protein complex that uses the energy stored across the photosynthetic membrane to add inorganic phosphate to ADP, thus creating ATP. (Also known as coupling factor.)

Calvin Cycle: The biochemical reactions, initiated by Rubisco, that result in the reduction of CO_2 to a carbohydrate (also known as the photosynthetic carbon reduction cycle).

Cytochrome: Heme-containing protein.

Cytochrome *bc* Complex: A membrane-bound electron-transfer protein complex, found in all anoxygenic photosynthetic organisms, that oxidizes reduced quinone and reduces a *c*-type cytochrome. The complex contains a *c*-type cytochrome, two *b*-type cytochromes, and an FeS center.

Cytochrome *bf* Complex: A membrane-bound electron-transfer protein complex, found in all oxygenic photosynthetic organisms, that oxidizes reduced plastoquinone and reduces plastocyanin (or cytochrome *c*). The complex contains a *c*-type cytochrome, two *b*-type cytochromes, and an FeS center.

Free Energy: The amount of energy in a reaction available to do work. Because most biochemical reactions occur at a constant temperature and pressure, the free energy is frequently the Gibbs energy.

Light-Harvesting Complex: A protein complex that harvests light energy and converts it to exciton energy that can migrate to a reaction center. The light is absorbed by pigment molecules (e.g., chlorophyll, bacteriochlorophyll, carotenoids, phycobilin) that are attached to the protein.

NADPH: Reduced form of nicotinamide adenine dinucleotide phosphate, a small water-soluble molecule that acts as a hydrogen carrier in biochemical reactions.

$NADP^+$: Oxidized form of nicotinamide adenine dinucleotide phosphate.

Oxidation: The removal of one or more electrons from an atom or molecule. In the case of a molecule, protons may be involved as well, resulting in hydrogen being removed.

Phosphorylation: The covalent attachment of a phosphate group to a molecule.

Photorespiration: The removal of O_2 from the atmosphere by Rubisco and the subsequent biochemical reactions that serve to recycle some of the reduced carbon.

Photosynthesis: The physical-chemical process by which certain chlorophyll- (or bacteriochlorophyll-) containing organisms use light energy for the biosynthesis of organic molecules.

Photosynthetic Membrane: A bilayer of lipid molecules in which are embedded proteins that transform light energy into chemical free energy. (Also known as the thylakoid membrane.)

Photosystem I: A protein complex located in the photosynthetic membrane. Photosystem I is one of two types of reaction centers found in higher plants, algae, and cyanobacteria. The photosystem I reaction center uses light energy to transfer an electron from a mobile electron-transfer protein (plastocyanin or cytochrome *c*) on one side of the photosynthetic membrane to a mobile electron-transfer protein (ferredoxin) on the opposite side of the photosynthetic membrane.

Photosystem II: A protein complex found in the photosynthetic membrane. Photosystem II is one of two types of reaction centers found in higher plants, algae, and cyanobacteria. The photosystem II reaction center uses light energy to transfer electrons from water to plastoquinone. Photosystem II is the source of the molecular oxygen in the atmosphere.

Plastoquinone: A small organic molecule involved in electron and proton transfer in photosynthesis.

Protein: A chemical structure composed of one or more polypeptides. In photosynthesis, proteins serve as the scaffolding that hold the cofactors that gather light energy, transfer electrons, and catalyze biochemical reactions.

Reaction Center: A protein complex that uses light energy to create a stable charge separation by transferring a single electron energetically uphill from a donor molecule to an acceptor molecule, both of which are located in the reaction center.

Reduction: The addition of one or more electrons to an atom or molecule. In the case of a molecule, protons may be involved as well, resulting in hydrogen being added.

Rubisco (D-ribulose 1,5-bisphosphate carboxylase/oxygenase): A water-soluble protein complex responsible for the removal of CO_2 from the atmosphere. The enzyme works by attaching CO_2 to a five-carbon compound (1,5 ribulose bisphosphate) that is split into two identical three-carbon compounds (phosphoglycerate). In addition to catalyzing the removal of CO_2 from the atmosphere, Rubisco also catalyzes the removal of O_2 from the atmosphere (less efficiently). The removal of O_2 is thought to be a consequence of poor design and leads to a complex set of compensatory reactions known as photorespiration.

INTRODUCTION

The photovoltaic effect (PVE) is the generation of an emf as a result of absorption of ionizing radiation. The absorbing medium can be a gas, a liquid, or a solid. For the PVE to occur, an electrostatic potential-difference site must be present in the absorbing medium. The positive and negative charges resulting from the ionization must then be separated by this internal electrostatic field. The separated charges can pass through an external resistive load connected across the potential barrier, thus transforming a portion of absorbed ionizing energy directly into electricity.

The first paper describing the PVE was published by E. Becquerel (1839). He observed an emf when he directed light onto platinum or gold electrodes immersed in acidic or alkaline solutions. The first report of a PVE observed in a solid was published by W. G. Adams and R. E. Day in 1877. They observed the effect in a small selenium rod into whose ends they fused platinum electrodes. During the following 30 years, research and development resulted in an im-

digital Encyclopedia of Applied Physics

proved selenium PV cell, which eventually found practical application as a light meter for photography and as a light sensor in optical instruments.

The next important step in the development of PV science and technology was the invention/discovery during the period 1930–1933 of the PV effect in copper/copper oxide devices by Lange (1930), Schottky (1930), and Grondahl (1933). Schottky's efforts to explain this PV effect made him a pioneer in the then fledgling science of semiconductors. A very important contribution by Schottky was his introduction of the concept of the metal–semiconductor electrostatic potential barrier, the Schottky barrier, to explain the PV effect in both the Cu/CuO_x and the metal/selenium cells. Because of simplicity of fabrication, the Cu/CuO_x cell became a competitor of the selenium cell in the gradually increasing commercial market for such devices.

However, a revolution in the application of the PV effect began with the invention of the transistor (Brattain and Bardeen, 1948; Shockley, 1949). The first transistors utilized as semiconductors the elements silicon and germanium. These new semiconductors could be grown as large single crystals whose electronic properties could be controlled by the addition of minute quantities of other elements. Furthermore, electric current in these new semiconductors could be carried by either positive or negative charges. The positive charges proved to be as mobile as the negative charges (known to be electrons). These mobile positive charged carriers are called "holes" because they result from holes in the electron bonding structures of these materials.

Germanium and silicon are elements from the fourth column of the periodic table; they have a valence of 4. Each atom shares its four valence electrons with its four nearest neighbors, thus forming a crystal consisting of two interlocking face-centered cubic lattices—the diamond structure. At absolute zero, all of the electrons are tied up in covalent bonds; there are no electrons free to move through the lattice if an electric field is applied across the semiconductor. As the temperature increases, some of the electrons are thermally excited and thus liberated from their covalent bonds, leaving behind "holes" in the bonding structure. The liberated electron and the hole can now move through the lattice; they are no longer bound to a specific atom. Generation of such free electrons and holes requires an external source of energy (heat, light, etc.). The minimum energy needed to generate a free electron-hole pair is the difference in energy between the highest valence band and the lowest conduction band in the semiconductor, i.e., the forbidden energy gap E_G.

In an intrinsic semiconductor, the concentrations of free holes and electrons are equal since a free hole is formed whenever a free electron is generated. If elements having a valence different from 4 are incorporated into the crystal, the concentrations of electrons and holes need not be equal any more. There can be an excess of electrons or an excess of holes, depending on the valence of the impurity atom. A semiconductor whose conductivity is controlled by such "extrinsic" elements is referred to as an extrinsic semiconductor. If the dominant impurity element has a valence of 5 (like phosphorus, arsenic, or antimony), then it can replace silicon or germanium atoms in the crystal lattice, forming four covalent bonds with its neighbors. The extra valence electron is not bound to the impurity atom as tightly as the electrons participating in the bonding with the column-four host element; it can move freely through the lattice at temperatures around room temperature. A semiconductor in which the dominant impurity contributes such free electrons to the conduction band is called an *n*-type semiconductor. If the dominant impurity element has a valence of 3 (like boron, aluminum, or indium), when it replaces a silicon or germanium atom in the lattice, it lacks one electron to satisfy the covalent bonding with its neighboring atoms, i.e., there is a "hole" in the bonds around the trivalent atom. This hole arises from the absence of an electron and, therefore, moves through the lattice as if it had a positive charge. A semiconductor in which the dominant impurity contributes free holes to the valence band is called a *p*-type semiconductor.

Shockley developed an elegant theory that explained what happens if a piece of semiconductor has a variable concentration of holes and electrons so that a transition from *p* type to *n* type occurs, thus forming a *p-n* junction. He showed that the *p-n* junction produced an internal electrostatic potential barrier whose properties were far more predictable and reproducible than the properties of Schottky barriers. Rectifiers based on such *p-n* junctions in germanium and silicon proved to be much better than those based on the metal-semiconductor junctions in metal-selenium and Cu/CuO$_x$ rectifiers.

They also proved to be much better photovoltaic cells, as the scientific world was to learn from three brief papers published in journals of the American Physical Society in 1954 (Rappaport, 1954; Chapin *et al.*, 1954: Reynolds *et al.*, 1954). These papers, which marked the beginning of the modern photovoltaic age, described the electron voltaic and photovoltaic effects in *p-n* junction devices made from single crystals of germanium, silicon, or cadmium sulfide. The new PV cells, more specifically those based on silicon and cadmium sulfide, were able to convert the radiant energy of sunlight directly into electricity with efficiencies in the 4% to 6% range, about an order of magnitude higher than the highest solar-energy conversion efficiencies measured on Cu/CuO$_x$ or metal-selenium devices of that time.

Subsequent developments in theory and in the experimental science and technology of PV cells are the subjects addressed in the balance of this article. These developments have led to the fabrication and study of PV cells made from many semiconductors besides silicon; to PV cells having solar-energy conversion efficiencies up to 35%; and to widespread application of PV cells as power supplies for earth satellites, pocket calculators, remote sites, etc. If continued—and it shows no signs of abating—this long-term trend toward improved performance accompanied by reduced cost will result in large-scale, environmentally benign PV power plants displacing conventional fossil fuel and nuclear plants as preferred sources of electricity.

1. PHYSICAL PRINCIPLES UNDERLYING THE PV EFFECT

To produce a PV effect, three events must occur. First, excess positive and negative carriers must be produced by the absorption of ionizing radiation. The ionizing radiation can be electromagnetic (infrared, visible, ultraviolet, x rays, γ rays) or charged-particle radiation (electrons, protons, α particles, β particles). The photons of the electromagnetic radiation must have an energy equal to or in excess of E_G, the forbidden energy gap of the semiconductor that is the internal ionization energy of the semiconductor. As energetic charged particles pass through the semiconductor, they produce internal ionization by liberating bonding electrons. The average energy expended by a charged particle to produce one hole-electron pair in silicon and germanium is about $3.5E_G$. When high-energy electrons are the ionizing radiation, the effect is called the electron-voltaic effect with similar nomenclature for other charged particles. All such effects are essentially the same and the photovoltaic effect can be viewed as a generic term describing them. Second, the excess charges of opposite signs must be separated by an internal electrostatic potential barrier like a *p-n* junction or a metal-semiconductor junction. Third, the mobile carriers generated by the ionizing radiation must "live" long enough to reach the charge-collecting or -separating barrier. For further details, see the following subsections and Loferski (1979).

1.1 Light Absorption in Semiconductors

Let a monochromatic beam of light containing photons whose energy exceeds the forbidden energy gap of a particular semiconductor be incident on that semiconductor. If the photon flux incident on the plane $x = 0$ is $N_{\mathrm{ph}}(0)$, then the photon flux remaining after traversing a thickness x of the semiconductor, $N_{\mathrm{ph}}(x)$, is given by the relation

$$N_{\mathrm{ph}}(x) = N_{\mathrm{ph}}(0)\exp(-\alpha x), \qquad (1)$$

where α is the absorption constant for that particular energy photon. The photon flux lost from the beam, $N_{\mathrm{ph}}(0) - N_{\mathrm{ph}}(x)$, is absorbed in the semiconductor and generates at least one hole-electron pair for each photon absorbed. The absorption constant α is a function of the wavelength λ or photon energy $h\nu$. The dependence of α on $h\nu$ is a fundamental characteristic of a semiconductor. Figure 1 shows curves of α vs $h\nu$ for a few semiconductors that have been used in PV cells. The threshold energy for the onset of absorption is the energy gap E_G of the semiconductor, which is a first-order parameter in determining the efficiency with which a PV cell can

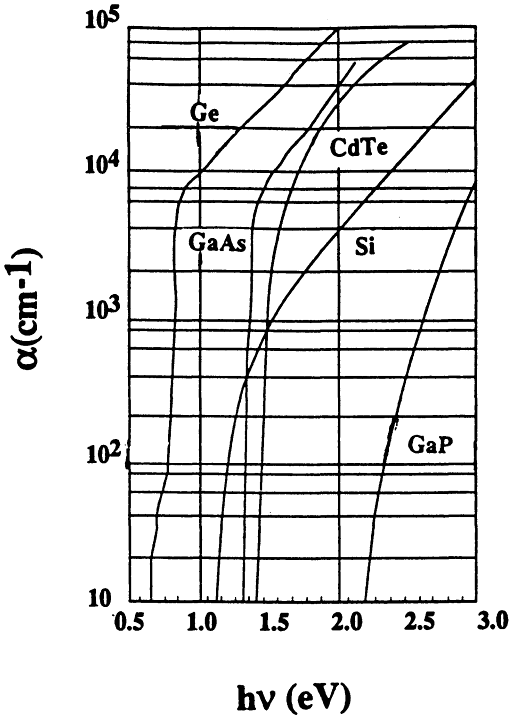

FIG. 1. Absorption constant α versus photon energy $h\nu$ for selected semiconductors of interest as photovoltaic cell materials.

convert the energy of ionizing energy into electricity. Closer examination of these curves of α vs $h\nu$ leads to the conclusion that they can be divided into two groups:

1. those in which α rises very rapidly from very low values, say 10 cm^{-1}, to values in excess of 10^4 cm^{-1} (the GaAs and CdTe curves are in this category); and
2. those in which α rises more gradually (the Si, Ge, and GaP curves are in this category).

Semiconductors with rapidly rising curves of α vs $h\nu$ are called direct-gap semiconductors; those with gradually rising curves of α vs $h\nu$ are called indirect-gap semiconductors.

A practical consequence of this difference for PV cells used as solar-energy converters can be seen in Fig. 2. Here we compare the fraction of photons in the solar spectrum that have an energy greater than the forbidden energy gap E_G and are absorbed in a given thickness of the indirect-gap semiconductor silicon with the same fraction in the direct-gap semiconductor gallium arsenide (GaAs).

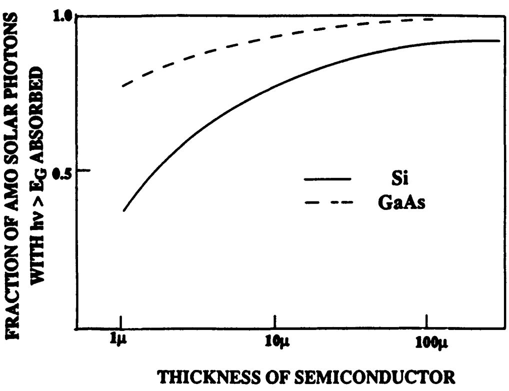

FIG. 2. Comparison of fraction of solar photons with energy greater than their energy gaps absorbed in a given thickness of the direct-gap semiconductor GaAs and the indirect-gap semiconductor silicon.

For example, to absorb 90% of the photons that silicon is capable of absorbing, we need a thickness of approximately 100 μm, whereas for GaAs, the corresponding thickness is only 10 μm. This difference is very significant for large-scale conversion of sunlight into electricity, which would require covering tens of thousands of square kilometers with solar cells, because the amount of direct-gap semiconductor required is much smaller and, therefore, should ultimately be less expensive than the amount of an indirect-gap semiconductor required for the same purpose. Of course, the relative abundance of the materials of which the semiconductor is composed has a strong effect on the cost. For example, silicon is an extremely abundant element, whereas gallium is not. Nevertheless, the amount of gallium available is sufficient to make direct-gap semiconductors in which it is a constituent strong candidates as building blocks for large-scale PV applications.

1.2 Charge Separation in PV Cells

As has been noted, charge separation requires the presence of an electrostatic potential barrier inside the PV cell. Figure 3 shows the electron energy-band diagrams of the three basic kinds of charge-separation barriers. In this figure, E_C is the electron energy at the bottom of the conduction band, E_V is the electron energy at the top of the valence band, and E_F is the electron energy at the Fermi

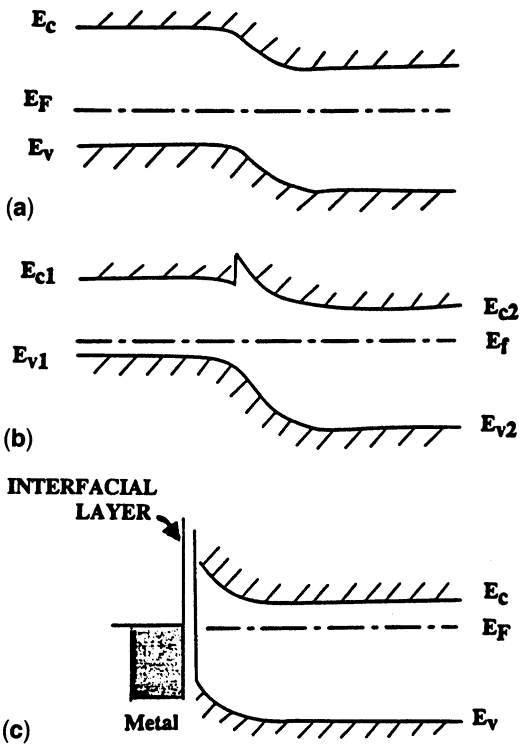

FIG. 3. Energy-band diagrams of (a) a *p-n* homojunction, (b) a *p-n* heterojunction, and (c) a metal-semiconductor (Schottky barrier) junction.

level. If the temperature across the barrier is uniform and there is no radiant energy input, i.e., the PV cells are in the dark, the Fermi energy is the same throughout the material including the ends of the junction. The energy differences $E_F - E_V$ and $E_C - E_F$ are determined by the temperature and the ionized-impurity (dopant) concentrations in the various regions of the semiconductor. The energy-band diagrams of Fig. 3 correspond to the case of uniform temperature and constant but different dopant concentrations in the p and n regions. When $E_F - E_V$ is less than $E_C - E_F$, the material is p type and the current carriers are predominantly holes. When $E_F - E_V$ is greater than $E_C - E_F$, the material is n type and electrons are the dominant charge carriers. So band diagrams (a) and (b) of Fig. 3 have p-type material on the left side of the barrier and n-type material on the right side of the barrier, i.e., they are the band diagrams of a p-n junction.

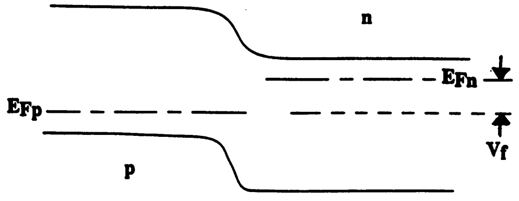

FIG. 4. Energy-band diagram of a *p-n* homojunction under forward bias.

Figure 3(a) is the band diagram of a p-n homojunction because the p-n junction spans a single semiconductor. Figure 3(b) is the band diagram of a p-n heterojunction because the p side (left side) consists of one semiconductor and the n side (right side) consists of another semiconductor. In Fig. 3(b), the energy gaps $E_C - E_V = E_G$ are substantially different on the p and n sides.

Figure 3(c) is the band diagram of a metal-semiconductor or Schottky barrier junction in which the work functions of metal and semiconductor bear such a relation to each other that the band edges of the n-type semiconductor bend upward at the junction. The sketch includes a thin interfacial layer (which may or may not be present) between the metal and the semiconductor. If this interfacial layer is thin enough, carriers can tunnel through it as they pass from the metal to the semiconductor or vice versa.

If a voltage V is applied across the p-n homojunction of Fig. 3(a), the band diagrams change to the forms shown in Figs. 4 and 5, depending on whether the n side is more negative than the p side (Fig. 4) or the n side is more positive than the p side (Fig. 5). The voltage bias of Fig. 4 is referred to as a forward bias, while the voltage bias of Fig. 5 is referred to as a reverse bias. When an open-circuited p-n junction absorbs ionizing radiation, it acquires a forward bias like that depicted in Fig. 4. This occurs because the elec-

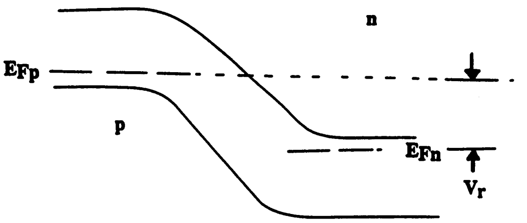

FIG. 5. Energy-band diagram of a *p-n* homojunction under reverse bias.

trostatic barrier associated with a *p-n* junction like that depicted in Fig. 3(a) is a "sink" for excess minority electrons generated on the *p* side and for excess minority holes generated on the *n* side. A flow of excess electrons from the *p* side to the *n* side and of excess holes from the *n* side to the *p* side would constitute an electric current flowing in the "reverse" direction. But if the junction is open circuited, by definition there can be no current flowing through it. So the junction reacts by biasing itself in the forward direction, i.e., it reduces the height of the electrostatic barrier just enough to produce a forward current equal in magnitude to the reverse current generated by the ionizing radiation. Thus, an illuminated *p-n* junction that is not open circuited acquires a forward bias and the current flows through it in the reverse direction, as shown in the *I–V* diagram of an illuminated solar cell of Fig. 6. The figure shows the open-circuit (forward) voltage (V_{oc}); the short-circuit (reverse) current I_{sc}; the maximum power point, P_{max}; the load voltage at maximum power, V_{mp}; and the load current at maximum power, I_{mp}.

1.3 Lifetime of Light-Generated Carriers

As noted above, the excess carriers generated by the absorbed ionizing radiation must remain mobile long enough to allow them to migrate to the charge-separating junction. Their lifetime is terminated when positive and negative carriers recombine with each other. Recombination can be intrinsic or extrinsic in origin; it can occur in the bulk or at the surface. The lifetime of the excess carriers is inversely proportional to the recombination rate.

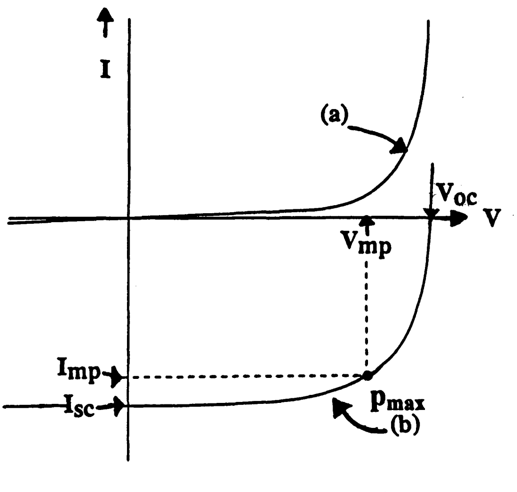

FIG. 6. Current–voltage characteristic of a solar cell (a) in the dark and (b) subjected to ionizing radiation, showing the open-circuit voltage V_{oc}; the short-circuit current I_{sc}, the maximum power point, P_{max}; the current at maximum power, I_{mp}; and the voltage at maximum power, V_{mp}.

For the case of bulk intrinsic recombination, the excess minority carriers generated in one of the bands by the ionizing radiation recombine with carriers of the opposite sign in the other band. Such band-to-band recombination sets an upper limit on the minority-carrier lifetime. Its value can be as high as 10^{-2} s in an indirect-gap semiconductor like Si and as low as 10^{-8} s in a direct-gap semiconductor like GaAs.

Indirect recombination requires the presence of recombination centers in the semiconductor. Recombination centers have energy levels that are closer to the middle of the forbidden energy gap than the energy levels of dopant impurities. In the case of silicon, typical energy levels E_r of recombination centers are located between 0.15 and 0.25 eV from one of the band edges. If the concentration of recombination centers N_r is high enough (10^{13} centers/cm^3 is high in silicon doped with 10^{16}/cm^3 donors or acceptors), the lifetime is determined by these centers. It is given by the expression

$$1/\tau_{\text{ext}} = N_r \sigma_r v f(E_r - E_{\text{F}}), \qquad (2)$$

where τ_{ext} is the extrinsic bulk minority-carrier lifetime; σ_r is the minority-carrier capture cross section of the recombination center (10^{-12} cm^2 < σ_r < 10^{-16} cm^2); v is the thermal velocity of the carriers (about 10^7 cm/s at 300 K); and $f(E_r - E_{\text{F}})$ is the probability that the recombination center is occupied by a majority carrier, i.e., it is the Fermi–Dirac statistics occupancy factor for the center. If $E_{\text{F}} - E_r > kT, f = 1$, and the range of values for $N_r\tau_{\text{ext}}$ is

$$10^5 \text{ s/cm}^3 \le N_r\tau_{\text{ext}} \le 10^9 \text{ s/cm}^3.$$

Therefore, with $N_r = 10^{13}$/cm^3 the range of values of extrinsic lifetime would be

$$10^{-8} \text{ s} \le \tau_{\text{ext}} \le 10^{-4} \text{ s}. \qquad (3)$$

The actual lifetime τ is related to τ_{ext} and the intrinsic lifetime τ_{int} by the relation

$$1/\tau = 1/\tau_{\text{int}} + 1/\tau_{\text{ext}}. \tag{4}$$

In an indirect-gap semiconductor, like silicon, the extrinsic lifetime dominates. In direct-gap material like GaAs, the intrinsic lifetime (which is low anyway) can dominate unless the concentration of recombination centers is greater than about $10^{15}/\text{cm}^3$.

If a PV cell is to achieve its optimum performance, its minority-carrier lifetime must be as high as possible. This in turn means that the lifetime should be close to the intrinsic lifetime, i.e., the concentration of recombination centers N_r must be as low as possible. For an indirect-gap semiconductor like silicon in which τ_{int} is large (10^{-2} s), N_r must be of the order of $10^{11}/\text{cm}^3$. For a direct-gap semiconductor like GaAs, N_r can be as high as $10^{15}/\text{cm}^3$ without affecting τ.

2. EQUATIONS GOVERNING THE PV EFFECT

2.1 Diode Equation

The derivation of equations for the PVE begins with the ambipolar diffusion equation formulated by Shockley (1951). This equation governs the transport of excess carriers (like those produced by absorption of ionizing radiation) in a semiconductor. The appropriate one-dimensional form of this equation for the light-generated excess minority-carrier population Δn on the p side of a p-n junction is

$$D_e \frac{d^2 \Delta n}{dx^2} + \alpha N_0 e^{-\alpha x} - \frac{\Delta n}{\tau} = 0. \tag{5}$$

An analogous equation applies to the excess minority hole population on the n side. In this equation, D_e is the free-electron diffusion constant, α is the absorption constant for the wavelength of the incident light, N_0 is the photon flux of that wavelength incident on the surface of the planar PV cell, and τ is the minority-carrier lifetime.

These same equations with $N_0 = 0$ were used by Shockley to derive the I–V relations for a p-n junction diode under forward and reverse bias conditions. He showed that the current flowing through the junction I_j with a voltage V_j applied across it was

$$I_j = I_0[\exp(qV_j/kT) - 1]. \tag{6}$$

The value of I_0 depends on semiconductor properties, junction parameters, and the boundary conditions appropriate to the particular cell. If the width w of each side of the junction is greater than the respective minority-carrier diffusion lengths (L_e and L_h), then

$$\begin{aligned} I_0 &= I_{0n1} + I_{0p1} \\ &= q[D_e n_p/L_e + D_h p_n/L_h], \end{aligned} \tag{7}$$

where I_{0n} and I_{0p} are the contributions to I_0 from the n and p sides, respectively; n_p and p_n are the minority electron concentration on the p side and minority hole concentration on the n side, respectively; and $L_e \equiv D_e\tau_p$ and $L_h = D_h\tau_n$. The term I_0 is proportional to n_i^2 because $n_p p_p = p_n n_n = n_i^2$, and therefore

$$I_0 = qn_i^2[D_e/N_A L_h + D_h/N_D L_e], \tag{8}$$

because in extrinsic semiconductors, $N_A \sim p_p$ and $N_D \sim n_n$; N_A is the acceptor concentration on the p side and N_D the donor concentration on the n side of the junction. Since $n_i^2 \propto \exp(-E_G/kT)$ we can write

$$I_0 = K(T)\exp(-E_G/kT), \tag{9}$$

where E_G is the energy gap and $K(T)$ is a weak function of absolute temperature T.

As we have already shown, when a PV cell is exposed to ionizing radiation, it acquires a forward bias (Fig. 6). The current generated by the ionizing radiation, I_{sc}, flows in the direction of a reverse current. From the principle of superposition, the equation for the current I_L through a load resistor R connected across the PV cell as shown in Fig. 7 is

$$I_L = I_j - I_{\text{sc}}, \tag{10}$$

where I_j is the junction current and I_{sc} is the current that flows through the short-circuited PV cell and is of course the current generated by the ionizing radiation. Substitution of Eq. (6) into Eq. (10) leads to

$$I_L = I_0[\exp(\Lambda V_L - 1)] - I_{\text{sc}}, \tag{11}$$

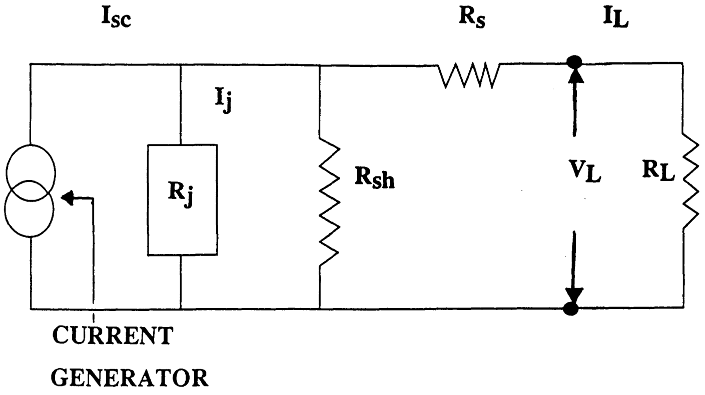

FIG. 7. Equivalent circuit of an illuminated solar cell. R_j is the nonlinear junction impedance, R_{sh} and R_s are the internal shunt and series resistances, respectively, and R_L is the load resistance.

where $\Lambda \equiv q/AkT$. The parameter A is equal to unity for the ideal Shockley diode [Eq. (6)]. However, in general $2 < A \leq 1$.

Figure 6(a) shows the I–V characteristic of a PV cell in the dark and Fig. 6(b) shows the I–V characteristic of the same cell under illumination. The dark I_j–V_j curve has a forward branch in the first quadrant where both voltage and current are positive and a reverse branch in the third quadrant where both the voltage and current are negative. Power (the product of current and voltage) is therefore consumed by the junction in either the forward or reverse directions. When the cell is illuminated, part of the characteristic drops into the fourth quadrant where the voltage is positive (a forward voltage) and the current is negative (a reverse current). Their product (the power) is negative, which means that the device is generating power. Figure 6(b) also shows the open-circuit voltage V_{oc}, the short-circuit current I_{sc}, the maximum power point P_{max}, the current at maximum power, I_{mp}, and voltage at maximum power, V_{mp}.

The expression for the open-circuit voltage V_{oc} is derived by setting $I_L = 0$ in Eq. (11). The result is

$$\exp(\Lambda V_{oc}) = (I_{sc} + I_0)/I_0. \tag{12}$$

The equivalent circuit of the PV cell (Fig. 7) must include an internal series (R_s) and an internal shunt (R_{sh}) resistance so that the complete equation for I_L assumes the form

$$\begin{aligned} I_L = {} & I_0[\exp\Lambda(V_L - I_LR_s) - 1] \\ & - I_{sc} - (V_L - I_LR_s)/R_{sh}. \end{aligned} \tag{13}$$

Observations on "good" PV cells lead to the conclusion that R_{sh} is usually large enough so that its effect can be neglected and R_s is small enough so that it can be neglected in a first-order calculation of the maximum power parameters. With these approximations ($R_s = 0$, $R_{sh} = \infty$) and applying the impedance-matching condition that must be satisfied for maximum power transfer from the PV cell to the load, i.e.,

$$R_{Lmp} = \left(\frac{\partial V}{\partial I}\right)_{mp}, \tag{14}$$

where R_{Lmp} is the load resistance for maximum power (mp) transfer and $(\partial V/\partial I)_{mp}$ is the dynamic impedance at the maximum power point, we can calculate the "mp" parameters. Algebraic manipulation leads to the following expressions for the load current at maximum power I_{Lmp} and the load voltage at maximum power V_{Lmp}:

$$\begin{aligned} (1 + \Lambda V_{Lmp}) \exp(\Lambda V_{Lmp}) &= I_{sc} + I_0/I_{sc} \\ &= \exp(\Lambda V_{oc}), \end{aligned} \tag{15}$$

$$I_{Lmp} = I_{sc}\Lambda V_{Lmp}/(1 + \Lambda V_{Lmp}). \tag{16}$$

These equations contain only three parameters that the PV cell fabricator can hope to control, i.e., I_{sc}, I_0, and the factor A (recall that $\Lambda \equiv q/AkT$). Their values are determined by the choice of semiconductor and PV cell parameters.

The maximum conversion efficiency η_{max}, i.e., the efficiency for matched load conditions, is given by

$$\begin{aligned}\eta_{\max} &= \frac{\text{Maximum Power Out}}{\text{Power In}} \\ &= \frac{I_{L\mathrm{mp}}V_{L\mathrm{mp}}}{P_{\mathrm{in}}} && (17) \\ &= \frac{\Lambda V_{L\mathrm{mp}}}{(1+\Lambda V_{L\mathrm{mp}})} \\ &\quad \times \frac{\Lambda V_{L\mathrm{mp}}}{\Lambda V_{L\mathrm{mp}} + \ln(1+\Lambda V_{L\mathrm{mp}})}\,\frac{I_{\mathrm{sc}}V_{\mathrm{oc}}}{P_{\mathrm{in}}} && (18) \\ &\equiv (CF)I_{\mathrm{sc}}V_{\mathrm{oc}}/P_{\mathrm{in}}, && (19)\end{aligned}$$

where CF is defined as the curve factor. The curve factor is the ratio of the area of the power rectangle $I_{L\mathrm{mp}}\ V_{L\mathrm{mp}}$ to the area of the $I_{\mathrm{sc}}\ V_{\mathrm{oc}}$ rectangle (see Fig. 6). Obviously it is always less than unity. In "good" cells, it can attain values close to 0.90.

2.2 Calculation of the Short-Circuit Current I_{sc}

The short-circuit current generated as a result of the absorption of ionizing radiation is calculated (Loferski and Wysocki, 1961) from the ambipolar diffusion equation [Eq. (5)] with two boundary conditions:

1. The junction is a sink for carriers, and therefore the excess carrier concentration at the edge of the space-charge region (SCR) is zero, i.e.,

$$\Delta n_{\mathrm{SCR}} = 0. \qquad (20)$$

2. At the outer surfaces of the PV cell,

$$(D_e\,\mathrm{grad}\Delta n)_{\mathrm{surf}} = s n_{\mathrm{surf}}, \qquad (21)$$

where s is the surface recombination velocity.

The surface recombination velocity is a parameter that is inversely proportional to the recombination lifetime of minority carriers at the surface. If $s = 0$, the minority carriers do not recombine at the surface and are "reflected" back into the bulk region. When $s = 0$, the surface is a minority-carrier "mirror." The parameter s will be zero if there are no recombination centers at the surface or if there are surface charges that generate an electrostatic field of such a polarity that the minority carries are repelled from the surface. When the surface recombination velocity is infinite, all minority carriers arriving at the surface recombine with carriers of the opposite sign. For s to be infinite, the surface concentration of recombination centers must be infinite or else there are surface charges of such a polarity that they give rise to an electrostatic field that drives minority carriers toward the surface where they recombine at surface recombination centers. From Eq. (21), it is clear that when $s = 0$, $\mathrm{grad}\Delta n$ at the surface is zero. As s approaches infinity, n_{surf} approaches zero, and $\mathrm{grad}\Delta n$ at the surface remains finite. For intermediate values of s, both n_{surf} and $\mathrm{grad}\Delta n$ at the surface have finite values.

The solution of the ambipolar diffusion equation for an n "skin" on a p-base cell in which ionizing radiation is incident on the $x = 0$ surface, the p-n junction is located at $x = l$, and the cell thickness is b is divided into two parts. The first of these is the contribution to I_{sc} from the n region and has the form

$$\begin{aligned}I_p(l) = \frac{qN_0(1-R)}{\alpha(1-\nu_p^2/\alpha^2)}&[\beta_p\nu_p\exp(\nu_p l) \\ &- \gamma_p\nu_p\exp(-\nu_p l)\alpha e^{-\alpha l}], \qquad (22)\end{aligned}$$

where N_0 is the flux of photons, characterized by having an absorption constant α, incident on the cell surface $x = 0$ and R is the fraction of these photons which are reflected, and the following definitions apply:

$$\beta_p\Delta_p = \exp(-\nu_p l)(h+\alpha) - e^{-\alpha l}(h+\nu_p); \qquad (23)$$

$$\gamma_p\Delta_p = e^{-\alpha l}(h-\nu_p) - \exp(\nu_p l)(h+\alpha); \qquad (24)$$

$$\Delta p = \exp(\nu_p l)(h+\nu_p) - \exp(-\nu_p l)(h-\nu_p); \qquad (25)$$

$$h = s/D_p, \qquad (26)$$

and

$$\nu_p = (D_p\tau_p)^{-1/2} = L_p^{-1}. \qquad (27)$$

Similarly, the contribution to the current from the p base is

$$\begin{aligned}I_n(l) = \frac{qN_0(1-R)}{\alpha(1-\nu_n^2/\alpha^2)}&[\beta_n\nu_n\exp(\nu_n l) \\ &- \gamma_n\exp(-\nu_n l) - \alpha e^{-\alpha l}], \qquad (28)\end{aligned}$$

$$\begin{aligned}\beta_n\Delta_n &= \alpha\exp[-(\nu_n l + \alpha b)] \\ &\quad - \nu_n\exp[-(\nu_n b + \alpha l)]; \qquad (29)\end{aligned}$$

$$\gamma_n \Delta_n = -\alpha \exp(\nu_n l - \alpha b) - \nu_n \exp(\nu_n b - \alpha l); \tag{30}$$

$$\Delta_n = 2\nu_n \cosh(\nu_n b - \nu_n l); \tag{31}$$

and

$$\nu_n = (D_n \tau_n)^{-1/2} = L_n^{-1}. \tag{32}$$

The total short-circuit current is

$$I_{sc} = I_p(l) + I_n(l). \tag{33}$$

It is convenient to define a collection efficiency for each value of α (i.e., for each wavelength of the incident light) as follows:

$$Q_{total}(\alpha) = \frac{I_p(l, \alpha)}{I_{max}(\alpha)} + \frac{I_n(l, \alpha)}{I_{max}(\alpha)} = Q_p(\alpha) + Q_n(\alpha), \tag{34}$$

where $I_{max}(\alpha)$ is the current that would have been produced if every photon with absorption constant α contributed one carrier to $I_{sc}(\alpha)$. Thus,

$$I_{max}(\alpha) = qN_0(\alpha)[I - R(\alpha)]. \tag{35}$$

Figures 8 and 9 show the results of calculations of $Q_p(\alpha)$ and $Q_n(\alpha)$ for various values of the cell parameters. The results of the calculations shown in Fig. 8 correspond to the case of a low surface recombination (about 100 cm/s) on the face $x = 0$. The parameter $\nu_p l = l/L_p$, where L_p is the hole diffusion length, is varied from 0.1, which corresponds to a cell in which the junction depth l is small compared to the minority-carrier diffusion length L, to $\nu_p l = 6.0$, a cell in which the inverse is true. If the calculation is conducted for higher values of $h = s/D$, i.e., higher values of surface recombination velocity, the values of Q_p are reduced for all values of α. Figure 9 shows the results of similar calculations for base collection efficiency Q_n as a function of α for various values of l/L_n with a fixed value for b (=0.5 cm). As expected, Q_n increases as the diffusion length in the base increases. Figure 10 shows $Q_{total} = Q_n + Q_p$ for a particular set of values of h, νl, and b.

Data like those presented in Figs. 8, 9, and 10 can be transformed into spectral response curves for specific semiconductors by transforming the abscissa to wavelength or photon energy with the help of curves of α vs λ like those shown in Fig. 1. If this is done for a Si cell having specific values of cell parameters, the result is a family of curves like those shown in Fig. 11, where νl in the diffused "skin" is varied. In the particular case chosen for Fig. 11, the surface recombination velocity $s = 0$ and so, for small values of l/L_p,

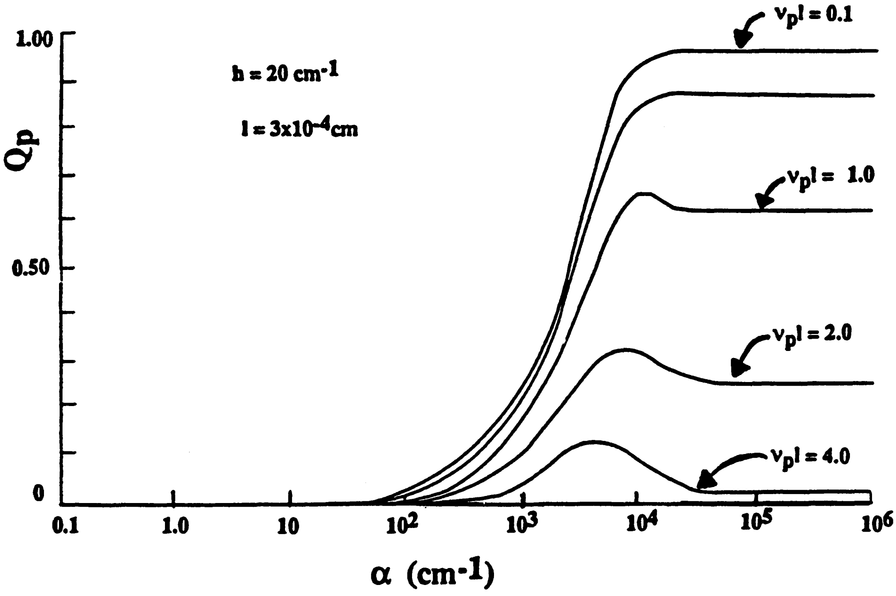

FIG. 8. Collection efficiency Q_p of the diffused *p*-type skin of a PV cell vs α for different values of νl ($n = L^{-1}$).

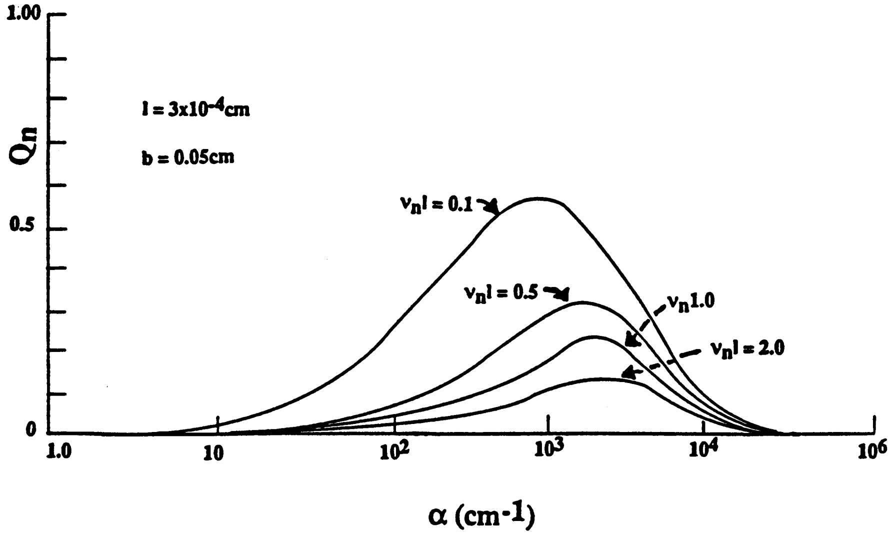

FIG. 9. Collection efficiency Q_n of the n-type base region of a PV cell vs α for different values of nl.

the total collection efficiency approaches unity value for short-wavelength radiation.

2.3 The Reverse Saturation Current I_0 and the Junction Quality Factor A

Most real junctions do not behave as predicted by the ideal Shockley diode equation, i.e.,

$$I_j = I_0[\exp(qV_j/kT) - 1], \tag{36}$$

where I_j is the current through the junction and V_j is the voltage across it. Rather their I_j–V_j characteristic can be approximated by the following expression:

$$I_j = \Sigma_i I_{0i}[\exp(\Lambda_i V_j) - 1], \tag{37}$$

where

$$\Lambda_i = q/A_i kT, \tag{38}$$

and A_i is the diode quality factor (Loferski, 1979). For the ideal diode ($i = 1$), $A_1 = 1$, and I_0 is given by Eq. (8).

A fundamental assumption underlying the derivation of the ideal diode equation and of the corresponding expression for I_0 is that there is no loss of carriers as they traverse the space-charge region. If this restriction is

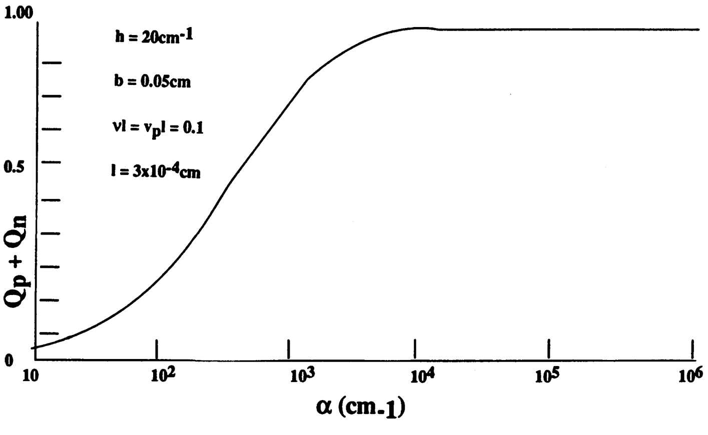

FIG. 10. Total collection efficiency $Q_p + Q_n$ vs α for $\nu l = 0.1$ in both the skin and base regions and with a low surface recombination velocity on the illuminated surface of the p-type skin.

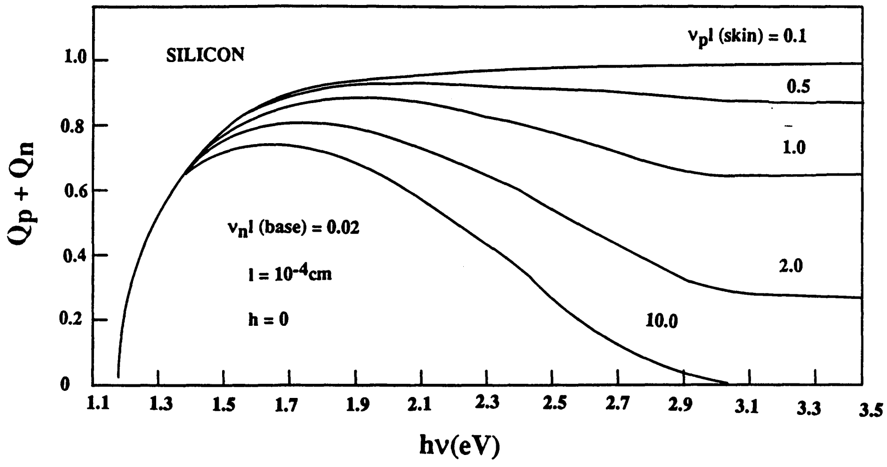

FIG. 11. Family of silicon PV-cell spectral response curves ($Q_p + Q_n$) vs photon energy for different values of $l/L_p = \nu_p l$ in the skin and a large diffusion length in the base.

removed and recombination and generation of carriers is assumed to occur in the space-charge region at recombination centers having their energy levels in the middle of the forbidden energy gap, then the dependence of I_0 on n_i can be shown to have the form

$$I_{02} = K_2(T)n_i. \tag{39}$$

Therefore,

$$I_{02} \propto \exp(-E_G/2kT) \tag{40}$$

and

$$I_{j2} = I_{02}[\exp(qV/2kT) - 1]. \tag{41}$$

More generally,

$$I_{0i} = K_i(T)\exp(-E_G/B_ikT) \tag{42}$$

and

$$I_{ji} = I_{0i}[\exp(qV/A_ikT) - 1]. \tag{43}$$

In the ideal diode case $A_1 = B_1 = 1$, while in the recombination–generation case $A_2 = B_2 = 2$. In real diodes, $2 \le A \le 1$ and $2 \le B \le 1$.

It is easy to show that a PV cell that obeys the ideal diode equation ($A = B = 1$) should have a higher value of $\eta_{\max}$ than a PV cell with $A = B = 2$. The short-circuit current I_{sc} is not affected by the values of A and B and, therefore, will be the same in either cell. There is, however, a difference in V_{oc} values for the two cases, namely

$$V_{oc2} - V_{oc1} = (kT/q)\ln(I_{01}/I_{02}). \tag{44}$$

Since I_{02} is always greater than I_{01}, V_{oc1} is always greater than V_{oc2}. Consequently, according to Eq. (19), $\eta_{\max 1} > \eta_{\max 2}$. It is, therefore, a goal of PV cell technology to produce junctions whose I_j–V_j characteristics are governed by the ideal diode equation.

There is evidence that ideal diode behavior is more likely to be observed in *p-n* junctions made from smaller-bandgap semiconductors like germanium (0.7 eV) than in larger-bandgap semiconductors like GaAs (1.35 eV). The bandgap of silicon (1.1 eV) places it in a transition region between low- and high-E_G materials; consequently, it has been difficult but not impossible to produce silicon cells having ideal diode behavior and, therefore, exhibiting the highest $\eta_{\max}$ of which silicon is capable.

2.4 Maximizing $\eta_{\max}$

The equations governing the PV effect provide guidance on extracting the highest efficiency from a PV cell made from any semiconductor. Most important of all, they show that both surface and bulk recombination rates must be minimized. Minimizing surface losses means passivation of the surface. In the case of silicon, passivation is achieved by covering the outer surfaces with a silicon oxide that has a low interface state density and/or that produces a band bending at the surface in such a direction that light-generated minority carriers are repelled from the surface region.

A more generally applicable method of reducing front-surface recombination losses is to employ the wide-bandgap window concept. The idea is to cover the photovoltaically active semiconductor (PVAS), i.e., the absorber of the ionizing radiation, with a different semiconductor whose bandgap is so large that none of the photons in the light source are absorbed in it. This can result in a heterojunction device like that shown in Fig. 12. There is an added small benefit to efficiency in that the contribution from the wide-E_G semiconductor to I_0 will be orders of magnitude lower than the contribution to I_0 from the PV-active material. Lower I_0, of course, leads to somewhat higher V_{oc} and η_{max}.

Minimizing bulk recombination means minimizing the concentration of bulk recombination centers throughout the light-absorbing volume of the PV cell. In the case of an indirect-gap material like silicon, the concentration of elements like Cu and Fe and defects like vacancies and interstitial atoms, all of which are effective recombination centers, must be minimized. Concentration of these defects must be held to values in the range 10^{12}–$10^{13}/\text{cm}^3$. Such defects can be introduced during crystal growth, during growth of thin films, or during preparation of the cell. As noted above, highest efficiency requires A values of unity. This in turn requires minimizing recombination-center concentration in the space-charge region.

If the surfaces that serve as boundaries of the PV-active region of the cell have zero surface recombination velocity, the value of I_0 calculated from the one-dimensional ambipolar diffusion equations for a cell in which $w \ll L$ has the value (Loferski, 1988)

$$I_0 = I_\infty \tanh(w/L), \tag{45}$$

where w is the distance between the edge of the space-charge region and the edge of the cell and I_∞ is the value of reverse saturation current for a cell in which $w \gg L$.

Since $\tanh x \rightarrow x$ as $x \rightarrow 0$,

$$I_0 \rightarrow I_\infty(w/L). \tag{46}$$

Thus, I_0 decreases as the thickness w decreases. But as w decreases, the photon-absorbing volume decreases and so does I_{sc}. This situation can be remedied by resorting to light trapping, i.e., by making the internal surfaces of the cell optically reflecting. Figure 13 shows how the cell efficiency depends on w for $s = 0$ and $s = \infty$ with 100% efficient optical reflection $R = 1$ and with zero internal reflection $R = 0$. Clearly the goal of the designer is to fabricate cells that approach the case $s = 0$ and $R = 1$, and indeed the highest-performance solar cells approach such values for s and R.

2.5 Dependence of η_{max} on E_G

Up to this point, the discussion has been focused on the performance of PV cells made from a given semiconductor. Clearly, the forbidden energy gap E_G has a first-order effect on the maximum efficiency that can be extracted from a semiconductor (Loferski, 1956). As E_G increases, I_{sc}, which is given by the

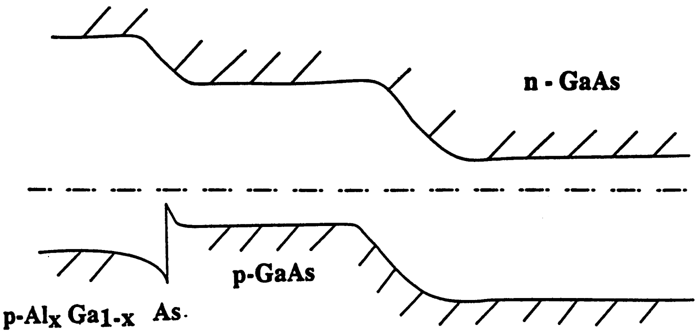

FIG. 12. Energy-band diagram of the p-Al$_x$Ga$_{(1-x)}$As, p-GaAs/n-GaAs solar cell.

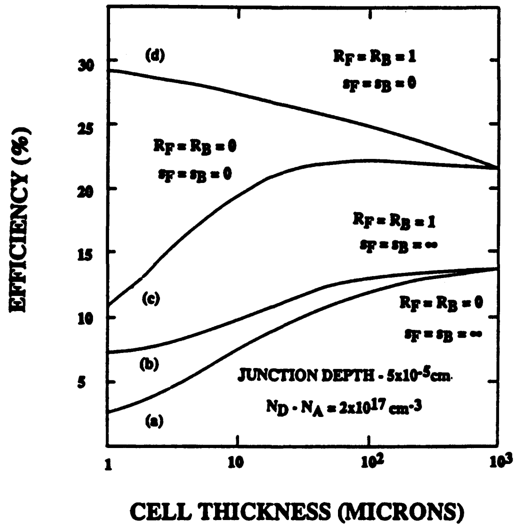

FIG. 13. Solar-energy conversion efficiency vs cell thickness calculated for a silicon solar cell for the four combinations of two extreme values of surface recombination velocity ($s = 0$ and $s = \infty$) and of internal reflectance ($R = 0$ and $R = 1$).

equation

$$I_{sc} = \int_{E_G}^{\infty} Q(h\nu)n_{ph}(h\nu)d(h\nu), \tag{47}$$

decreases. For the solar spectrum, it turns out that

$$I_{sc} = I_{sc0}\exp(-K_E E_G). \tag{48}$$

The value of I_{sc0} is the value of I_{sc} if every photon in the incident solar spectrum contributed a carrier to I_{sc}. The term K_E has a value between 1.5 and 2, depending on the distribution of photons in the spectrum.

The value of I_0 also decreases with E_G because

$$I_0 = K_i(T)\exp[-(E_G/B_i kT)]. \tag{49}$$

At $T = 300$ K and with $B = 1$,

$$I_0 \sim K_1(300\text{ K})\exp(-40E_G). \tag{50}$$

Now, Eq. (12) can be written in the form

$$V_{oc} = \frac{A_i kT}{q}\ln\left(\frac{I_{sc}}{I_0}\right). \tag{51}$$

For $A = 1$ and 300 K, and with $K_E = 2$,

$$V_{oc}(E_G) \sim 0.025[38E_G + \ln(I_{sc0}/K_1)]. \tag{52}$$

So V_{oc} increases as E_G increases. Therefore, since

$$\eta_{max} = I_{sc}V_{oc}(CF)/P_{in}, \tag{53}$$

η_{max} passes through a maximum.

Figure 14 shows η_{max} vs E_G for the Air Mass Zero (AM0) solar spectrum for two cases: $A = B = 1$, i.e., the ideal diode case, and $A = B = 2$, i.e., the case of recombination-generation in the SCR. (The AM0 solar spectrum is the spectrum above the earth's atmosphere.) In generating these curves, the value

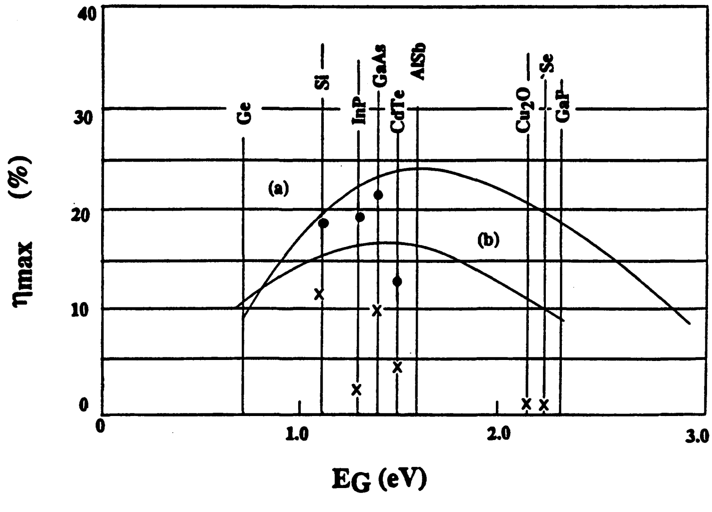

FIG. 14. Efficiency η_{max} vs energy gap E_G for solar cells exposed to AM0 solar spectrum for (a) an ideal p-n junction ($A = B = 1$) and (b) a p-n junction including recombination generation in the space-charge region ($A = B = 2$). The crosses indicate the best experimental values of η_{max} when this theoretical curve was constructed (Loferski, 1956) and the solid dots show the best experimental values in 1994.

of I_0 was calculated for Si for these two cases and it was assumed that the values of K_i are the same as in Si for all other semiconductors. This of course is not true; a separate calculation of K_i should be made for each semiconductor. However, the values of K_i do not vary by large amounts from semiconductor to semiconductor and so the curves of $\eta_{\max}$ vs E_G based on the indicated assumptions correctly predict the gross dependence of $\eta_{\max}$ on E_G.

The major conclusions of this exercise are as follows:

1. The maximum efficiency for solar energy conversion for a single-junction solar cell is around 26%.
2. The best semiconductors for PV solar cells have bandgaps between 1.0 and 2.2 eV with the highest $\eta_{\max}$ occurring around 1.5 eV for AM0 illumination.
3. Cells in which $A = B = 1$ have much higher potential efficiencies than cells with $A = B = 2$.
4. Although the data of Fig. 14 do not show it, the shape of the curves of $\eta_{\max}$ vs E_G changes as the solar spectrum changes.

2.6 Ultimate Efficiency Calculation

The $\eta_{\max}$ vs E_G calculations presented above are based on empirical values of the parameters of semiconductors and of the *p-n* junctions made from them. An important result of these calculations is that qV_{oc} can never be equal to E_G and the curve factor is less than unity. If, however, one assumes that $qV_{oc} = E_G$, which is the maximum imaginable value qV_{oc} can attain, that $CF = 1$, and that every absorbed photon contributes one carrier to I_{sc}, then the efficiency for a cell made from a semiconductor with energy gap E_G would be

$$\eta(E_G) = E_G N_G / E_{\text{total inc}}, \tag{54}$$

where

$$N_G = \int_{h\nu_G = E_G}^{\infty} n(h\nu)d(h\nu); \tag{55}$$

i.e., N_G is the total number of photons having energy equal to or greater than E_G and $n(h\nu)d(h\nu)$ is the photon distribution in the spectrum. The total incident energy is given by

$$E_{\text{total inc}} = \int_0^{\infty} h\nu n(h\nu)d(h\nu). \tag{56}$$

If the solar spectrum is approximated by the spectrum of a 6000-K blackbody, the peak in the curve of η vs E_G calculated from Eq. (54) lies at $E_G \sim 1.1$ eV with $\eta(1.1 \text{ eV}) = 44\%$ (Trivich and Flinn, 1955).

2.7 Higher Efficiencies through Spectrum Splitting

The maximum imaginable energy that a light-generated carrier can deliver to a load in a PV cell is the energy gap E_G. The energy in excess of E_G delivered to the cell by photons with $h\nu > E_G$ is converted into heat inside the cell. This loss of photon energy can be reduced by splitting the spectrum among a stack of cells made from semiconductors having different energy gaps. For example, suppose the smallest bandgap of an absorber semiconductor in a PV cell stack is E_{G1}, and suppose further that the solar spectrum incident on this cell produces a current I_{sc1}. Construct a stack of N cells whose energy gaps are chosen so that each cell in the stack absorbs such a number of photons that the value of $I_{scN} = I_{sc1}/N$. Then the conversion efficiency of the stack will be higher than the conversion efficiency of any one cell in the stack acting alone because the fraction of energy deposited by absorbed photons that is converted into heat (i.e., all the energy of the photon in excess of E_G) is less in the stack than in a single cell. For a three-cell stack with $E_G = 0.94$, 1.34, and 1.91 eV and the AM0 solar spectrum, the theoretical efficiency is about 37%, a value considerably higher than the 26% calculated for a single cell made from the semiconductor having the "optimum" bandgap.

The upper limit on the conversion efficiency of such a stack of PV cells has been the subject of much discussion in the literature. Calculations of the efficiency of a stack of cells with absorber bandgaps varying from 0 to ∞ has shown that for the case of maximum possible concentration of sunlight with lenses or mirrors, namely a concentration ratio of 46 747, the limiting efficiency is $\eta_L \sim 86\%$. The concentration ratio C is the ratio of radiant power per unit area delivered to the PV cell by the concentrator (a lens or a mirror) to the radiant power per unit area that the PV cell receives from the sun if no concentrator is used, in which case $C = 1$. The concentrator focuses all of the sun's rays that it intercepts into an image of the sun. If the cell is a disk and it is placed in the focal plane and the image of the sun just covers the cell, then C is equal to the ratio of the geometrical area of the concentrator or aperture to the area of the solar image it produces, which, in this example, is equal to the area of the PV cell. The maximum attainable value of C is the ratio of the maximum solid angle aperture of a concentrating mirror that is focusing the solar image onto a cell of the same dimension and shape as the image (this solid angle is π steradians) to the solid angle subtended by the solar disc [$\pi \sin^2(\frac{1}{2}\theta)$ steradians; $\frac{1}{2}\theta = 15.9$ minutes]. In this case, $C_{\max} = 46\,747$. For the case of no concentration, $\eta_L \sim 68\%$ (Landsberg *et al.*, 1991). The efficiency is higher as the concentration is increased because the value of I_{sc} increases with light intensity while the voltage increases as the logarithm of the light intensity. Figures 15 and 16 show the results of empirical calculations of the efficiency of a finite number of cells based on the model of PV cells used to calculate the curves of $\eta_{\max}$ vs E_G of Fig. 14 for the case $A = B = 1$ (Gocsen and Loferski, 1979). For this calculation, the bandgaps of the cells were selected so that each of them would absorb the same number of photons and, therefore, generate the same I_{sc}. Figure 15 shows the results for unconcentrated AM0 sunlight and Fig. 16 for a concentration C of 1000. For example, the efficiency of a 26-cell optimized stack at 300 K is about 48% for $C = 1$ and about 59% for $C = 1000$. Note that as T increases, η decreases.

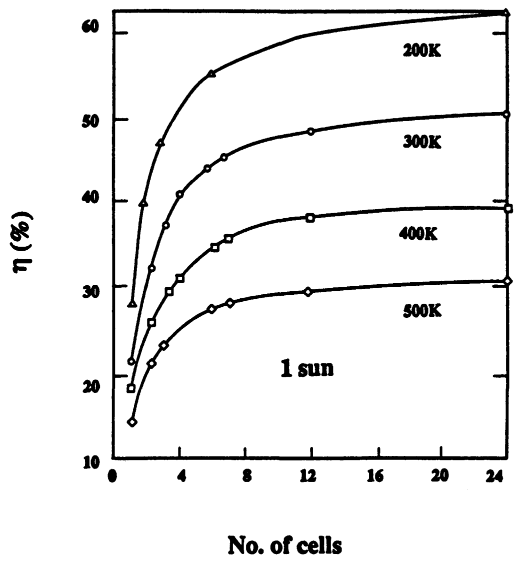

FIG. 15. Calculated optimized efficiencies at various temperatures for tandem PV cell stacks consisting of N solar cells with bandgaps of PV active semiconductors selected so that $I_{sc1} = I_{sc2} = I_{scN}$. AM0 spectrum, no concentration, i.e., $C = 1$.

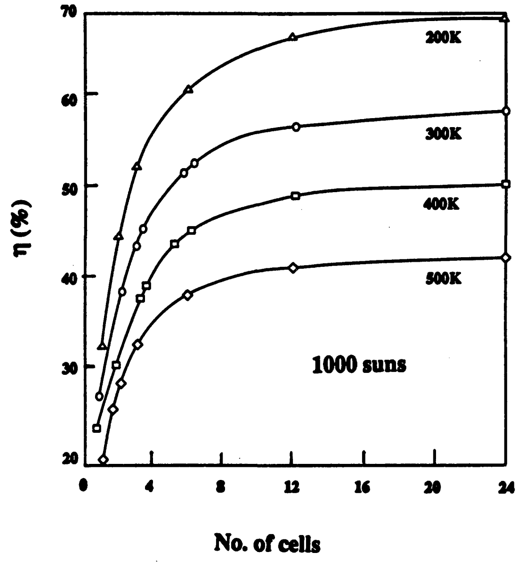

FIG. 16. Same as Fig. 15 except that concentration $C = 1000$.

These calculations do not take into account losses, which are unavoidable in tandem cell systems or for that matter in any PV cell. For example, there will always be an internal resistive loss ρ, a grid transmissivity loss γ, and a reflection loss β. In a three-cell stack, if we assume that each of these loss factors is only 2%, a very optimistic value, then the accumulated fractional loss F_L for a three-cell stack would be (Bennett and Olsen, 1978)

$$F_L = \prod_{1}^{3} (1-\rho)(1-\gamma)(1-\beta) = 0.83, \qquad (57)$$

i.e., the efficiency of the third cell in the stack would be 83% of the lossless value. For more realistic loss factors of 0.05, $F_L = 0.63$. Such losses would limit the number of cells in a stack to perhaps four cells.

2.8 Dependence of $\eta_{\max}$ on Temperature

The open-circuit voltage V_{oc} is a strong function of temperature and, therefore, so is $\eta_{\max}$ (Wysocki and Rappaport, 1960). From Eqs. (12), (42), and (48),

$$V_{oc} = \frac{AkT}{q}\left[\frac{E_G}{BkT} - E_G K_E + \ln(I_{so0}/K_i)\right] \quad (58)$$

$$\approx \frac{AE_G}{Bq} - \frac{AkT}{q}[K_E E_G + \ln(I_{so0}/K_i)]. \quad (59)$$

It turns out that I_{sc0} is always larger than K_i and, therefore, V_{oc} always decreases as T increases. Figure 17 shows a family of curves of $\eta_{\max}$ vs E_G calculated for the AM0 solar spectrum using the same assumptions as those used to establish the curves of $\eta_{\max}$ vs E_G of Fig. 14 with $A = B = 1$. The curves of Fig. 17 show that $\eta_{\max}$ of all cells decreases as T increases and that the peak in the curves of $\eta_{\max}$ vs E_G shifts toward larger E_G as T increases.

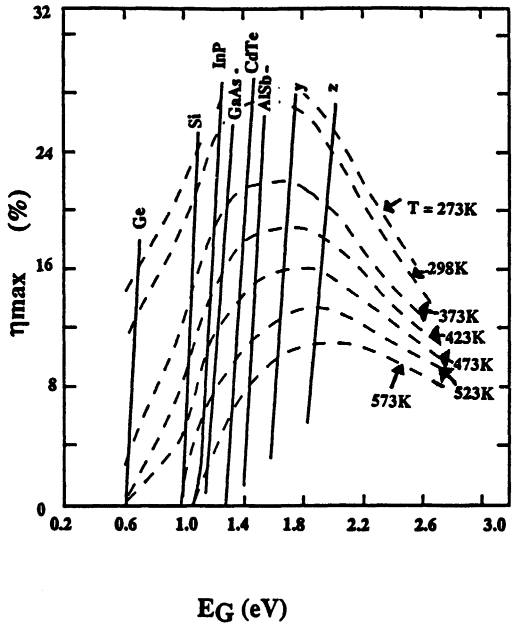

FIG. 17. Efficiency $h_{\max}$ vs energy gap E_G as a function of temperature.

3. SEMICONDUCTOR MATERIALS USED IN PV CELLS: HISTORY AND CURRENT STATUS

The calculations of $\eta_{\max}$ vs E_G show that the best semiconductors for PV cells have energy gaps in the range 1.0 eV $\leq E_G \leq$ 2.2 eV and that the maximum efficiency to be expected is around 26%. To attain the highest efficiencies, the minority-carrier diffusion lengths in the photovoltaically active volume (PVAV) of the cell must be as large as possible. Furthermore, the surface recombination velocity must be vanishingly small on the surfaces of the PVAV.

Photovoltaic cells have been fabricated from many materials having bandgaps in the interesting range. The most successful of these materials have crystal lattice structures related to the diamond lattice, which consists of two interpenetrating face-centered cubic lattices displaced with respect to each other by one-fourth of a lattice constant in each of the three mutually perpendicular directions. These materials include silicon; the III-V semiconductor compounds [gallium arsenide (GaAs), indium phosphide (InP)]; III-V semiconductor alloys thereof like $Ga_xAl_{1-x}As$, $GaAs_yP_{1-y}$, etc.; certain II-VI semiconductor compounds [cadmium telluride (CdTe); cadmium sulfide (CdS); zinc telluride (ZnTe)] and their alloys; and the chalcopyrite semiconductors [copper indium diselenide (CISe), copper gallium diselenide (CGSe), copper indium disulphide (CISu)] and their alloys. Most of the cited materials have served as the constituent of the PVAV, but some of them, notably CdS, have served mainly as wide-bandgap windows or have other functions to perform in the cells. Other materials having different crystal lattices, like ZnP_2, WSe_2, CuO, and CuO_2, have also been explored, but none of them has performed as well as the best of the diamond-lattice materials. There is another important class of PVAV materials that holds promise, namely certain amorphous semiconductors, notably hydrogenated amorphous silicon and its "alloys" with germanium and carbon. The next few paragraphs are devoted to brief commentaries on solar cells made from these materials.

3.1 Silicon Monocrystalline and Polycrystalline Cells

The silicon cell has been the workhorse of the modern PV age. The most successful, most utilized, and oldest of the modern PV cells is the single-crystal silicon cell. In its original form (Chapin *et al.*, 1954), it consisted of a diffused boron-doped p-type "skin" region on a phosphorus-doped, n-type single-crystal base wafer. The p-n junction was located about 1 μm below the surface. As shown in Fig. 18, a gridded metallic Ohmic contact was deposited over the diffused region and the back surface was covered with a metallic Ohmic contact. The area of individual cells was (and continues to be) controlled by the diameter of silicon single-crystal ingots, which had a maximum value of about 3 cm in 1954 and about 15 cm and even 20 cm in 1994. The solar-energy conversion efficiency of the 1954 cell was around 10% for terrestrial sunlight. In 1993, the highest efficiency of crystalline cells having an area of 4 cm^2 was about 23% (Green *et al.*, 1987; Green and Emery, 1993). The cells that produce such efficiencies are of a design radically different from that of the simple 1953 cell. These high-performance cells incorporate surface passivation to reduce surface losses; light trapping to improve utilization of the incident photons; and high minority-carrier lifetime silicon material and cell fabrication techniques that preserve the lifetime. The PVAV has a relatively high resistivity; the heavily doped p and n regions are both located on the side opposite the one on which light is incident.

Special-design, high-efficiency single-crystal silicon cells have also been fabricated for concentrator applications. The highest efficiency reported for such cells is about 28% with $C \sim 200$. These cells had a small area (3×5 mm^2); they had a high-resistivity PVAV and "point-contact" p^+ and n^+ collector regions on the back of the cell (Verlinden *et al.*, 1993).

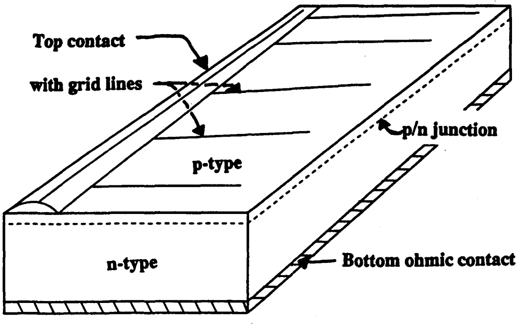

FIG. 18. Schematic representation of standard planar solar cell.

These concepts have been applied to polycrystalline silicon having grain volumes of at least several cubic millimeters. The best of the cells made from such polycrystalline silicon have exhibited solar-energy conversion efficiencies in excess of 17% in cells having an area of 4 cm^2 (Green and Emery, 1993).

3.2 Gallium Arsenide Cells

The first GaAs solar cells were reported in 1956 (Jenny *et al.*, 1956). They were prepared by diffusing cadmium into n-type single-crystal wafers. Their area was small (between 0.1 and 6.0 mm^2) because only small single crystals were available at that time, and the highest efficiency was 6.5%. By 1961, the size of GaAs single-crystal ingots had increased and processing had improved so that 10% efficient cells having areas up to 2 cm^2 were being fabricated.

A significant breakthrough in efficiency was achieved in 1972 by the invention of the wide-bandgap window concept and its application to GaAs (Woodall and Hovel, 1972). Analyses of extant GaAs cells showed that, in this direct-gap material, surface recombination losses exacted a high toll on excess carriers generated in the diffused skin. Incorporation of a wide-bandgap p-Ga$_x$Al$_{1-x}$As window (see Fig. 12) reduced surface losses dramatically and pushed the efficiency up to 15%. Further refinement of this type of cell has resulted in GaAs cells with efficiencies up to 25% in 1993.

Another approach to reducing surface losses is to make the diffused surface layer so thin that a negligible fraction of photons are absorbed in it (Gale *et al.*, 1984). This also has resulted in 23% efficient cells by 1993 (Green and Emery, 1993).

3.3 Cadmium Sulfide/Copper Sulfide

The 1954 CdS cell was made by depositing a thin layer of copper onto a cadmium sulfide single crystal; its actual solar-energy conversion efficiency was only about 1.5% (Reynolds *et al.*, 1954). By 1956, the efficiency of such cells had increased to about 5%. The first thin-film CdS cell was reported in 1954 and the attention of researchers was thereafter directed to the thin-film cell (Nadjakov *et al.*, 1954). At first it was thought that the cell was based on a p-n junction in CdS since it was observed that incorporation of copper into *n*-type CdS eventually resulted in a *p*-type material. However, by the mid-1960s it was clear that this cell was based on a heterojunction between *n*-CdS having a bandgap of 2.4 eV and a *p*-type copper sulfide having a bandgap around 1.0 eV. The copper sulfide was the photovoltaically active material; the CdS was serving as a wide-bandgap window. The Cu-S binary system includes many compounds having various crystal structures. Only the chalcocite form, whose chemical composition is close to Cu_2S, could produce good PV cells. However, the compound is not stable. Efficiencies up to 10% were achieved in *n*-CdS/*p*-Cu_xS cells, but the efficiency was not stable. Consequently, interest in this type of cell waned and the cell was practically abandoned.

3.4 *p*-Copper Indium Selenide/*n*-CdS Cells

CdS continues to play an important role in PV cell science and technology because of its role as the wide-bandgap window in the *p*-$CuInSe_2$ (CISe)/*n*-CdS cell. The first of these cells was made in 1974 by depositing a thin layer of CdS onto a small-area CISe crystal; its efficiency was 12% and it was stable (Shay *et al.*, 1975). By 1976, thin-film CISe/CdS cells with efficiencies up to 6% were made by vacuum deposition of the constituents (Kazmerski *et al.*, 1976). In 1981, a 1-cm^2-area, 10% efficient, stable CISe/CdS cell was reported (Mickelsen and Chen, 1980). It was made by simultaneous controlled-rate evaporation of Cu, In, and Se onto a substrate heated to a high enough temperature (about 500 °C) to react the elements so that CISe is formed. These cells have been further improved by using alloys of CISe with $CuGaSe_2$ and alloys of CdS with ZnS. In 1993, the efficiency of 1-cm^2-area cells of this type had reached 16.9% active area, 14.8% total area (Hedstrom *et al.*, 1993, 1994). In 1994, a total-area efficiency of 16.4% was reported (Gabor *et al.*, 1994). At the time of this writing, this is the highest confirmed efficiency for a thin-film polycrystalline cell measured under standard conditions.

CISe cells have been produced from electrodeposited films, by reactively sputtered films, and by sputtering from a previously synthesized CISe target. These deposition methods are less expensive than the simultaneous evaporation technique, but the cells produced by these methods have not as yet been as efficient as cells made by three-source evaporation.

3.5 Cadmium Telluride Cells

Cadmium telluride has a bandgap of about 1.45 eV, which is close to the peak of the curve of $\eta_{\max}$ vs E_G. It can be made *n* or *p* type so that *p*-*n* junction CdTe cells are possible. The first of these cells was made in 1954 but its efficiency was only around 2%. In 1963, a thin-film *p*-Cu_xTe/*n*-CdTe cell having $\eta \sim 6\%$ was reported (Cusano, 1963). Subsequent research showed that the most successful CdTe cells were heterojunction devices with wide-bandgap window semiconductors including CdS, ZnO, ZnS, and alloys of these materials. Values of $\eta_{\max}$ up to 15.8% (total area) have been achieved (Chu and Chu, 1993).

The films for CdTe cells have been made by close spaced sublimation ($\eta \sim 15.8\%$), electrodeposition (12%), screen printing (11.3%), vacuum evaporation (11%), and chemical spray pyrolysis (12.7%). These low-cost production methods make CdTe cells among the most promising candidates for large-scale PV power plants.

3.6 Amorphous Silicon Solar Cells

The invention of the amorphous Si solar cell at RCA Laboratories in 1974 unleashed a worldwide research effort on this promising device. The first 1974 cells had $\eta \sim 0.2\%$, but by 1976 devices using *a*-Si had reached $\eta \sim 5.5\%$ (Carlson and Wronski, 1976).

The amorphous silicon layers were prepared by electrodeless rf discharge in silane (SiH_4) so that the resulting layers were actually "alloys" between Si and H_2. The best solar cells were made from hydrogenated *a*-Si (*a*-Si:H) films containing between 10% and 20% H_2. The H_2 passivates the dangling bonds in the Si atoms with the result that the "forbidden energy gap" has a much lower density of states than a pure amorphous Si layer contains and, therefore, the material can be doped substitutionally with elements from column 3 or 5 of the periodic table. To make *p*-type layers, some borane (B_2H_6) is added to the SiH_4; to make *n*-type layers, some phosphene (PH_3) is added to the SiH_4. Consequently it is possible to make *p*-*n* junctions in *a*-Si:H. The best solar cells utilize a *p-i-n* structure.

The optical bandgap E_o of *a*-Si:H varies with H_2 content between 1.5 and 1.8 eV. The absorption constant rises rapidly from E_o to values around 10^5 cm^{-1} so that the layer thicknesses of the order of 1 μm absorb all the photons with energies in excess of E_o.

The optical bandgap can be increased by incorporating carbon and decreased by incorporating germanium. Therefore, tandem cell structures can be made from *a*-Si:H. By 1993, the best *a*-Si:H single-junction cells had initial η values of about 11%. Multijunction cells reached initial η values of about 12% (Green and Emery, 1993).

Unfortunately, *a*-Si:H cells have exhibited degradation during illumination. In the best cases, the decay of efficiency from its initial value is about 10%. However, in 1994, it was reported that after several thousand hours of operation under constant illumination by simulated sunlight, the efficiency of certain *a*-Si:H modules stabilized at a value slightly in excess of 10%.

3.7 Cells Based on Other Semiconductors

Many semiconductors have been explored as the PVA material in PV cells. They include InP, WSe_2, ZnSe, Zn_3P_2, $GaAs_xP_{(1-x)}$, organic semiconductors, etc.

The most notable in this group is indium phosphide (InP), which has a bandgap around 1.25 eV. The first InP cells were made in 1956; their efficiency was only about 2%. For the next few decades, InP was neglected because GaAs with its larger energy gap was a more promising material. Research on InP was revived in the late 1980s and cells with efficiencies up to 22% were prepared by epitaxial growth techniques in 1990. These InP cells proved to be extremely radiation-resistant high-efficiency cells, and, therefore, they may play a role in power supplies of future satellites.

There may be other materials which could produce high-performance solar cells, but the research effort that must be expended to realize the potential of each material is formidable. The dominance of Si, GaAs, and InP results, to a considerable degree, from the large effort expended on these materials for more commercially lucrative applications like integrated circuits and optoelectronics devices. The amount of research expended on materials whose only application appears to be in PV cells (like CISe and *a*-Si:H) is very modest and this impedes progress in the field.

4. EFFECTS OF HIGH-ENERGY RADIATION ON PV CELLS

From Eqs. (23) through (33), it is clear that the short-circuit current I_{sc} of an illuminated PV cell is a strong function of the minority-carrier diffusion lengths L_n and L_p in the *n* and *p* sides of the junction. The diffusion lengths in turn are functions of the respective minority-carrier lifetimes τ through relations of the type

$$L^2 = D\tau, \tag{60}$$

where D is the respective minority-carrier diffusion constant. From Eq. (2), τ is inversely proportional to the product of the concentration of recombination centers of interest, N_r; the capture cross section σ_r of the centers; and $f(E_r - E_F)$, their Fermi–Dirac occupancy factor, where E_r is the energy level in the forbidden energy gap associated with the particular recombination centers under consideration.

When a solid is exposed to irradiation by high-energy particles (electrons, protons, α particles, neutrons, γ rays, β rays, etc.), collisions between the high-energy particles and lattice atoms can lead to dislodging of lattice atoms resulting in the generation of vacancy-interstitial pairs (Frenkel defects), provided that the energy transferred to the lattice atom during the collision exceeds the threshold energy for the displacement, E_{th}. For silicon and germanium, E_{th} has a value of about 15 V (Loferski and Rappaport, 1958). This amount of energy can be delivered to a Si atom by an electron having an energy of about 130 keV or a proton having an energy of about 500 eV. The corresponding quantities for Ge, which has a higher mass than Si, are about 350 keV for electrons and about 1100 eV for protons.

In a semiconductor, radiation-generated vacancies and interstials act as recombination centers having energy levels lying between about 0.10 and about 0.25 eV from the band edges. Sometimes the vacancies and interstials form complexes with impurity atoms already present in the semiconductor. The resulting complexes have E_r values in the same 0.10- to 0.25-eV range, and therefore they too can serve as recombination centers. In either case, τ decreases as the concentration of recombination centers introduced by bombardment N_{rB} increases. If the lifetime before irradiation is τ_0, then after bombardment by N_{rB} particles

$$1/\tau = 1/\tau_0 + N_{rB}\sigma_{cB}f_B V. \tag{61}$$

The reason why these irradiation effects are important for PV solar cells is that the cells are used as primary sources of power on artificial earth satellites. In this application, they are exposed to irradiation by electrons and protons trapped in the radiation belts surrounding the earth. Indeed, the discovery of the so-called Van Allen radiation belts by the first satellite launched by the U.S. in 1960 raised questions about the longevity and, therefore, the usefulness of solar cells in space. The cells used on that first satellite were silicon *p* skin on *n*-base cells. Experiments with electron beams from accelerators showed that these cells would lose about 25% of their power output after about 1 year of exposure to the electrons in the Van Allen belts of low Earth orbits. When these irradiation experiments were repeated on silicon *n* skin on *p*-base cells, it was found that they were more tolerant of electron irradiation by almost an order of magnitude. Consequently, *n*-on-*p*-base cells became the silicon cell of choice for use in satellite power supplies. The search for even more radiation-resistant cells eventually led to the discoveries that GaAs and InP cells are substantially more tolerant of radiation than any of the cells made from silicon. They are also more efficient converters of AM0 radiation than silicon, and therefore they are strong candidates for eventually replacing silicon in space applications.

5. ENVIRONMENTAL ASPECTS OF PV CELLS

PV solar cells are completely silent, nonpolluting generators of electricity. They produce no smoke, no carbon dioxide, and no radioactive wastes and are very attractive from an environmental point of view.

One objection to their large-scale use is, however, that generation of large amounts of electricity would require covering large areas with solar panels because sunlight, the primary source of power, is so diffuse. At high noon at the equator, the density of sunlight normally incident on a receiver is about 1 kW/m^2. Over the course of 1 year, such a square meter of surface area would receive about 2 MWh of solar energy. If this solar energy is converted into electricity by 15% efficient solar PV panels, each square meter covered by the panels would generate about 0.3 MWh of electrical energy per annum. For comparison, a 1000-MW(e) fossil fuel or nuclear power plant generates about 8.7×10^6 MWh(e) per annum. A solar power plant based on 15% efficient PV panels would need to cover about 30 km^2 to equal the capacity of one such conventional electrical power plant. This is a large area; however, the solar power plant need not be concentrated at a single site. In fact, it may be preferable to distribute the PV panels over a wide geographical area so that the power would be produced close to where it will be consumed.

There are other potential causes of environmental concern. For example, the production of solar cells requires the use of toxic substances, like silane, phosphene, arsene, etc. Furthermore, the major constituents of some solar cells can be hazardous in themselves, elements like cadmium, selenium, and tellurium. However, studies of these potential problems have lead to the conclusion that they will not be serious, provided that standard safe industrial procedures are followed (Goetz *et al.*, 1994; Patterson *et al.*, 1994).

6. APPLICATIONS OF PV POWER SUPPLIES

The current (1994) annual production of PV cells is such that if all the cells were gathered in some one place and illuminated by solar radiation having an intensity of 1 kW/m^2, their total power output would be about 40 MW. This amount of solar cells is referred to as 40 MW peak or 40 MW$_p$. By 1994, the world production had been at this level for about 15 years so that the accumulated production of PV cells was about 600 MW$_p$ in 1994. About 70% of these cells have been single-crystal or polycrystalline silicon cells; most of the balance have been thin-film amorphous silicon cells. These cells have been used in satellite power supplies, for remote applications, and in electronic products.

6.1 Satellite Power Supplies

Satellite PV power supplies have always utilized the highest-performance solar cells available because the penalty for failure of the power supply is unacceptably high; it is difficult or impossible to repair or replace cells in satellites. The cells have therefore always been single-crystal cells, overwhelmingly silicon, although gallium arsenide cells have begun to be used on some satellites, partly because GaAs cells are more radiation resistant than silicon and even more importantly because they have a higher conversion efficiency. The cost of solar cells is not as important in space applications as in most terrestrial applications because the cost of the power supply for the satellite is a small fraction of the combined cost of the satellite and of launching it. Space applications account for only a few hundred kilowatts of the annual solar-cell production.

6.2 Remote Power

When there is a need for up to a few kilowatts at a remote site in a developed country, it is often more economical to install a PV power supply than to extend the electric grid. Such sites include power for microwave repeater stations, for cathodic protection of oil and gas pipelines, for railroad crossing signals, etc.

In developing countries, where the electric power grid covers only small fractions of the country, PV power is the cost-effective way to provide a few kilowatts for villages far from the grid. The power can be used for educational television receivers, night lighting, refrigerators for medical supplies, etc. The cells used in such remote applications are based either on single-crystal or on polycrystalline silicon.

6.3 Other Applications

Most hand-held calculators use a small solar-cell power supply. These power supplies usually utilize amorphous silicon cells because they cost less and are more suited to indoor artificial lighting where the calculators are commonly used. Amorphous silicon cells have also been used in toys, clocks, battery trickle chargers, etc.

7. ECONOMICS OF PV POWER PLANTS FOR LARGE-SCALE ELECTRICITY GENERATION

The principal impediment to the utilization of PV cells to produce electricity on a large scale has been their cost, even though the cost has decreased dramatically over the past 40 years. In 1955, the price of single-crystal silicon PV cells was about \$2/cm^2 (in 1955 dollars) for 10% efficient cells. In 1994, the price of 12% efficient single-crystal cells has dropped to about \$0.04/cm^2 (in 1994 dollars).

Economic studies of large-scale PV power generation lead to the conclusion that the price must still drop by a factor of about 5, if electricity produced by PV cells is to be competitive with electricity produced by fossil-fuel and nuclear power plants (Wolf, 1981). Furthermore, these studies conclude that there is a minimum efficiency that these low-cost solar PV cells and panels made from them must exhibit if the PV plant is to produce electricity at a competitive price. This is because the solar power plant is not built from PV cells alone. The other components of the system can be classified into two groups:

1. components whose cost is proportional to the area occupied by the PV plant, which in turn is inversely proportional to the PV panel efficiency η (e.g., these components include the site and its preparation, panel support structures, wiring, etc.), and
2. components whose cost is proportional to the power generated but not to the area (e.g., dc-to-ac converters, etc.).

The cost C_T of a PV plant per unit power produced will therefore be given by

$$C_T = A(C_A + C_{PV}) + C_{PW},$$

where A is the area of the PV plant required to produce unit power when the incident solar power is I; C_A and C_{PV} are the costs per unit power produced per unit area of the area-proportional components and of the PV panels, respectively, and C_{PW} is the cost per unit power of the power-proportional components. The total power produced by the PV panels is given by

$$P_0 = A_0 \eta I,$$

where η is the panel efficiency. From the definition of A, $P_0 = 1$ unit when $A_0 = A$. Therefore, $A = 1/\eta I$ per unit power produced. Consequently,

$$C_T = C_{PV}/\eta I + C_A/\eta I + C_{PW}.$$

The intended price of unit power at the output of the plant sets the value of C_T. If PV panels are free, i.e., $C_{PV} = 0$, then for given values of C_A and C_{PW}, there exists a minimum efficiency η that the panels must have if the target value of C_T is to be achieved. Figure 19 shows the results of one such calculation for a solar power plant with specific (reasonable) costs for C_A and C_{PW}. The calculation includes a "planning target" for the price of electricity at the output busbar of the solar PV power plant; it was set at 6 cents (U.S.) per kWh. The figure shows that if the solar-energy conversion efficiency of the PV modules used in the plant is 10%, then the allowable module cost (C_{PV}) will be about \$10/m^2. Since 10% cells produce about 100 W/m^2 when illuminated by 1 kW/m^2 sunlight, this translates to \$0.10/peak watt. For 15% modules, the numbers are \$45/m^2 and \$0.30/peak watt; for 20% modules, \$75/m^2 and \$0.37/peak watt; and for 25% modules, \$120/m^2 and \$0.48/peak watt. PV modules with efficiencies of 15% have been fabricated from silicon cells. Individual tandem cells having efficiencies in excess of 30% and an area of 1 cm^2 have also been made. Thus, cells with the efficiencies required for large-scale power plants have been made but their price remains too high.

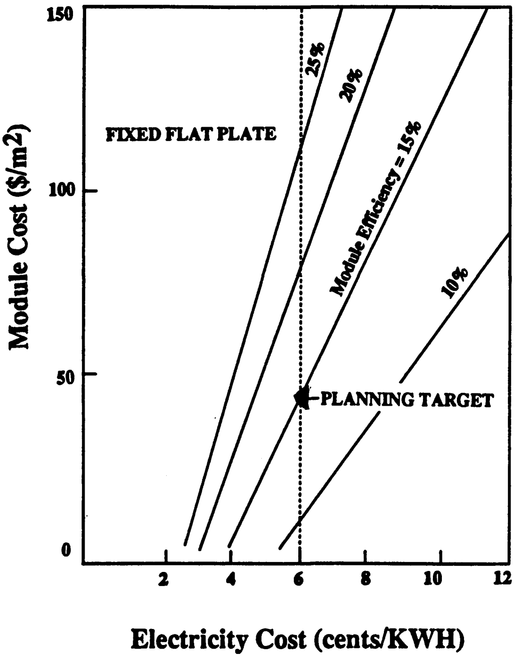

FIG. 19. Allowable cost/unit area of solar-cell panels vs busbar cost of electrical energy produced by a PV power plant.

Note also that if the "planning target" cost of electricity is increased to say 12 cents (U.S.)/kWh, then the allowable module cost for 10% efficient modules rises to about \$70/m^2 and \$0.70/peak watt. For 15% modules, the corresponding numbers are \$160/m^2 and \$1.10 peak watt. For orientation purposes, note that the cost of 10% efficient modules in 1994 is about \$4/peak watt so that reaching the allowable cost goals for 12 cents (U.S.)/kWh electricity is in sight, but the requirements for 6 cents (U.S.)/kWh module cost goals are formidable indeed. It can be expected that the price of PV modules will continue to decrease and that PV power plants will eventually become economically competitive.

8. SUMMARY AND CONCLUSIONS

1. Although the PV effect was first reported in 1839, its first limited applications occurred around 1910 and its first significant applications occurred only after 1953, which date marks the beginning of the modern PV age.
2. By 1955, theoretical analyses of the new PV cells led to the conclusion that solar-energy conversion efficiencies of about 26% were possible in single-junction PV cells. Multijunction PV cell systems can have efficiencies in excess of 30%, according to theory.
3. By 1955, single-crystal silicon cells with efficiencies of about 10% were being fabricated. By 1985, the gap between the 1955 theory and experimentally observed Si efficiencies was closed. The same was true

for cells made from single crystal of GaAs. Multicell efficiencies in excess of 30% have also been reported by the mid-1980s.

4. Thin-film cells have attracted attention since the earliest times because of the anticipated lower cost of such cells. By 1994, stable polycrystalline thin-film cells having efficiencies up to 16.4% were reported.
5. Amorphous silicon-hydride PV cells were invented in 1974 and continue to attract attention because of ease of fabrication and the promise of low cost. Their highest stabilized efficiencies in 1994 were around 10%.
6. Applications of PV cells include satellite power supplies, remote power, hand-held calculators, etc. The technology for large-scale generation of electricity from PV power plants exists, but its application awaits reduction in cost of high-performance PV cells.

GLOSSARY

Air-Mass Zero (AM0) Solar Spectrum: The solar spectrum just outside the Earth's atmosphere, which has an intensity of about 1.4 kW/m^2 and a specific, never changing spectral composition.

Air-Mass One Solar Spectrum: The solar spectrum at the surface of the Earth when the sun is at the zenith. This is necessarily an idealized spectrum since water vapor and other impurities in the atmosphere can change the intensity and spectral content of the sunlight. The AM1 intensity is about 1.0 kW/m^2, and the spectral composition is a best estimate of what it would be if water vapor and other impurity content were negligible. It can be approximated by the spectrum of a 5800-K blackbody.

***p-n* Junction:** An interface between an n-type and a p-type region in a semiconductor structure. It is a homojunction if the n and p sides are differently doped regions of the same semiconductor. It is a heterojunction if the n-type semiconductor is a different material than the p-type semiconductor.

Peak Watt Definition: An amount of solar cells that deliver 1 watt of electrical power to a matched load when the cells are illuminated by sunlight having a specified intensity and spectrum at normal incidence. The appropriate intensity for terrestrial solar cells is 1 kW/m^2; for space cells, 1.4 kW/m^2. Thus, one peak watt of 10% efficient solar cells would have an area of 100 cm^2, whereas one peak watt of 20% efficient solar cells would have an area of 50 cm^2.

Photovoltaically Active Volume (PVAV): That part of a PV cell in which absorption of light leads to the generation of excess carriers that contribute to the PV effect. Wide-bandgap windows are not part of the PVAV.

PV Solar-Energy Efficiency: The ratio of electrical power output to the solar power input. If comparisons of efficiency are to be made, the efficiency must be measured under comparable conditions. These conditions have been standardized so that the spectral composition and intensity of the solar radiation is fixed (usually AM1.5 for terrestrial PV cells) and the temperature of the cell is kept at some specified value (usually room temperature). The power delivered to a load whose resistance is equal to the resistive part of the impedance of the PV cell is measured. This is the maximum power that can be transferred to a load and the efficiency is called the maximum efficiency $\eta_{\max}$.

Semiconductor: A material whose electrical conductivity is higher than that of an insulator but lower than that of a conductor. The room-temperature conductivities of semiconductors lie between about 100 S/cm and 10^{-5} S/cm. The conductivity of semiconductors increases with temperature, whereas the conductivity of metals decreases with increasing temperature.

A detailed history and current status of PV science and technology are to be found in the conference records and proceedings of the three sets of international photovoltaic conferences. The oldest continuous set is the Institute of Electrical and Electronic Engineers Photovoltaic Specialists Conferences, the first of which was held in 1956 and the twenty-third in 1993. The conference proceedings are published by the IEEE Press, New York. The second set is the European Community Photovoltaic Solar Energy Conferences, the first of which was held in 1977 and the 12th in 1994. Their proceedings are published by Kluwer Academic Publishers, Dordrecht, Germany. The third set of conferences is held in the countries of the Eastern Pacific and is entitled the Photovoltaic Science and Engineering Conferences, the first of which was held in 1980 and the seventh in 1993. Their proceedings are published as separate books. These three sets of conferences are so synchronized that one of them takes place every 6 months.

There are two archival journals devoted to PV, namely *Solar Cells and Solar Energy Materials,* Elsevier, which appears monthly, and *Progress in Photovoltaics,* John Wiley & Sons, which appears quarterly.

INTRODUCTION

The foundation of physical sciences is physics, which emphasizes fundamental understanding of physical processes in nature. Physics is based on theoretical concepts supported by experimental data. In contrast to the physical sciences, engineering is concerned with the man-made world. It applies the understanding gained from all the sciences and also generates new knowledge in support of the creation of products and services useful to mankind. The principal engineering disciplines have been civil, mechanical, electrical, and chemical engineering. These names alone suggest that the central sciences applied by engineering are the physical sciences.

The professional institutions that serve physicists and engineers are physics and engineering organizations, respectively. This article summarizes the national and international histories and roles of these organizations, primarily from a U.S. perspective.

1. PHYSICS ORGANIZATIONS

Physics organizations provide the institutional framework that enables physicists and those in related fields to develop and distribute their knowledge; thus, they advance science and technology to meet the needs of government, of industry, and of society at large. They do so by arranging scientific meetings, publishing peer-reviewed research and education journals, and doing other profession-related services.

From the earliest days of the study of physics, the body of fundamental knowledge grew slowly, nourished by physicists working almost exclusively in academia. That slow growth changed dramatically in the twentieth century. With the exigencies of wars, scientific advances brought the world into the nuclear and the space ages.

Critical contributions by physicists in meeting national needs led to recognition of physics worldwide as a science to be encouraged by governments to obtain technological and economic advancements. The result was a 25-year period beginning in 1946 when physics and physicists prospered and basic physics received an increasing share of national funds in many industrialized countries. Then in the 1970s, with worsening economic conditions, due in part to the world oil shortage and increasing national debts, abundant financial support for basic physics research slackened. The emphasis for the next two decades or so was increasingly on applications of physics.

As physics expanded in the twentieth century, so, too, was there a need for expansion within existing physics organizations and for different types of organizations. What are those physics organizations? How do they serve the science of physics and related disciplines, the nation, and physicists themselves? This section and Sec. 2 aim to answer those questions.

1.1 Science Disciplines in Natural and Engineering Sciences

The characteristics of physics organizations are determined by the science that requires them. An understanding of that science can be obtained from the diagram in Fig. 1 that schematically relates the "things" in our natural universe and the science disciplines in the natural and engineering sciences that study them.

The shaded, outer ring of Fig. 1 identifies the four categories of things in our natural universe. They are nonliving materials, living materials, man-made systems, and natural systems.

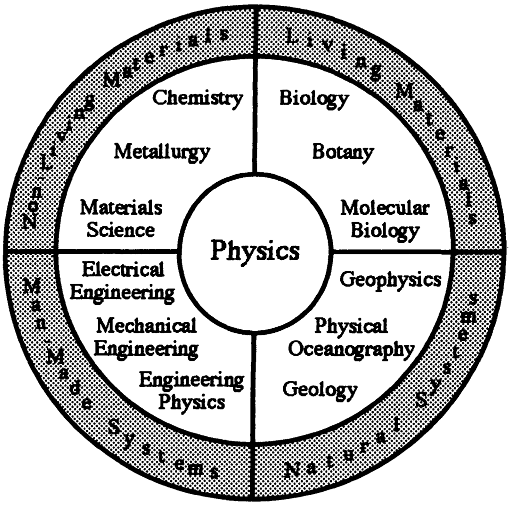

FIG. 1. "Things" in our natural world (shaded areas) and their relation to science disciplines in natural and engineering sciences.

Within the ring are four quadrants containing examples of the names of four groups of science disciplines. The sciences listed in the quadrant study "things" named in the part of the outer ring closest to the quadrant. For example, chemistry, metallurgy, and materials science study nonliving materials, while biology, botany, and molecular biology study living materials. Similarly for the parts of the ring and quadrants that deal with systems. Engineering physics and other sciences fundamental to electrical, mechanical, civil, or chemical engineering, for example, are usually involved with man-made systems, while geophysics, physical oceanography, and geology, for example, study natural systems.

The sciences in the four groupings are largely observational in character. Their scientists observe materials and systems as found in our natural world.

Physics is a science that is in its own grouping in the central small circle of Fig. 1. It is separate from, but coupled to, the other four. Partly observational in character, physics usually confines its observations to basic materials and systems that are simple and sometimes idealized. Physicists also use observational data obtained by others in other science disciplines, and provide the analysis and interpretation that clarify the underlying simplifications. Thus, physics is primarily regarded as a conceptual science because its involvement is principally with concepts of matter, motion, and energy that are fundamental to all of the natural and engineering sciences. Theoretical concepts form a significant part of all work done in physics. Consider, for example, the roughly 30% of all U.S. doctoral theses in physics that are devoted to theoretical topics.

Because of its coupling to all the other sciences, physics is very interdisciplinary. Evidence of this characteristic can be found in the interdisciplinary nature of subdisciplines, organizations, conferences, and journals in which physicists routinely participate. Examples of such subdisciplines are chemical physics, biophysics, geophysics, and physical oceanography. Other evidence to be discussed later is the unusual interdisciplinary mix of primary science disciplines represented in the members of physics membership societies in the U.S.

The diagram of Fig. 1 is not to be taken too literally, even though it does give some useful understanding of the way sciences relate to one another. As an example of such understanding, the relationship among the sciences is perhaps confirmed from the number of graduate doctorate degrees awarded each year by the physics graduate schools in the U.S.A. Data on these degrees have been collected by the U.S. National Academy of Sciences (NAS) since 1920. For each year since that time, the ratio of the number of degrees awarded in physics to the total in natural and engineering sciences has been remarkably constant at 11% to within one percentage point. "Rough statistics from Canada and the United Kingdom, with rather different educational systems, show this same fraction and constancy" (Physics Survey Committee, 1972). Thus, the science enterprises in the U.S., Canada, and the United Kingdom (at least) invest a fixed fraction (11%) of their respective resources each year in the development of concepts in physics to maintain the "health" of their natural science communities.

1.2 Chronology and Operational Tenets of Physics Organizations

By definition, the science of physics has benefited from physics organizations, ever since physics was established as an important branch of science in the mid 1800s. The precursors of physics organizations were science organizations, in which a physics component developed.

Thus, the history of physics organizations really began with the formation of an all-science, honorific society in 1660, the Royal Society of London. The Berlin Academy of Science followed in about 1720 (Evan, 1981). Membership in these organizations and counterparts elsewhere was limited because of the selection criteria, and they were followed by all-science, open-membership societies called associations for the advancement of the sciences. The British Association for the Advancement of Science (BAAS) was founded in 1831, while the American Association (AAAS) followed in 1848. These organizations satisfied the need for meetings and journals of scientific record, even in specialty sciences such as physics, until the German Physical Society (GPS) was founded in 1845, the Physical Society in London (PS) in 1873, and The American Physical Society (APS) in

1899, to cite only a few examples. The chronological development of physics organizations in Europe and the U.S. was consistent with the increases in the numbers of trained physicists.

As the numbers increased, so did the understanding of the basic tenets under which most physics organizations believe they must operate. The tenets are based on the demonstration that physics, with its heavy emphasis on pure physics and original ideas, requires for its healthy development strong interdisciplinary coupling plus free, open, voluntary interchanges of scientific information among all participating scientists. Thus, the important operational tenets are these:

1. All physics publishers should subject proposed contributions for archival journals to peer review.
2. A single language—English—should be accepted internationally for communicating physics information.
3. National policies should allow free, open, voluntary interchanges of scientific information among scientists.
4. National policies should honor intellectual property rights by use of patents and copyrights.

Examples of the application of these tenets during the last 50 years are the following:

1. "Rochester" conferences, named after the first high-energy-physics conference at Rochester University, Rochester, New York, have been held annually since 1952 in different parts of the world (including Moscow). Soviet scientists were able to convince their authorities that open communication with physicists in the U.S. and Europe was essential for their participation in high-energy research. Permission by the communist regimes in the USSR (before its dissolution) was given to Soviet high-energy physicists to participate openly in international conferences.
2. An important requirement for an international conference to be endorsed by the International Union of Pure and Applied Physics (IUPAP) is that participation in the conference must be open to physicists independent of their home country's politics.
3. English-language journals of American physics societies were sent most articles on pure physics of high quality by Japanese, Chinese, and Russian physicists during the last two decades. The selection of American journals is motivated by the desire to reach as large an audience of readers doing similar research as possible. Thereby, these foreign physicists attempt to establish their scientific credentials in the western world and to communicate more effectively with their American peers.
4. In about 1976, a decision was made by the German Physical Society (GPS) and the German government to encourage journal articles and abstracting services published by GPS to be published in the English language, because German physicists were reluctant to publish in journals read by limited audiences. One indirect result of that decision led to the creation of an English-language abstracting service called PHYSICS BRIEFS that replaced a service in the German language called PHYSIKALISCHE BERICHTE, which had been started in 1885.

2. PRECURSORS AND PHYSICS SOCIETIES

The physics organizations and their precursors to be treated in this article are those that now serve effectively the international community of physicists. They are

1. national academies of sciences,
2. the International Union of Pure and Applied Physics (IUPAP) of the International Council of Scientific Unions (ICSU),
3. associations for the advancement of science, and
4. physics societies.

A general discussion of each type in the order listed follows, with details for several outstanding examples. Many examples are from the United States of America (U.S.) and England, because here the information was readily available and because societies in the U.S. and England are large with interesting evolutionary characteristics. The information for both the U.S. and England will show the interrelationships of the four types of organizations, including their roles in the development of strong national physics programs.

2.1 National Academies of Sciences

National academies of sciences are defined as honorary organizations that afford membership and preferential treatment to those who have made outstanding contributions to the advancement of science. An example is the Japan Academy, which was established in 1877 and which now has two sections. Section 1 in the Humanities and Social Sciences has 59 members, none of whom is a physicist; Section 2 in the Pure Sciences and their Applications has 68 members, of whom 12 are physicists (Anon., 1994). Similarly, the Royal Societies in the separate territories within Australia and New Zealand are also honorary only.

Some national academies not only have an honorific role but also officially provide scientific advice to their federal governments. The U.S. National Academy of Sciences (NAS) is an example.

In addition to providing honor and advice, some academies are also the chief coordinating bodies of scientific research in their countries. Two important examples are in the Soviet Union (before its breakup) and in the People's Republic of China.

2.1.1 ICSU and IUPAP An important international role of many national academies of sciences is their adherence to the International Council of Scientific Unions (ICSU). ICSU was founded in 1919 "largely through the representatives of the National Academy of Sciences, Washington, and of the Royal Society, London, to coordinate international efforts in the different branches of sciences, under whose aegis international associations or unions in different branches of science could be formed" (International Union of Pure and Applied Physics Secretariat, 1992). Ninety-five countries are now members of ICSU, headquartered in Paris.

According to ICSU principles, physicists at the General Assembly in 1922 decided that an International Union of Pure and Applied Physics (IUPAP) should be formed. National physics committees or groups of physicists from 43 countries adhered to IUPAP in 1990. IUPAP "promotes international cooperation in physics and the use of international symbols, units, nomenclature, and standards; provides assistance in organizing committees and meetings; encourages research and publication of papers and tables; and fosters free circulation of scientists" (Irvin, 1993). General assemblies are held triennially.

The list of 18 IUPAP scientific and technical commissions in Table 1 (International Union of Pure and Applied Physics Secretariat, 1992) shows the major subdisciplines regarded by IUPAP to be active in the field of physics.

2.1.2 National Academy of Sciences, Washington A Congressional charter approved by President Abraham Lincoln created the National Academy of Sciences (NAS) in 1863, not only to obtain scientific advice regarding the execution of the Civil War, but also as an honorific, private, nonprofit, self-governing membership body responsible for advising the federal government, upon request and without fee, on questions of science and technology. Under this charter, the National Academy of Engineering (NAE) was established in 1964 and the Institute of Medicine (IOM) in 1970.

Specific examples of three of the NRC committees are the Space Science Board that advises on the activities of the National Aeronautics and Space Administration (NASA), the Defense Science Board that advises the Department of Defense (DOD), and the Visiting Committees to the National Institute of Standards and Technology (NIST) in the U.S. Department of Commerce.

Surveys of Physics in 1964 by a committee chaired by George Pake, in 1972 chaired by D. Allan Bromley (Physics Survey Committee, 1972), and in 1984 chaired by William Brinkman are examples of *ad hoc* assignments to the NRC.

2.1.3 The Royal Society, London The Royal Society of London (RS) for Improving Natural Knowledge was founded as The Royal Society in 1660. RS was granted a Royal Charter under the full title in 1663 (Anon., 1976).

Most academies provide honor and advice and/or coordinate scientific research largely for their own nations, and they tend to pursue their scholarly activities in like manner. The single exception is the Royal Society, London. The Russian physicist, Peter Kapitza, has referred to "Newton's active role in the affairs of the Royal Society, observing that the Royal Society 'in contrast to all academies, has still the character of a non-state society. . . . Since Newton's time, the Royal Society has maintained a lively contact with scientific societies the world over'" (Evan, 1981).

The Royal Society has 763 Fellows and 74 Foreign members. Fellows are elected, on the basis of distinction in science, at each annual meeting of the Society. The Society has a long tradition in publishing with *Philosophical Transactions* (Series A and B) and *Proceedings* (Series A and B).

2.2. Associations for the Advancement of Science

Because academies are highly selective in choosing members, scientists in most countries require organizations that reach out also to the rest of the scientific community. Associations for the advancement of science are one such organizational type.

These associations attempt to be broadly inclusive of all sciences, interested individuals, other societies, companies, and audiences. Examples are the Australian and New Zealand Association for the Advancement of Science (founded in 1886 and now with 1000 members), the China Association for Science and Technology (founded in 1958), the British Association for the Advancement of Science (founded in 1831 and now with 2000 members), the French-Canadian Association for the Advancement of Science (founded in 1923 and now with 23 societies as members), and the American Association for the Advancement of Science (AAAS). The founding, history, and current status are treated next.

2.2.1 American Association for the Advancement of Science The American Association for the Advancement of Science (AAAS) was founded in 1848 with about 400 members. Then, physics was still not fully established as a separate discipline, but as part of natural philosophy or science. It was not until 1876 that the first Professor of physics was appointed at a U.S. university. Henry A. Rowland of the Johns Hopkins University had that distinction (Phillips, 1990). Physics received further recognition in the AAAS Constitution of 1874 that established physics in the name of a new Section: Section A—Mathematics, Physics, and Chemistry; Section B was Natural History. Nine Sections date from 1882, and they include a Section B, Physics. By 1895, there were 12 Sections, and the number has now expanded to 21. Section B in 1899 decided that their growing numbers required them to have a separate society. Thus was formed The American Physical Society, with Professor Rowland as the first president. Currently, the AAAS has 140 000 individual members and 300 affiliated societies and regional and state academies.

The AAAS holds large national meetings, publishes a weekly news magazine—*Science*—, publishes books, and manages many advisory committees. Some of the committees serve important sociopolitical roles. They address matters that influence science and technology generally, such as secrecy in government, civil rights of scientists, and scientific information exchange.

As the membership of AAAS grew, particularly after 1950, management by a very large governing council became unwieldy. At that time, AAAS was an association in which representatives of member societies on a large Council (then 500 members) had direct involvement in governance and which was advised by a Board of Directors (then 13 members). In 1970, it changed to an association in which the council was the group advising the Board (Wolfle, 1989).

2.2.2 British Association for the Advancement of Science The British Association (BAAS) was established at York in 1831 by Royal Charter. Membership was and still is open to all interested in science without proposal or election. 2000 members are active.

The annual meeting, held by invitation in a different city each year, is the main activity to achieve the ends of advancing science. It is generally held in provincial cities of the United Kingdom and the Republic of Ireland and in the past has been held in certain cities of the Commonwealth. It lasts for a week, and the program of the meeting is arranged by scientists from the major disciplines of modern science (Anon., 1976).

2.3. Physics Societies

Science societies were founded by small groups of scientists who wanted to share their ideas and scientific discoveries. They originated "in Renaissance Italy in the sixteenth century, spreading across Europe in the seventeenth, and over the American continents in the eighteenth and nineteenth century, and now in the twentieth century, rapidly invading the cities of Asia . . ." (Bates, 1965).

Thus, the concept of a science society was well established before the concept of a science of physics was established in the mid nineteenth century. Once the German physicists founded a German Physical Society in 1845, others followed in a relatively short time in France in 1873, England in 1873, Switzerland in 1887, Hungary in 1891, Netherlands in 1921, and Poland in 1921. The spread to the Pacific Rim began first with astronomical societies in China and Japan, both in 1908, and then later with physical societies in China in 1932 and Japan in 1946. In the case of the Americas, the Canadians and the Mexicans founded their astronomical societies in 1890 and 1878, respectively, followed in the mid 1900s by physical societies. In the U.S., physicists and astronomers founded both of their independent societies, The American Physical Society and the American Astronomical Society, respectively, in 1899 (Anon., 1994). Incidentally, in this article, physical and astronomical societies are both regarded as physics societies, because of the close relationship the subjects of physics and astronomy have in academic departments and because the American Astronomical Society (AAS) elected to be affiliated with other U.S. physics societies in 1966, as is discussed later.

Physics societies are now organized in many industrialized nations of the world. They currently establish the standards of their profession. They do so by arranging open scientific meetings, specialized review conferences, and peer-reviewed scientific journals. These societies usually are open to anyone interested in joining who meets certain minimum qualifications. Other societies can sometimes join if permitted by the bylaws of the parent societies. Physics societies are outstanding examples of organizations that accomplish their purposes of advancing and distributing knowledge in physics.

They may elect to focus only on science-related matters, profession-related matters (such as employment and career information), or education, or any combination of these. They may function in a national sphere only, or they can be international as well. They may also be business or commercially oriented. If they limit themselves to cultural matters, such as education, science, literature, philosophy, and charity, the societies have little in the way of resources with which to operate. To help such societies, their federal governments often provide direct or indirect financial subsidies. In some countries, the subsidies consist of free housing; in the U.S., the subsidies consist usually of freedom from the payment of certain federal and state taxes. Physics societies vary enormously in size. They range from the 20 or so physicists in a school's physics club to the 40 702 members of the world's largest physics society, The American Physical Society (APS).

For the purposes of this article, the highlights of physics societies will be covered by

1. an overview of the principal physics societies in three key regions of the world for which information can be found in the published literature;
2. a description of The American Physical Society headquartered near Washington, DC, in College Park, Maryland;
3. a description of a membership corporation of U.S. physics societies that includes The American Physical Society, called the American Institute of Physics;
4. comments on other U.S. physics and related-science societies;
5. a report on a new American Center for Physics at the APS address; and
6. comments on the Institute of Physics, London, on the German Physical Society (GPS), and on a few other societies in other regions of the world.

2.3.1 Overview of Physics Societies in Three Regions of the World The data in Tables 2 through 4 give an overview of some

Table 2. Principal physics societies in Europe (including Nation Group, Society, Year Founded, and Total Current Members). The 29 societies listed are incorporated as members in a membership society, the European Physical Society. EPS, founded in 1968, currently has 3700 individual members.

[a] NA = Not available.

of the principal physics societies in the world today (Anon., 1994; Burek, 1993; Irvin, 1993).

In Europe in 1968, 29 nation groups organized their physics societies (but not including their astronomical societies) in the European Physical Society (EPS) (see Table 2). These societies have grown in the 1990s to a total of more than 50 000 members (European Physical Society, 1992). Although EPS is a membership corporation of societies similar to the American Institute of Physics (AIP), the EPS selected at its formation a name that was analogous to The American Physical Society (rather than to the AIP). The reason is presumed to be that APS is the U.S. physics organization that European physicists wanted the EPS most to emulate.

Before the founding of the EPS, a major problem for European physicists had been the many individual societies in Europe. These societies tended to arrange local or regional meetings and local or regional journals. Very few Pan-European physics meetings had been available. The result was that European physicists had to come to meetings in the U.S. arranged by the APS, and others, to participate in free, large, and multidisciplinary exchanges of useful scientific information. Besides the meaningful choice of name, the EPS has identified appropriate operations for itself such as *Europhysics Journals*, and for individual nation groups who are qualified to contract to do publishing on behalf of the EPS community. Also, the EPS has begun holding triennial congresses, the most recent of which was held in 1993. It is evident that the European Physical Society represents a big step forward in meeting the organizational needs of European physicists.

In the Pacific Rim, three major sets of physics societies are to be found in the nations of Japan, Australia, and China (see Table 3).

Of these three, the nation that has had considerable investments in technology, but small investments before 1980 in basic physics, is Japan. The result has been that Japan has not generally developed a strong tradition for publishing journal articles in pure physics, although their journal *Progress in Theoretical Physics* has been an important exception since the 1950s. They have emphasized applications of physics. It is to be expected that the investments in the 1990s will be more directed to pure, long-range research in physics, in order to improve Japan's scientific and technological competitiveness. The general physics society is the Physical Society of Japan (PSJ), founded in Tokyo in 1946. PSJ has 15 859 members and publishes *Butsuri* (monthly, in Japanese), *Journal* (monthly), *Progress in Theoretical Physics* (monthly), and, jointly with the Japan Society of Applied Physics (JSAP), *Japanese Journal of Applied Physics* (monthly). JSAP was founded in 1932 and presently has 9000 members. The Crystallographic Society of Japan (founded 1950—now 10 007 members), the Acoustical Society of Japan (founded 1936—now 2600 members), and the Astronomical Society of Japan (founded 1908—now 2400 members) are the other Japanese physics societies.

Australians have made significant contributions to physics, in spite of having had limited resources of funds and personnel. Their general physics society is the Australian Institute of Physics. Their Institute was founded in Victoria in 1963, has 2400 members, and publishes *The Australian Physicist* (monthly). Two other Australian physics societies are the Australian Acoustical Society (founded 1971—now 390 members) and the Astronomical Society of Australia (founded 1966—now 250 members).

The final nation in this grouping is China. China has been slow to develop technologically; nevertheless, there is tremendous potential that will eventually be tapped when the Chinese accept the importance of free and open exchange of scientific and technological information. Their general physics society is the Chinese Physical Society (CPS) founded in Beijing in 1932. The CPS has 25 000 members and publishes various journals, mostly in the Chinese language, such as *Advances in Physics, Chinese Physics Letters, Wuli (Physics), University Physics,* and *Physics Education.* The CPS has nine subsocieties: the Chinese High Energy Physics Society, the Chinese Nuclear Physics Society, the Chinese Liquid Crystal Society, the Chinese Electron Microscopy Society, the Chinese Mass Spectrometry Society, the Chinese Luminescence Society, the Chinese Particle Accelerator Society, the Chinese Gravitation and Relativity Astrophysics Society, and a Special Society on Phase Diagrams (Anon., 1990). The Chinese Optical Society (founded 1979—now 9019 members), the Acoustical Society of China (founded 1985—now 2879 members), and the Chinese Astronomical Society (founded 1908—now 2400 members) are three other Chinese physics societies.

Of the three nations that make up North America, Canada has two physics societies, Mexico has two, and the U.S.A. has ten member societies of the American Institute of Physics (AIP) (see Table 4). Representatives of the Canadian Association of Physicists, the Mexican Physical Society (Sociedad Mexicana de Fisica), and The American Physical Society have met to identify feasible steps to strengthen physics in North America. Joint meetings, long-term exchange agreements, and reciprocal memberships are some of those steps, some of which have been carried out.

2.3.2 Details of Selected Societies

2.3.2.1 The American Physical Society. The American Physical Society (APS) is the oldest and largest of the U.S. physics societies (Phillips, 1990). The APS was formed in 1899, the same year the American Astronomical Society (AAS) was formed. The two organizations went their independent ways until 1966.

The original intent of the APS was to focus on meetings. They did so by organizing joint meetings with AAAS's Section B until 1940. Journals joined meetings in 1903 as important communication vehicles. At that time, the APS began "cooperation" in the publication of *The Physical Review* with Cornell University editors who had initiated the journal in 1893. *The Physical Review* was subsequently published by the APS beginning in 1913, published for the APS by the AIP from 1932, and, as of 1975, is now published by the APS through the AIP.

The meetings and journals arranged by the APS displayed that pure physics, very narrowly defined, was to be the province of the APS. "APS was elitist from the beginning. It was expedient, and undoubtedly wise, to persuade the most prestigious physicists in the country to take leadership positions in the new society.... Members might raise questions of applications and of pedagogy, but the decisions of the APS Council did not reflect these concerns.... Applied physics and even fundamental physics related to applications suffered much the same neglect" (Phillips and Wilson, 1989).

Obviously, the most prestigious physicists who were leaders of the APS in the early 1900s recognized their responsibilities to the profession. They were defining the very nature of physics by controlling the scientific content of APS meetings and journals. As some unknown seer has observed, "physics is what physicists do." Therefore, the contents of the APS meetings and journals defined what physicists did and so defined physics.

The role of APS leaders in establishing strict standards for defining physics during the formative years of the APS was appropriate. Now, a century later, when the membership has grown to more than 40 000, the society leadership is no longer autocratic. The APS has become a democratically run society that is much influenced by the current needs and interests of its membership. The Governing Council of the APS now consists of present and past officers, 23 Divisional Councillors, 12 Councillors-at-large, and two committee chairs. The total is 44. The Council meets twice a year.

Any 200 or more members who wish to advance the knowledge of a subfield of physics may petition the Council to establish a Topical Group. If a Topical Group attains a size specified in the By-laws for two consecutive years, it can become a division. Continuation of a division depends on continuation of membership interests in that division according to stated criteria. If at least 200 members wish to advance knowledge regarding the interrelation of physics with matters not exclusively in physics, they may petition the council to establish a forum.

The names of divisions, forums, and topical groups listed in Table 5 show the wide breadth of coverage of what is today considered physics appropriate for the meetings and journals of the APS. These organizational units plus 19 bylaw committees, three constitutional committees, and 31 prize committees provide the membership input to two annual general meetings, plus numerous subunit meetings and a journal program in which some 20 000 articles are published annually.

4. Laser Science
5. Shock Compression of Compressed Matter

Several measures of the success of The American Physical Society in achieving its purpose of "advancement and diffusion of the knowledge of physics" are available. One measure is the continued, considerable growth in the total membership of the society as plotted as a function of time in Fig. 2: from 30 000 in 1980 to 40 702 in 1993 (American Institute of Physics, 1993). Another measure is the continued growth in attendance at meetings and in the total number of pages published annually in APS journals. A final measure is the many interdisciplinary activities sponsored by the APS.

2.3.2.2 American Institute of Physics. During the first 25 years of the 1900s, in which the Council of the APS exerted strict management and editorial control, other scientific and educational interests became so important to some physicists as to threaten the formation of several new societies and the fragmentation of the APS. For example, the Optical Society of America (OSA) and the Acoustical Society of America (ASA) were founded in 1916 and 1929, respectively, as societies independent of the APS. This dispersal of physicists was of great concern to the APS. However, "unlike the American Chemical Society, which embraced all aspects of chemistry, the APS continued to take a very narrow view of its role" (Phillips and Wilson, 1989).

An APS Committee on Applied Physics in 1930 took steps to stop the organizational disintegration as well as to overcome the financial distress in their and other societies. They did so by proposing a federation of societies to be called the American Institute of Physics (Barton, 1956). The societies supporting the proposal were the APS, OSA, and ASA. Invited to join also was the Society of Rheology (SOR); and when the American Association of Physics Teachers (AAPT) was incorporated in 1932, it was invited also. Table 4 gives the name, year founded, year of affiliation with the AIP, and total current membership for each of the five founder societies together with the same data for the five societies that have joined the AIP in the more than 50 years since.

The original assignments to the AIP were the complete responsibility, including journal ownership, for the publishing programs

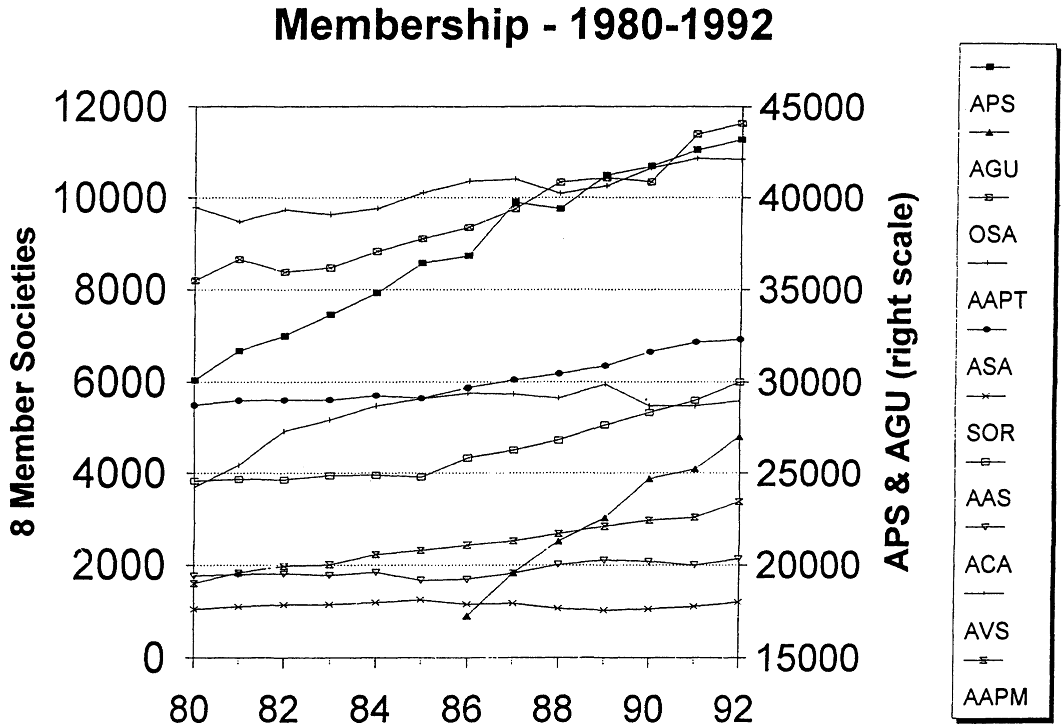

FIG. 2. AIP member society growth chart: the logarithms of total society membership plotted as a function of time.

of the societies and also some limited scientific responsibility. More specifically, the AIP was not to be a mere joint publishing department, but was "to be the joint instrument of the societies for the gaining of any of their collective ends in which success would be gained by combining" (Barton, 1956). One area of scientific responsibility was the applications of physics not covered by any other member society. Thus, several applications journals were begun by the AIP and continue to be the sole responsibility of the AIP.

Although the AIP was formed to be a "federation," in which some autonomy of the member society was to be transferred to the AIP, the development over the years has been to increase the independence of each of the AIP societies from each other and from the AIP. For this reason, the change of the publishing arrangement between the APS and the AIP cited above was made in 1975. For this reason, also, the AIP is referred to as a membership corporation and not a federation, since it is now clear that the members of the AIP are principally the societies and not their individual members.

In retrospect, the organizational relationship of the AIP and its member societies has been of great mutual benefit. The societies, who have relied on volunteer help from their memberships, have been able to focus on scientific matters, while assigning some business matters, including the development of new facilities as required, to the permanent professional staff at the AIP. Also, the early fixation on "pure" physics has made it possible for the APS to spawn new societies in close liaison with the rest of the physics community.

The first 25 years in the history of the APS must have been difficult years for their members interested in "pure" physics as well as for physicists about to form new societies focusing on physics applications and education. The difficulties were little indication of the flourishing success that has resulted in the 1990s both for the APS and for the other U.S. physics societies that have been formed separate from the APS.

Several measures of success in the development of all U.S. physics societies affiliated in the AIP are available. The most obvious is

Table 6. Type of employer for each society, 1990.

	AAPT	ACA	AAS	APS	AGU	ASA	SOR	AAPM	OSA	AVS
Academic	89	53	51	45	38	37	35	29	26	17
Industry/self	7	24	16	30	26	40	59	16	56	71
Federal	3	16	28	23	31	16	4	5	15	12
Nonprofit	1	7	5	2	5	7	2	50	3	0

the healthy growth in the memberships of all of the member societies as shown in the graph of Fig. 2. The total number of individuals represented by the 10 member societies is about 110 000 (American Institute of Physics, 1993).

Another measure is the mix of the types of employers represented among the physicist members of the member societies as shown by the percentages in Table 6 (American Institute of Physics, 1990). Note particularly that the AAPT has the largest percentage in academic institutions and that the AVS has the largest percentage in the industry/self category.

A similar measure is the unusual interdisciplinary mix of professions represented by the memberships of AIP member societies as shown by the data in Table 7 (American Institute of Physics, 1990). The mixtures of professions and of employers should lead to excellent exposures of ideas, methods, and applications in meetings and journals operated by the various member societies.

A final measure of success of the AIP created by its societies is the variety of programs operated by the AIP for the benefit of the member societies and their members that are exemplified by the listing in Table 8. Further details on publishing by U.S. physics societies can be found in the related article PHYSICS LITERATURE AND PUBLICATIONS.

2.3.2.3 Other U.S. Physics and Related-Science Societies. An additional class of membership in the AIP is the Affiliated Society that is any local, regional, or national organization interested in physics. Eighteen societies have so affiliated. They include such societies as the American Nuclear Society, the American Meteorological Society, the Geological Society of America, and the Materials Research Society. The total membership in the Member and Affiliated Societies is more than 200 000 and can be assumed to be most of the U.S. physics organizations (except for the NAS, the U.S. Liasion Committee to IUPAP, and the AAAS) of interest in this article.

Each of the Member and Affiliated Societies successfully serves important and well-defined constituencies. Several of them have organizational and historical characteristics that are particularly noteworthy in understanding U.S. physics organizations, as follows:

1. The American Astronomical Society has a history equivalent to that of the APS in that they were both founded in 1899. The AAS presently includes most U.S. astronomers though its membership is only 5900. Although physicists and astronomers are closely affiliated in U.S. academic departments, the AAS was not organizationally affiliated with other physics societies until 1966, when it became a Member Society of the AIP.
2. The American Geophysical Union, now a

very large society with 29 766 members, is like AAS in that it developed independently of the APS. Although the AGU was founded in 1919, it did not elect to join other Member Societies in the AIP until 1986.

3. The American Vacuum Society is a society that splintered off from the APS in 1953 and that elected to become an AIP Member Society in 1976.
4. The Materials Research Society is a relatively new society (founded in 1973) that has mostly physicists or chemists as members. The society considered affiliation with other Member Societies of the AIP as a Member in 1986. Instead, it elected to become an Affiliated Society. Thereby, it has developed strong ties to the other Societies in the AIP without being characterized as either a physics or chemistry society, because it indeed is both.

2.3.2.4 American Center for Physics. A common and highly visible home for the physics community in the U.S. called the American Center for Physics has been built jointly by The American Physical Society, the American Association of Physics Teachers, and the American Institute of Physics. The Center is built on a 24-acre tract of land in College Park, Maryland, 12 miles from the nation's capital in Washington, DC. The building contains 120 000 square feet of floor space, enough initially to house the headquarters of the three founder societies and at least one other member society of the AIP, the American Association of Physicists in Medicine. Most of the AIP professional programs itemized in Table 8 have been relocated to the Center. A featured element in the new building is the Niels Bohr Library, used for studies of the history and philosophy of physics.

2.3.2.5 The Institute of Physics, London. The Physical Society (founded in 1873 and since having developed into a society primarily for university physicists) and the original Institute of Physics (founded in 1918 and since having developed into a society primarily for industrial physicists) were amalgamated in 1970 to form the current Institute of Physics (IOP). Both organizations were based in London, and, upon their amalgamation, they received a Royal Charter.

The object of the Institute is to promote the advancement and dissemination of a knowledge of and education in the science of physics, pure and applied. The total membership is over 16 000, including 2400 Fellows of the Institute and 820 Fellows of the former Physical Society.

The Institute makes a great effort to be a "democratic organization which needs contributions from physicists with wide experiences if it is to be fully representive. By working through the Boards, Committees, Branches, Divisions, and Groups, members can actively participate in the work of the Institute influencing its activities and policies and representing its views to official bodies" (Institute of Physics Secretariat, 1993).

There are currently five divisions of the Institute (see Table 9) that act as forums for reviewing research and development in their respective fields of physics. The divisions collaborate with 32 subject and professional groups in arranging meetings and conferences.

IOP Publishing is a wholly owned subsidiary company of the Institute and one of the largest publishers of physics information in the world. The publishing activity has its origins in the *Proceedings of the Physical Society*, first published over a century ago. Today, it publishes over 70 new books and proceedings a year and over 30 journals.

2.3.2.6 German Physical Society. Germany has probably the longest tradition for educating physicists of any nation in the world. The universities in Germany were the schools of choice for most of the nineteenth century for many students who wanted to enter careers in physics and for many U.S. physicists. Also, the German Physical Society

(GPS) (Deutsche Physikalische Gesellschaft) founded in 1845 represents the oldest physics society in the world as well as the largest in Europe with 18 400 members.

Thus, it is useful to compare this tradition and history with the relatively small size of the publishing program of GPS. In 1992, they published only two primary publications, called *Physikalische Blätter* (monthly) and *Verhandlungen der DPG* (eight issues per year). They also had an abstracting service called *Physikalische Berichte* (every two weeks). After a study of the large number of members and the small number of authors in their publications, they concluded that their solution would be to encourage authors in their publications to switch to the use of the English language, not only for their primary journals but also for their abstracting service. The English-language abstracting service is now called *Physics Briefs* and is highly successful because it is available worldwide on a computer network called STN International (Scientific and Technical Network International).

2.3.3 Other Physics Societies in the Rest of the World Many industrialized nations may not have physics societies, though they may have chemical, geology, mineralogy, meteorology, or other natural-science societies. The small number of physicists that are educated each year compared with the other natural-science professionals in all countries is the reason. Therefore, the occurrence of physics societies may be spotty in any given region of the world.

A few of the outstanding physics societies not covered by this article are the following:

1. The Indian Physics Association (IPA) was founded in Bombay in 1970. IPA has 30 chapters in different cities of India and has a total membership of about 2500.
2. The Malaysian Institute of Physics was founded in Malaysia in 1973 and has 60 members.
3. The Institute of Physics, Singapore, was founded in 1972. It has 237 members.
4. The African Union of Physics was founded in Oyo, Nigeria, in 1982.

3. ENGINEERING ORGANIZATIONS

3.1 General

Engineering has strongly influenced the development of human society. As the capability of engineers has increased, many technologies have been created that have extended and are continuing to extend human abilities. Examples are the ability to travel more widely and rapidly, to communicate globally and almost instantaneously, to control large amounts of energy, to make many new types of materials, and to modify environmental conditions. Engineers have assisted in effecting these changes and, in turn, have been affected by them. A primary means by which engineers interact with society is through the many organizations the profession has developed. An examination of these engineering organizations can provide insight on the functioning of the engineering profession and how it interacts with society.

In the U.S.A., engineers have created a number of nongovernmental and not-for-profit organizations during the last 150 years during which the modern profession emerged. These organizations range from those concerned with advancing the knowledge base of the profession and educating future engineers to those concerned with industrial practice and public policy on engineering-related issues. They reflect the common interests of engineers as a community and represent these interests to other elements of society. They operate in local, regional, national, and international contexts.

3.1.1 Organization of This Section Engineering-related organizations may be considered in four categories. The first includes the technically oriented organizations whose major concern is the advance of engineering knowledge and know-how—the research and development that make advances possible. The major group in this category, the engineering professional societies, have developed along both disciplinary and industrial sector lines.

In a second category are the education-oriented societies. Although the professional societies and some other engineering-related organizations carry on educational activities, there are several organizations primarily devoted to education-related activities. One such is the Accreditation Board for Engineering and Technology, which accredits engineering and engineering technology postsecondary educational programs.

The third category includes industrially oriented organizations that carry on engineering-related activities. In many industrial sectors, trade associations have been organized that support the engineering interests of their member companies. Another type of organization in this category comprises the standards-writing organizations, which develop the standardized procedures and processes used in many commercial transactions.

A fourth category includes organizations with a major focus on public policy related to engineering. Principal among these are the National Academy of Engineering, the National Society of Professional Engineers, the American Association of Engineering Societies, and the American Association for the Advancement of Science.

These four categories are in no sense mutually exclusive. Most engineering organizations have activities in several categories. Each organization is described here in the category that represents its major activity and the one in which the organization is most widely recognized.

3.1.2 International Counterparts There are counterpart organizations to these U.S.-based organizations in other nations. In the highly industrialized nations, there are usually well-developed organizations with a broad range of activities similar to those in the U.S.A. The national professional societies are typically organized along disciplinary lines, with the holding of meetings, publication of technical periodicals, and recognition of outstanding technical achievements as their principal functions.

However, there are also significant differences among the developed countries. In the United Kingdom, for example, the certification of professional competence, or registration, of engineers is linked to the membership category of the relevant engineering professional society. Thus, "chartered engineer" is a title conferred by a professional society and is used to designate someone recognized as qualified for the public practice of a particular branch of engineering. In the U.S.A., registration of engineers is a responsibility of the state governments, which they carry out with the assistance of the various professional societies. Such national differences occur in many of the industrialized countries.

Strong professional organizations are not the norm in most developing countries. Professional engineers in these countries often lack the benefits of good technical periodicals and regular meetings and conferences. As a consequence, they are not as able to develop effective technical networks with fellow specialists. Having recognized this weakness, some developing countries are in the process of organizing a professional society infrastructure to compensate.

It is beyond the scope of this article to survey the numerous engineering organizations that have been established throughout the world. But it is noteworthy that, in general, engineers everywhere have found that professional societies provide them with services essential to the well-being and health of their professional communities.

There are a number of international organizations in which U.S. engineering societies are members; among these are the World Federation of Engineering Organizations and the Union of International Technical Associations. Typically, their purpose is to facilitate collaboration among engineers throughout the world. While these two organizations operate on a global basis, others operate on a regional basis in a major geographical area, such as Latin America or Southeast Asia.

Some exceptions to the norm of engineering professional societies being organized on a national basis can be found. In the U.S., the most notable is the Institute of Electrical and Electronics Engineers (IEEE), which has a transnational organizational structure. It is described in detail in Sec. 3.3.4. Also, the United Kingdom system of "chartered engineers" is recognized in many other countries that are or have been part of the British Commonwealth.

3.2 Inherent Characteristics of Engineering

3.2.1 Integration of Knowledge Engineers both generate and apply knowledge. Thus, the activities of engineers range from research and development, in which the creation of new knowledge is the principal objective, to manufacturing, construction, and other operations in which knowledge is applied to deliver products and services. To encompass this wide range of functions, engineers draw on and integrate a variety of sources of information and knowledge. The process of integration, drawing on knowledge and experience from many fields, is an inherent characteristic of engineering. The services and products that are the output of engineering must meet the requirements of customers and competition in the marketplace.

3.2.2 Relation to Mathematics and Science Mathematics and the natural sciences provide much of the knowledge needed by engineers. As these disciplines advance, they give engineers the ability to improve on existing products and services and to create new ones. However, as the complexity of the products and services has increased, engineers have had to undertake fundamental research to improve the performance of the systems they have created and to understand their limitations. For example, as communication systems became more powerful and complex, a deeper understanding of their characteristics was needed. This need was met by the development of information theory at the Bell Telephone Laboratories in the 1940s. It enabled design engineers to determine the information-carrying–capacity limitations of existing systems and to improve their performance. While engineers, particularly in academic environments, carry on fundamental research driven by individual initiative as well as research in strategic areas, engineering research in industrial laboratories is primarily driven by needs of a strategic nature. The traditional engineering disciplines are linked closely to the most relevant science: chemical engineers to chemistry, electrical and mechanical engineers to physics, and civil and mining engineers to geology.

As the complexity of engineering-designed systems has increased, these traditional knowledge sources have been complemented by others. New analytical techniques have been created to handle the greater complexity. The field of systems engineering has gradually evolved to enable highly complex systems to be designed, produced, and operated. To optimize the performance of systems that involve both complex instrumentation and human operators requires improved analysis, modeling, and simulation techniques. Engineers who specialize in the design and production of such complex systems are no longer closely linked to one of the natural sciences.

The characteristics of engineering research and an identification of some research fields in which there are fruitful opportunities are discussed in a report written by a panel of the National Research Council Engineering Research Board (National Research Council, 1987). Figure 3, from this report, illustrates the relationship between

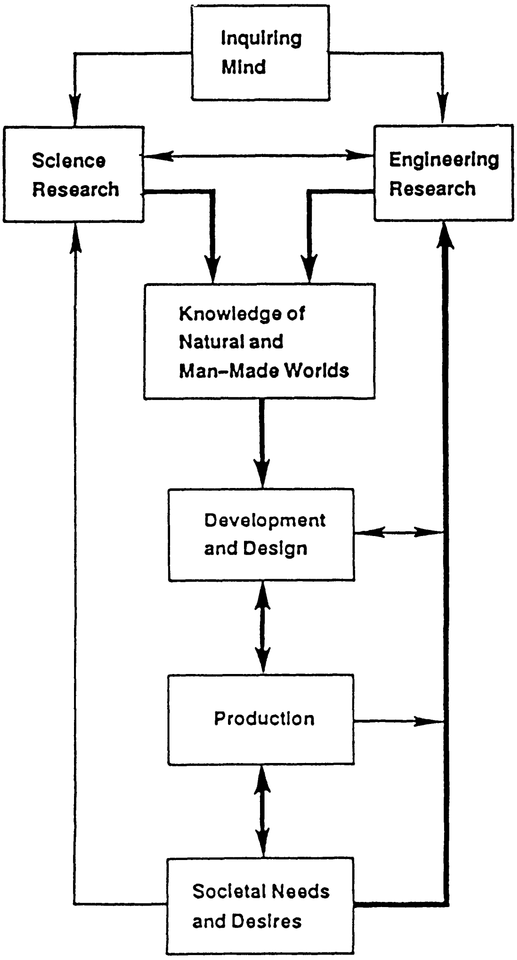

FIG. 3. Relationship between engineering and scientific research (from National Research Council, 1987).

engineering and scientific research in the perception of this panel. The broad distinction is made that scientific research seeks to gain more knowledge about the natural universe, while engineering research seeks more knowledge of the man-made world. Thus, technological advances can open up new branches of engineering, which become areas in which new research efforts are launched. One such branch of engineering, which is still in an early stage of development, is software engineering (*q.v.*). Its fundamental concepts are still in the process of being identified (Gibbs, 1991).

3.2.3 Societal Impact As technologies of increasing power have been developed, engineering's effect on human society has become more far-reaching, and the knowledge sources that engineers must draw on have widened. As medical technology has advanced, engineers have worked more closely with physicians and biologists. The need to control pollution and to protect the environment has required engineers to work closely with behavioral scientists as well as government officials. To meet competition in the global marketplace, engineers must work with economists and international experts. To meet changing conditions, engineers must integrate not only quantitative knowledge in their design and production of products and services but also the nonquantitative knowledge that characterizes many nonscientific disciplines.

The existing engineering societies have responded to these new demands by creating new publications and jointly sponsoring meetings. In some cases, new societies have been formed to facilitate the development of new fields of knowledge. The new modes of handling information have resulted in computer experts and other engineers working with specialists in medicine, education, organizational behavior, and governmental affairs as well as the natural sciences. Expanding frontiers have put new requirements on both individual engineers and the organizations that serve their interests.

3.3 Technically Oriented Organizations

3.3.1 Services of Professional Societies

The engineering professional societies, organized to provide services needed by the developing engineering professions, have, in turn, influenced the actual development of engineering. Their primary service is to provide an efficient and cost-effective way for their members to communicate with other specialists in their fields. Through meetings and publications, the societies bring geographically dispersed engineers together intellectually, to learn from each other both the theory-based and the practice-based knowledge needed to advance the engineering state of the art. New research results as well as information about new instrumentation and techniques are rapidly disseminated to those working in the field or those interested in new applications. In addition, they provide the crucially important archival function of recording and preserving the evolving knowledge base in their discipline.

Second, they provide their members an opportunity to address issues of common concern, whether related to education of future engineering practitioners, to industrial practice, or to governmental policies. In a number of these arenas, professional societies provide the most effective means of developing, presenting, and implementing positions that reflect the judgment of the engineering community.

Third, they give their members recognizable credentials. By requiring those seeking society membership to meet specified professional criteria as determined by peers, the societies give their members professional recognition. By identifying the outstanding work of individual engineers, they encourage and reward above-average professional achievements. Through a system of membership grades and awards, individual accomplishments are publicized to peer groups and to external communities.

3.3.2 Founder Societies In the U.S.A., the first engineering professional societies were organized in the latter half of the nineteenth and early twentieth centuries. These first societies later became known as the Founder Societies.

The first, the American Society of Civil Engineers founded in 1852 (Wiseley, 1974), had the task of establishing the concept of civil as distinct from military engineering. Prior to the 1850s, the Military Academy at West Point was the major source of U.S. engineering graduates; there was little recognition of engineering as a civilian activity crucial to the construction of bridges, railroads, canals, and water supply and sewage disposal systems. Within the next few decades, the American Institute of Mining Engineers (1871), the American Society of Mechanical Engineers (1880), and the American Institute of Electrical Engineers (1884) were formed. As a result of the frequent explosions of poorly designed boilers during the late 1800s and the consequent danger to the public, the new mechanical engineering society was immediately involved with the development of safety standards for boilers, an activity that persists to the present day. Also during this period, there were major new technical developments in electrical power generation, lighting, and telegraphic and telephonic communications. The new electrical engineering society had a major influence in these fields by initiating the publication of technical papers on topics in which secrecy to protect commercial advantages had previously prevailed.

In the early 1900s, chemical engineering developed as a discipline distinct from both chemistry and mechanical engineering. The American Institute of Chemical Engineers (Reynolds, 1983) played a major role in defining the field and designing appropriate undergraduate curricula. Also at this time, the invention and use of wireless communications resulted in the formation of a new but rapidly growing society, the Institute of Radio Engineers.

These Founder Societies combined their efforts to build facilities in New York City to house their headquarters. A gift of more than $1 million in 1903 from Andrew Carnegie, an engineer who became a successful businessman, provided impetus. Appendix A includes detailed information about the organizational structure, budget, membership, publications and meetings, and other activities of the Founder Societies.

3.3.3 Organizational Characteristics As the various engineering disciplines matured, the societies developed internal structures with both geographical and technological components. The geographical units typically feature local and regional meetings and support student activities at local schools and universities; the technological units focus on national conferences and technical publications. Both entities provide useful membership services. The volunteer officers, elected by the members, typically reflect both of these structural components.

The membership requirements of the Founder Societies as well as the more recently formed engineering societies are usually similar. The typical requirement is a baccalaureate degree for the entering member grade, while senior grades are given to more experienced engineers. Student grades are used to encourage those preparing for engineering careers to develop university-based engineering activities and to facilitate their joining the appropriate society after graduation. The top membership grade is frequently restricted to a small percentage of the members elected in recognition of outstanding accomplishments.

3.3.4 Unique Character of the IEEE Many of the U.S. engineering societies have the term "American" in their title and consider themselves national organizations. Although they accept overseas members, they do not directly compete with their counterpart societies in other countries. A major exception is the Institute of Electrical and Electronics Engineers (IEEE), which was formed by the merger of the American Institute of Electrical Engineers and the Institute of Radio Engineers in 1962 (McMahon, 1984).

Although headquartered in the United Engineering Center in New York with the other Founder Societies, the IEEE organized and structured its geographical and technological activities on a global basis. It has attracted approximately 50 000 overseas members, one-sixth of its total membership of more than 300 000. Many meetings and conferences are held outside the U.S.A. These meetings and the Institute's publications are widely considered the most prestigious in their fields.

The IEEE has developed into a federation of more than 30 societies in the various specialties into which the electrical, electronics, and computer fields have evolved. The Institute's internal structure readily permits the organization of additional specialty groups as new technological fields emerge (Ryder and Fink, 1984). For example, the explosive growth of the computer field after World War II was accompanied by the rapid expansion of the newly organized Computer Society of the IEEE. It now has a membership of more than 70 000 and publishes 17 technical periodicals.

The IEEE Computer Society growth has been paralleled by the growth of another professional society in the computer field, the Association for Computing Machinery (ACM). In their early development, these societies were primarily focused on hardware and software, respectively. But as the computer technology advanced, this separation was no longer valid; both societies currently have publications in software engineering. The emergence of this latter field of engineering is being studied by joint committees of the two societies. With strongly overlapping memberships, the two societies have both flourished and have cooperated. Appendix B gives information about these societies' membership and activities and illustrates some of their complementarity.

3.3.5 Nontechnical Activities While the primary activity of the engineering professional societies has focused on the advance of the discipline, there has also been concern about engineering careers. For example, are enough students being attracted to the field? What are the salary ranges and fringe benefits available to practicing engineers? What are the legal obligations of engineers in public practice? The societies have responded by undertaking professional—in contrast to technical—activities; many standing committees and boards have been established to address such issues.

Currently, almost all major U.S. engineering societies have offices or representatives in Washington, DC, and devote both staff and volunteer time to relations with the federal government. On one hand, they serve as a valuable resource to federal agencies and to the Congress in supplying specialized technical information. On the other, they seek to avoid legislation or regulations that are considered to be inimical to the engineering profession. In this arena, the societies operate differently; most are still exploring how to respond to changes in the environment in which engineering is practiced.

3.4 Educationally Oriented Organizations

3.4.1 Studies of Engineering Education The engineering professional societies have had a strong interest in academic programs in engineering and have had considerable effect on their development. In addition to the educational activities of the disciplinary societies, another society, the American Society for Engineering Education (ASEE) devoted solely to engineering education, was founded in 1893. It has served as the sponsor for a number of major reports on engineering education that have influenced the philosophy and content of engineering education at the undergraduate and graduate levels. Its membership includes primarily engineering faculty members with strong interest in undergraduate and continuing education and teaching methods (Reynolds and Seely, 1993). In addition to engineering faculty members, it also includes engineering technology faculty members who teach in two- and four-year colleges offering degrees in engineering technology. Most ASEE members also belong to at least one disciplinary society.

There have been a number of major ASEE studies of engineering education spanning more than 70 years. Although none of them has had an effect as great as the Flexner report on medical education in the 1920s, they have served to highlight the problems that engineering educators have faced and to point to new directions. In the post–World War II era, one report written in 1952–1955 was notable for involving a large segment of the academic engineering community in gathering data and in stimulating discussions. The wartime experience at laboratories such as the MIT Radiation Laboratory had demonstrated that engineers educated before the War did not have the academic background needed to contribute to such new engineering developments as radar and microwave communications. The fact that the authors of the 25-volume series of books published by the MIT Radiation Laboratory in the late 1940s were primarily physicists and mathematicians had a profound effect on engineering educators. As a result, much of the handbook-based material in undergraduate curricula was replaced with more advanced courses in calculus, physics, and chemistry. The "Report on the Evaluation of Engineering Education" by an ASEE committee chaired by L. E. Grinter (American Society for Engineering Education, 1955) reflected this trend. It urged increased emphasis on what were labeled the engineering sciences and less emphasis on current engineering practice. Thus, postwar engineering curricula differed from the prewar in requiring engineering students to gain much greater depth of understanding in mathematics and the physical sciences.

Another major ASEE study resulted in the publication of a report entitled "The Goals of Engineering Education" (American Society for Engineering Education, 1968). By drawing an analogy between engineering and medical education, this report sought to replace the four-year undergraduate programs as preparation for an engineering career and require a master's degree as the first "professional" degree. Such proposals, although frequently discussed, have never gained the endorsement of either the academic community or industrial companies, the major employers of baccalaureate-degree engineers. Thus, engineering remains one of the few professions for which the baccalaureate is considered to be a professional degree. In some engineering specialties, such as sanitary engineering, the first professional degree is at the master's level. However, students undertaking such programs frequently complete a four-year civil engineering program first and so already have a professional degree.

A 1987 ASEE report, "A National Action Agenda for Engineering Education" (American Society for Engineering Education, 1987), chaired by Edward E. David, Jr., endorsed the four-year baccalaureate programs as the appropriate "launching platform" for an engineering career. The report also recommended a practice-oriented master's degree as a follow-on for students interested in technical specialties where greater academic depth is needed. This degree would complement the research-oriented Ph.D. degree. Much current thinking in engineering education is reflected in this report.

3.4.2 Accreditation of Academic Programs The disciplinary societies are also active in various aspects of engineering education. They frequently support programs concerned with the continuing education of their members as well as for students majoring in their respective specific disciplines. They exert significant influence on the content of undergraduate curricula through their participation in the accreditation process.

The Accreditation Board for Engineering and Technology (Accreditation Board for Engineering and Technology, 1993) is a creation of the engineering professional societies. ABET accredits programs in the various engineering disciplines in schools of engineering and of engineering technology. Both federal and state agencies recognize ABET as the accepted accrediting body for these fields. The ABET board of directors includes representatives of the professional societies that have curricular responsibilities, as well as some other engineering-related organizations. The professional societies develop the criteria used by accreditation teams that visit engineering schools and inspect their academic programs at three- or six-year intervals. Team members, selected from lists of engineers submitted by the disciplinary societies, typically include engineers employed by industry as well as by universities.

Essentially, the accreditation process sets a floor for the academic quality of the approved programs. While the accreditation process keeps pressure on all the more than 300 U.S. engineering schools and 120 engineering technology schools to keep their courses and laboratories up-to-date, many academicians feel that the accreditation process stultifies innovation. Currently, a number of innovative undergraduate programs are being developed as a result of the availability of curriculum development funding from the National Science Foundation. These programs are testing the ability of ABET to respond to nontraditional programs.

ABET has a powerful position with respect to the engineering schools because of its link to the legal process of registration. Registration, which is required for engineers in the public practice of engineering, is controlled in the U.S.A. by state governments. The state registration boards recognize graduation from an ABET-accredited school as completing a major requirement for registration. Since schools want their graduates to qualify for registration, they must retain ABET-accredited programs. Some schools offer both accredited and nonaccredited programs to allow some students greater flexibility in course selection. The National Council of Engineering Examiners, the organization of the state engineering examiners, is also represented on the ABET board of directors.

3.5 Industrially Oriented Organizations

In this category are two major types of engineering-related organizations: those that develop standards and the industrial trade associations. While these latter organizations typically engage in many nontechnical activities, some of their programs have significant engineering content.

3.5.1 Standards-Writing Organizations Much engineering practice depends directly on the use of standards, that is, concepts and procedures systematically developed and approved by experts in a technical specialty. Standards development is primarily an industry-based activity since industrial products and processes must usually meet standardized requirements set by customers, regulatory authorities, and other external bodies. The term *standards* is used to include methods of test, technical specifications, definitions and terminology, and recommended practices.

In the U.S.A., in contrast to most other industrialized countries, the writing of voluntary standards other than those related to national defense is largely a private-sector activity (Toth, 1991). Committees of engineers are convened from a variety of companies, testing laboratories, public agencies, and universities to draft voluntary standards. These documents are then subjected to wide review and comment before being accepted and put into general use. Since a consensus is sought among divergent interests, the time needed to develop a standard can vary from about six months to several years. Standards were first widely used in the specification of commercially important materials such as metals and plastics and hardware devices but have now also become an important means of specifying processes and procedures in many industrial sectors such as telecommunications and computers.

The U.S. government is involved in the standards-writing process through technical support provided by federal agencies such as the National Institute for Standards and Technology (NIST), formerly the National Bureau of Standards, and through the participation of federal engineers on standards-writing committees. Of great importance in both domestic and international commerce, standards can serve to facilitate or impede trade. Some privately developed voluntary standards adopted by public agencies attain the force of law. A prime example is building construction: Most mandatory building codes cite many voluntary standards that have been developed in the private sector.

The U.S. standards-writing community currently maintains some 94 000 standards. While about a third of these relate to the Department of Defense, more than a half were developed and maintained by the private sector. Among the leading standards-writing professional societies are the Society of Automotive Engineers, the American Society of Mechanical Engineers, and the Institute of Electrical and Electronics Engineers. Among the leading trade associations active in standards-writing are the Aerospace Industries

Association, the Association of American Railroads, and US Pharmacopeia.

There are also several other organizations whose primary function is standards development. Principal among these are the American Society for Testing and Materials, the National Fire Protection Association, and Underwriters Laboratories, which also provides certification services. The private-sector American National Standards Institute (ANSI) serves as a coordinator for domestic standards and represents the U.S.A. internationally in standards-writing activities.

3.5.1.1 International Standardization. Complementing the domestic U.S. activity are the international standards-writing organizations and national standards-writing societies in other countries. In most countries, standards-writing is considered both a private- and a public-sector activity, and public funding supplements private-sector resources. Such countries are better organized than the U.S.A. to participate systematically in international activities since they are not as totally dependent on private company personnel. However, when the industrial sector is well organized and U.S. companies are in a technological leadership position, the U.S.A. is very effective in international standards activities.

There are several hundred regional and international organizations conducting standards-related activities (Breitenberg, 1989); the U.S.A. participates in almost 200. Some organizations have primarily scientific concerns in fields such as physics, chemistry, and geology and devote their efforts to developing consistent terminology and agreed-on procedures for data handling. There are also engineering-related groups that cover the entire range of technical subjects with which U.S. domestic groups are concerned.

The major umbrella-type international organizations for engineering-related issues, the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC), establish standards that are increasingly accepted internationally. The absence of agreed-on international standards can be an effective nontariff barrier to trade. The U.S. member in these organizations is ANSI. The major federal agency concerned with standards, the Department of Commerce, has no direct role in representing U.S. interests in ISO or IEC. There is general agreement in both the private and public sectors that this arrangement is far from optimum.

3.5.2 Trade Associations The 1993 issue of the Encyclopedia of Associations lists more than 23 000 national associations in the U.S.A. Among these are trade associations that represent the interests of their industrial sectors in political and public relations as well as in technical arenas. These arenas are not always separable in issues such as environmental protection, where there are strong political forces as well as scientific and engineering factors involved.

Trade associations in some major industrial sectors such as chemical processing, semiconductors, gas technology, and electric power have undertaken research programs to solve problems generic to their technology. Most such efforts have been funded from private sources; but increasingly, public funding is being provided to support generic technology development. Since changes in antitrust legislation have encouraged industrial companies to carry on cooperative research programs, it is probable that even more industrial associations will undertake engineering projects in the future.

Trade associations are also active in many other industrialized countries. In the United Kingdom, for example, there are trade associations in nearly every industrial sector. Their activities include not only presenting the point of view of their industry to the government but also the dissemination of information about issues such as health and safety, environmental protection, and other topics of general concern. They also recommend "best practices" for use by their member companies. In other European countries, such associations are also active. Currently, these associations are developing links throughout the European Community to bring their influence to bear throughout the Community.

In Japan, trade associations are very important actors in both the technical and the public policy arenas (Bloom, 1990). Associations can be licensed by the Ministry of International Trade and Industry (MITI) and in some cases receive modest funding. They have the significant function of facilitating communication between public policy makers and the various industrial sectors and providing a forum where consensus positions are developed. On the technical side, they are sometimes organized on a temporary basis to carry out a specific research program. On a continuing basis, many associations provide services for their members including collecting and disseminating information from both domestic and international sources, development of standards, and educational programs.

3.6 Public Policy Oriented Organizations

3.6.1 National Academy of Engineering In varying degrees, all the engineering-related organizations discussed are concerned with public policy issues. Most of them operate at the federal level, although some have significant operations at the state and local levels. Their ability to affect legislative action or executive branch program decisions varies. Among the most influential is the National Academy of Engineering (NAE). The Academy was organized in 1964 under the congressional charter of the National Academy of Sciences, granted in 1863, which charges the Academy to respond to requests from federal entities for advice and recommendations. As part of the National Academy complex, the NAE participates in the governance and operation of the National Research Council, which produces about 300 reports a year in response to requests from executive and legislative federal agencies. These reports, which cover a wide variety of scientific and technological topics, involve some 10 000 scientists and engineers serving as volunteers. The NAE has initiated a number of its own studies on broad issues such as sustainable technology and national strategies in an era of global technologies. As an honorary society of approximately 1700 leading engineers from industry, academia, and government, the NAE has become increasingly effective in its relatively brief span of existence (Edson, 1989).

3.6.2 National Society of Professional Engineers The National Society of Professional Engineers (NSPE) is a society that restricts its membership to registered engineers (Robbins, 1984). It was established more than 50 years ago to consolidate the activities of a number of engineering associations operating at the state level. The state societies are primarily concerned with the registration process by which engineers are certified as competent to practice engineering publicly. These state societies frequently bring considerable influence to bear on engineering-related issues with which state governments are involved. These issues range from policies of state agencies concerned with engineering projects to budgetary allocations for engineering schools in state universities. NSPE's headquarters in Washington is primarily concerned with federal legislation and monitors federal programs that involve the interests of registered engineers. The society is active in promoting the recruitment of young engineers, in surveying salaries of practicing engineers, and in analyzing ethical and legal issues confronting engineers.

3.6.3 Umbrella Organizations To increase its effectiveness in influencing public policy, the engineering community has made several attempts since the 1920s to form a single organization that speaks for the entire engineering profession. The current umbrella society is the American Association of Engineering Societies (AAES), which includes in its membership the engineering professional societies and associations listed in Table 10. The combined membership of its constituent societies is some 700 000 U.S. engineers. The positions it develops on public policy issues must be compatible with those of the major member societies, which are generally unwilling to abdicate power on issues vital to their members. Since the member societies possess technical expertise in their disciplinary fields, they usually prefer to speak to such issues directly before congressional or executive branch committees.

However, there are issues on which most engineers can agree. Examples are more portable pension plans, improving engineering's public image, and forging better links with international engineering organizations. In such arenas, the AAES serves as the voice and surrogate for U.S. engineering societies. It is the U.S. member in international engineering organizations such as the World Federation of Engineering Organizations (WFEO/FMOI) and also in regional groups such as the Panamerican Federation of Engineering Societies (UPADI), a federation of engineering societies in Latin and North America. In general, these groups have not been as effective as the International Council

Table 10. List of member, associate, and regional societies in the AAES as of 1993–1994.

- Member Societies
  - American Academy of Environmental Engineers
  - American Indian Science and Engineering Society
  - American Institute of Chemical Engineers
  - American Institute of Mining, Metallurgical and Petroleum Engineers
  - American Institute of Plant Engineers
  - American Nuclear Society
  - American Society for Engineering Education
  - American Society of Agricultural Engineers
  - American Society of Civil Engineers
  - American Society of Mechanical Engineers
  - Institute of Electrical and Electronics Engineers
  - National Institute of Ceramic Engineers
  - National Society of Professional Engineers
  - Optical Society of America
  - Society of Fire Protection Engineers
  - Society of Women Engineers
- Associate Societies
  - American Council of Independent Laboratories
  - Association for International Practical Training
  - Federation of Materials Societies
  - National Action Council for Minorities in Engineering
  - National Association of Corrosion Engineers
  - Operations Research Society of America
  - Tau Beta Pi Association
- Regional Societies
  - Engineering Society of Detroit
  - Engineers' Society of Western Pennsylvania
  - Washington Society of Engineers
  - Western Society of Engineers

of Scientific Unions (ICSU) in launching programs that involve technical specialists and financial resources from many nations.

Within the U.S.A., the American Association for the Advancement of Science (AAAS) (see Sec. 2.2.1) has developed activities that affect both science and technology policy. While most engineers regard the AAAS as primarily a spokesman for the sciences, many engineers have been prominent in its activities. The major engineering professional societies are affiliates of the AAAS. They are active participants in the AAAS Congressional Fellows program, which has supplied the Congress with fellows drawn from the ranks of midcareer scientists and engineers to serve as members of congressional staffs. The AAAS annual analysis of the proposed federal research and development budget has involved several of the engineering societies. The editorial board of the AAAS's weekly publication *Science* usually includes engineers.

Although engineers constitute one of the largest professional groups in the U.S.A., they have not been a powerful influence on public policies. This lack of effectiveness may be traced to the reluctance of individual engineers to participate actively in politics. Engineers who work in industrial companies may also feel obligated to defer to their employer's views on public policy issues. Few engineering organizations have developed the skilled staffs or devoted the necessary resources to become forceful advocates of engineering interests in public policy arenas.

3.7 Challenges for Engineering Organizations

Engineering organizations are challenged to respond effectively to both rapid technological changes and worldwide changes in the industrial, political, and social environment. Engineers who are at the forefront of technological advances must be able to adapt to both types of change and still retain their operational effectiveness. Cutting-edge engineers need appropriate means to communicate with colleagues throughout the world. Those professional societies that provide such domestic and global communication services efficiently and cost-effectively will continue to grow. Others may well disappear.

Engineers will also require educational services beyond those currently available. Education is being increasingly recognized as a career-long activity for practicing engineers. The content of such educational programs should be determined cooperatively by active engineers in industry, government, and universities. The engineering organizations can contribute by providing educational materials and also the means for delivering them. While the problem of designing and delivering career-long educational programs is largely unsolved, the need is growing and engineering organizations have many assets to offer.

As the marketplace for engineering-intensive products and services becomes more global, engineering operations are being carried on in many cultural contexts. Many multinational corporations currently operate with relative ease in many different nations with little concern about national boundaries. Both individual engineers and the organizations they have created must learn how to operate effectively in this changing environment.

As new technologies affect more and more the way industry, government, and academia operate, engineers must not only add to their technical competence but must also be concerned with the nontechnical implications of what they create. The broader issues can no longer be considered someone else's responsibility. If engineering organizations help impart such broader perspectives, they will continue to serve as well as influence the future development of the profession.

APPENDIX A. ENGINEERING'S "FOUNDER SOCIETIES"

The first organized of the major engineering professional societies are known as the Founder Societies. These societies have played a crucial role in the development of the United Engineering Center in New York City, where many engineering societies maintain their headquarters. This Appendix presents data about each of these five societies: the number of members, their publications, and their stated objectives. The Founder Societies are listed in the order of their formation: American Society of Civil Engineers (ASCE) in 1852; American Institute of Mining, Metallurgical and Petroleum Engineers (AIME) in 1871; American Society of Mechanical Engineers (ASME) in 1880; Institute of Electrical and Electronics Engineers (IEEE) in 1884; and American Institute of Chemical Engineers (AIChE) in 1908. The AIME has undergone several organizational changes since its founding and is now a federation of four societies, with the Society for Mining, Metallurgy and Exploration (SME) as the continuing society.

The data about these societies have been excerpted from the *International Directory of Engineering Societies and Related Organizations 1993*, published by the American Association of Engineering Societies, and are used with permission.

- **American Society of Civil Engineers—ASCE**
  345 East 47th Street, New York, NY 10017,
  U.S.A.

MEMBERSHIP:

Individual	56 736
Student	14 177
Honorary	26 574

OBJECTIVE: The advancement of the science and profession of engineering to advance the welfare of mankind.

PUBLICATIONS: Publications catalog is available on request. The following is a sampling of periodicals published by the Society: *ASCE News*, monthly; *Civil Engineering*, monthly; *ASCE Publications Information*, bimonthly; journal *Hydraulic Engineering*, monthly; journal *Environmental Engineering*, bimonthly; journal *Structural Engineering*, monthly; journal *Engineering Mechanics*, monthly; journal *Irrigation and Drainage Engineering*, quarterly; journal *Geotechnical Engineering*, quarterly; journal *Surveying Engineering*, quarterly; *Transactions*, annual; journal *Aerospace Engineering*, quarterly; *Combined Index*, annual; *Cumulative Index*, quinquennial. Approximately 70 books are published annually, in addition to periodicals.

- **American Institute of Mining, Metallurgical and Petroleum Engineers, Inc.—AIME**
  345 East 47th Street, New York, NY 10017,
  U.S.A.

MEMBERSHIP:

Societies	4

AIME is a separate corporation controlled jointly and severally by its four Member Societies: Society of Mining Engineers, The Metallurgical Society, Iron and Steel Society, and Society of Petroleum Engineers. Individual nonvoting membership consists of AIME Honorary Members and Legion of Honor Fifty-Year Members.

OBJECTIVES: The advancement of knowledge of the arts and sciences involved in the production and use of useful minerals, metals, energy sources, and materials and to record and disseminate significant developments in these areas of technology for the benefit of mankind.

- **Society for Mining, Metallurgy and Exploration, Inc.—SME**

MEMBERSHIP:

Individual	18 702
Student	1 095

OBJECTIVES: To furnish a common ground to members of AIME interested in the fields of mining engineering, minerals exploration, geological engineering, rock mechanics, and minerals benefication; to promote the advancement of the profession through the exchange of information, the preparation and presentation of technical papers, their discussion and circulation; to advance education in the fields covered above and to promote high standards among the members of the profession.

PUBLICATIONS: *Mining Engineering*, monthly; *Minerals and Metallurgical Processing*; various proceedings and textbooks.

- **The American Society of Mechanical Engineers—ASME**

345 East 47th Street, New York, NY 10017,
U.S.A.

MEMBERSHIP:

Individual	96 100
Student	20 000
Honorary	100
Emeritus	1 800

OBJECTIVES: To promote the arts and sciences connected with engineering and mechanical construction for scientific purposes, and to that end to meet and associate together to read and discuss professional papers, and to circulate by means of publication among its members the information thus obtained, and for the purpose of maintaining a library. Also, in 1971, the following Goal was adopted: to move vigorously from what is now a Society with essentially technical concerns to a Society that, while serving the technical interests of its members ever better, is increasingly professional in its outlook, sensitive to the engineer's responsibility to the public interest, and dedicated to a leadership role in making technology a true servant of man.

PUBLICATIONS: *Mechanical Engineering*, monthly; *ASME News*, monthly; *Transactions Journals* (18), quarterly; *Applied Mechanics Reviews*, monthly; Technical Preprints, approximately 1200/yr; Symposia and Proceedings, approximately 165/yr; *Codes and Standards*, approximately 270/yr.

- **The Institute of Electrical and Electronics Engineers—IEEE**

345 East 47th Street, New York, NY 10017,
U.S.A.

MEMBERSHIP:

Individual	270 800
Student	49 500

OBJECTIVES: Its purposes are: (1) Scientific and educational, directed toward the advancement of the theory and practice of electrical engineering, electronics, radio, and the allied branches of engineering and the related arts and sciences. Means to these ends include, but are not limited to, the holding of meetings for the reading and discussion of professional papers and the publication and circulation of works of literature, science, and art pertaining thereto. (2) Professional, directed toward the advancement of the standing of the members of the professions it serves. Means to this end include, but are not limited to, the conduct and publication of surveys and reports on matters of professional concern to the members of such professions, collaboration with public bodies and with other societies for the benefit of the engineering profession as a whole, and the establishment of standards of qualification and ethical conduct. The IEEE shall not engage in collective bargaining on such matters as salaries, wages, benefits, and working conditions customarily dealt with by labor unions.

PUBLICATIONS: Sixty-seven periodicals, including *IEEE Proceedings, Spectrum, Transactions & Journals*, plus more than 50 000 pages annually in nonperiodicals (conference records, reports, standards, etc.).

MEMBER SOCIETIES: Aerospace and Electronic Systems Society (AES), Antennas and Propagation Society (AP), Broadcast Technology Society (BT), Circuits and Systems Society (CAS), Communications Society (COM), Components Hybrids and Manufacturing Technology Society (CHMT), Computer Society (C), Consumer Electronics Society (CE), Control Systems Society (CS), Dielectrics and Electrical Insulation Society (DEI), Education Society (Ed), Electromagnetic Compatibility Society (EMC), Electron Devices Society (ED), Engineering Management Society (EM), Engineering in Medicine and Biology (EMB), Geoscience and Remote Sensing (GRS), Industrial Electronics Society (EI), Industry Applications Society (IA), Information Theory (IT), Instrumentation and Measurement Society (IM), Lasers and Electro-Optics Society (LEO), Magnetics Society (Mag), Microwave Theory and Techniques Society (MTT), Nuclear and Plasma Sciences Society (NPS), Oceanic Engineering Society (OE), Power Electronics Society (PEL), Power Engineering Society (PE), Professional Communication Society (PC), Reliability Society (R), Robotics and Automation Society (RA), Signal Processing Society (SP), Social Implications of Technology Society (SIT), Systems Man and Cybernetics Society (SMC), Ultrasonics Ferroelectrics and Frequency Control Society (UFFC), Vehicular Technology Society (VT), Neural Networks Council (NN), and Solid-State Circuits Council (SSC).

- **American Institute of Chemical Engineers—AIChE**

345 East 47th Street, New York, NY 10017, U.S.A.

MEMBERSHIP:

Individual	40 800
Student	6 500
Honorary	800
Emeritus	3 900

OBJECTIVES: The objectives of the Institute are the advancement of chemical engineering in theory and in practice, the maintenance of a high professional standard among its members, and to serve society, particularly where chemical engineering can contribute to the public interest.

PUBLICATIONS: *Chemical Engineering Progress*, monthly; *AIChExtra*, monthly; *Chapter One*, 3/yr; *AIChE Journal*, bimonthly; *International Chemical Engineering*, quarterly; *Energy Progress*, quarterly; *Environmental Progress*, quarterly; *Plant/Operations Progress*, quarterly; *Biotechnology Progress*, bimonthly; *Symposium Series*, bimonthly; *The Directory of Chemical Engineering Consultants*, annual; *Chemical Engineering Faculties*, annual. Also, process safety procedures, education series, symposium proceedings.

APPENDIX B. COMPARISON OF TWO LEADING U.S. COMPUTER SOCIETIES (FROM *INTERNATIONAL DIRECTORY OF ENGINEERING SOCIETIES, 1993*).

- **Association for Computing Machinery Inc.—ACM**

1515 Broadway, 17th Floor, New York, NY 10036, U.S.A.

MEMBERSHIP:

Individual	65 000
Student	16 000
Corporate	800

OBJECTIVES: To advance the sciences and arts of information processing including, but not restricted to, the study, design, development, construction, and application of modern machinery, computing techniques and appropriate languages for general information processing, for scientific computation, for the recognition, storage retrieval, and processing of data of all kinds, and for the automatic control and simulation of processes; to promote the free interchange of information about the sciences and arts of information processing both among specialists and among the public in the best scientific and professional tradition; to develop and maintain the integrity and competence of individuals engaged in the practices of the sciences and arts of information processing.

PUBLICATIONS: *Communications of the ACM (CACM)*, monthly; *Computing Reviews*, monthly; *Journal of the ACM (JACM)*, quarterly; *Computing Surveys*, quarterly; *CALGO*, quarterly; *Transactions on Database Systems*, quarterly; *Transactions on Mathematical Software*, quarterly; *Transactions on Programming Language and Systems (TOPLAS)*, quarterly; *Transactions on Office Information Systems (TOOIS)*, quarterly; *Transactions on Computer Systems (TOCS)*, quarterly; *Transactions on Graphics (TOG)*, quarterly; *Transactions on Software Engineering and Methodology (TOSEM)*, quarterly; *ACM Guide to Computing Literature*, annual.

- **Computer Society of the IEEE**

IEEE Computer Society, 1730 Massachusetts Avenue, Washington, DC 20036, U.S.A.

MEMBERSHIP:

Individual	69 756
Student	9 995

OBJECTIVES: To advance the theory, practice, and application of computer and information-processing science and technology and to maintain a high professional standing among its members. The society shall promote cooperation and exchange of technical information among its members and to this end shall hold meetings for the presentation and discussion of technical papers, shall publish technical journals, and shall through its organization and other appropriate means provide for the needs of its members. The scope of the Society shall encompass all aspects of theory, design, practice, and application relating to computer and information-processing science and technology.

PUBLICATIONS: *Annals of the History of Computing*, quarterly; *Computer Magazine*, monthly; *Transactions on Knowledge and Data Engineering*, bimonthly; *Transactions on Parallel and Distributed Systems*, bimonthly; *Transactions on Pattern Analysis and Machine Intelligence*, monthly; *Transactions on Software Engineering*, monthly; *Computer Graphics and Applications Magazine*, bimonthly; *Design and Test of Computers Magazine*, quarterly; *Expert Magazine*, bimonthly; *Micro Magazine*, bimonthly; *Software Magazine*, bimonthly; *Transactions on Computers*, monthly.

Further Reading

There is not a well-defined body of literature on the various types of engineering organizations discussed in this article. A description of the historical context in which the engineering societies emerged is given by Haber, Samuel (1991), *The Quest for Authority and Honor in the American Professions, 1750–1900*, Chicago: Univ. of Chicago Press. He devotes a chapter to "The Engineers: A Profession in a Business Bureaucracy."

One of the series of reports issued by the Carnegie Commission on Science, Technology, and Government (1993), *Facing Toward Governments, Nongovernmental Organizations and Scientific and Technical Advice*, Washington, DC: Carnegie Commission, views the activities of the many types of nongovernmental organizations (NGOs) as policy advisers to government. The engineering organizations discussed in this article fit under the broad NGO rubric.

Most of the engineering professional societies, typically on a special anniversary of their founding, have commissioned the writing of a history of the organization. Many of these are long on organizational aspects and short on technical development of their field.

There are a large number of directories that provide detailed information about organizations. Some contain lists of engineering-related organizations. There are two such directories that give detailed information about the engineering-related organizations discussed in this article. One is the *International Directory of Engineering Societies and Related Organizations 1993*, 14th ed., Washington, DC: American Association of Engineering Societies. This edition includes updated data about 950 organizations in 70 countries. The second is a more general directory of some 7000 entries including trade associations and labor unions as well as professional and scientific societies: *National Trade and Professional Associations of the United States*, Washington, DC: Columbia Books, published annually. By scanning such directories, a reader can gain a feeling for the number, diversity, and scope of currently existing organizations related to engineering.

PHYSICS AND TECHNOLOGY OF ION AND ELECTRON SOURCES

INTRODUCTION

Electron (ion) sources are most commonly used to obtain electron (ion) beams of limited transverse size, which are often necessary for focusing into very narrow beams ($\approx 10^{-6}$ m wide, and in the near future 10^{-10} m wide), but wide electron or ion beams (1 to 3 m wide) are also often used. Transport of beams as far as 10^2 m is rather common. In circular accelerators and storage rings, they cover distances of about 10^{10} to 10^{12} m, but the most widely used beams are those no more than 0.5 m long, as used for electronic displays, indicators, microwave generators, and electronics. Before the discovery of the electron, gas-discharge tubes with low gas density and high-voltage discharge were used as the first sources of electrons (cathode rays), as demonstrated by E. Goldstein in 1876. Electrons were emitted by a cold flat (or concave) cathode as it was bombarded with gas-discharge plasma ions (ion–electron emission); then the electrons were accelerated by cathode surface fields and moved along the tube to strike the opposite end, causing luminescence of the glass. Through an aperture in the opposite end, the electron beam was let out of the gas-discharge tube into another vacuum reservoir for further use. In 1883, T. A. Edison observed the flow of electric current in a vacuum between a closely placed negative electrode (cathode) and anode. Since that time, the solid sources of thermal-electron emission have been extensively improved, and they have become widespread. However, as late as 1927, in studying electron diffraction, G. P. Thomson used a gas-discharge electron source because narrow beams were necessary for that purpose, while C. Davisson used a burning hot tungsten emitter in his work. Both were awarded the Nobel prize in 1937. Gas-discharge electron sources were used for high-voltage installations such as x-ray generators. In recent years, new kinds of plasma sources have been developed for accelerators, especially for pulsed high-current accelerators. Thermionic cathodes became mass produced as components of electron tubes and, later, in a great number of other products of emission electronics. After tubes were replaced by semiconductor devices, the electron-beam devices with thermionic cathodes became most widespread.

Electron and ion fluxes are important components of a wide and growing variety of applications in many areas of fundamental scientific research, in sophisticated control systems, in large-scale industrial manufacturing, and in everyday life. Indeed, much of modern high technology is closely related to sophisticated techniques that enable us to manipulate atoms and their components—electrons and ions. The sources of electrons

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

and ions are the real sources of technology power. The starting point for the development of this basis of modern technology was J. J. Thomson's discovery of the electron in 1897, which initiated regular work with electrons, ions, and atoms. The first Nobel prize winner was K. Röntgen, who discovered x rays generated by electrons in a high-voltage discharge (together with ion generation). Most of the early scientific works that led to Nobel prizes included the generation of electrons and ions as an important component. In modern experiments, the efficiency of the generation of polarized Z bosons (elementary particles 97 times as massive as protons) in the Stanford electron–positron Linear Collider beams is determined by the operation efficiency of a small photoemitting source of polarized electrons and of multimegawatt electron tubes—klystrons.

Practical application of electron sources and their development was initiated by the manufacture of x-ray tubes and electron tubes for radio communication. The physics and technology of emission electronics was developed for this application. Electron accelerators, a variety of microscopes, television tubes, displays, oscilloscopes, radio-frequency and microwave generators, gas-discharge tubes and lasers, focused electron beams, and electron-projection microlithography are the basis of modern microtechnology; these represent only a small part of the modern applications of electron sources. The development of field-emission sources producing electron and ion beams of high brightness has made it possible to carry out control and treatment on nanometer scales. The discovery of precisely controlled tunneling emitters has initiated the development of the technique that enables controlled manipulations with single atoms. Electron beams with high brightness and superhigh-frequency modulation have been obtained with the help of efficient photocathodes irradiated by lasers.

The development of ion-beam production was stimulated by the needs of mass spectrometry and accelerators for nuclear physics. The first essential application—electromagnetic separation of isotopes—stimulated the development of the physics and technology of highly intense ion sources. These developments and further improvements provided the ion sources that are widely used for ion implantation in the semiconductor industry. Many variants of ion sources have been optimized for different applications. Progress in plasma physics helped to transform the development of ion sources from a fine art to an applied science; however, in obtaining optimal parameters, the art of an experimenter still plays an important role. Ion sources with up to 100-A beam intensity have been developed for controlled nuclear fusion. New ways of using a negative ion instead of a positive one were revealed by the discovery of significant enhancement of negative-ion generation in gas discharges due to the addition of small admixtures of catalysts, such as cesium or other substances with low ionization potential. The stable generation of ion fluxes with an emission current density of 10^8 A/cm^2 was achieved because of the development of electrohydrodynamic emitters (made of liquid metals and dielectrics). The great increase in source brightness has initiated new applications of beams, such as colliding-beam experiments, long-distance transportation of energy, focused-beam and ion-beam projection lithography, and implantography with nanometer resolution.

The development and use of new materials, such as high-temperature alloys, ceramics and composite materials, strong permanent magnets, new microwave generators, power supplies, and control systems have been very important in the improvement of the source characteristics.

Particle sources, as far as size and cost are concerned, are only a small part of the device in which they are used; but some of the most important characteristics of the devices are often determined by the properties of the sources, and the improvement of these characteristics is an essential physical and technological problem. Recently, electron and stochastic cooling have been developed to increase beam brightness, but obtaining high-quality beams right from the sources appears to be a very attractive method.

1. PHYSICS OF ELECTRON EMISSION

Negative electrons and a positive nucleus are bound in neutral atoms by electromagnetic forces. An electron with charge $e = 1.6 \times 10^{-19}$ C in a potential difference $U = 1$ V attains the energy $eU = 1$ eV $= 1.6 \times 10^{-19}$

J. At the atomic-scale distance from the proton $r \sim 10^{-10}$ m, the electric field is $E = -e/4\pi\epsilon_0 r^2 \sim -10^{10}$ V/m, and the binding energy of the electron (ionization potential I) has a value of several electron volts (from $I = 3.89$ eV for cesium to $I = 24$ eV for helium). Such energy must be transmitted to the electron to make it leave the atom.

Bound electrons in atoms and molecules can occupy allowed discrete levels of energy, while free particles can have a continuous spectrum of positive energies. An electron in a hydrogen atom can occupy states with energies $E = -2\pi me/h^2n^2 = -I/n^2$, where $m = 0.9 \times 10^{-30}$ kg is the mass of the electron, $h = 6.6 \times 10^{-34}$ J is the Planck constant, $I = 13.6$ eV, $n = 1$ is the ground state, $n = 2, 3, \ldots$ are the excited states. In such complex systems as molecules, allowed electron states transform into bands of levels with less energy difference, and the bands of allowed energies in a solid (as in a very big molecule) have a pseudocontinuous distribution of electron states. The potentials and electron states in different systems are shown schematically in Fig. 1.

When electrons are drawn apart from atoms or molecules, there appear free electrons and atomic (A^+, A^{++}, . . .) or molecular (M^+, M^{++}, . . .) ions with different charges. More complex cluster ions, consisting of many weakly bonded atoms and molecules, can be formed. Electrons can be attached to any atom, molecule, or cluster, with negative ions A^-, A^{--}, . . ., M^-, M^{--}, . . . being formed if the system has any electron affinity, S (binding energy).

Usually systems have allowed states with very low ionization energy, but the probability of being in these states is low. The energy quantum that is necessary for liberation of electrons is several electron volts. This energy can be transmitted to an electron in a system in collision with other particles such as an electron, an ion, or a neutral particle, or by a photon of light, or by heating complex systems.

The emissive properties of a solid are determined by an electron's behavior, and simple models (as in the Sommerfeld approximation) can be used for better understanding (Blakemore, 1985). The interaction of particles in a solid creates a boxlike potential well of average depth $-W_0$ for electrons. The form of the potential barrier at the solid–vacuum boundary, which is important for emissive properties, can be approximated by the "image force potential" $U(x) = -e^2/16\pi\epsilon_0 z$. It is shown in Fig. 1(c).

In the periodic potential of a crystalline lattice, the wave functions and movement of electrons are much like those of free electrons (Bloch theorem). The interaction with the lattice changes the effective mass m^* of electrons and divides the phase space of motion into bands of allowed energies and forbidden gaps (Brillouin zones of the Fermi surface). The phase-space distribution of electrons is determined by Fermi–Dirac statistics. The density of states in the allowed energy band is proportional to the phase volume $d(p^3/h^3)$, and for free particles it is proportional to the square root of the distance W from a minimum or maximum energy of

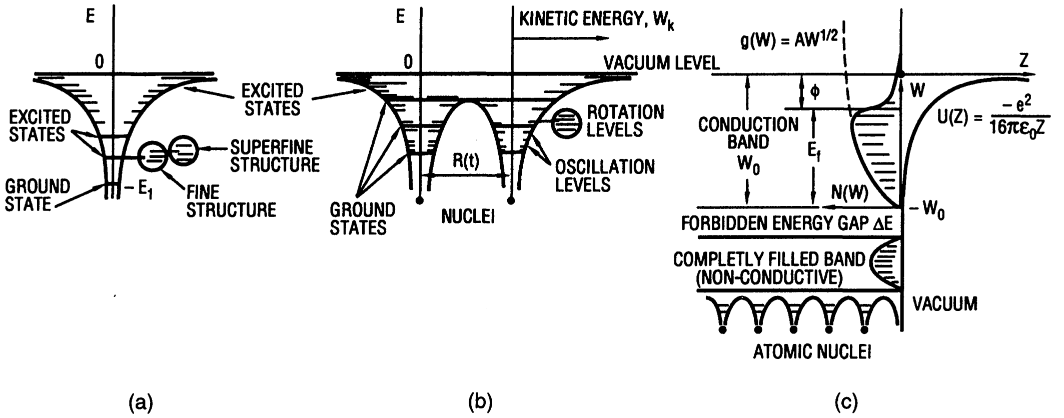

FIG. 1. The potentials and electron states in different systems.

the allowed band:

$$g(W) = A'W^{1/2}. \tag{1}$$

The probability of these states being occupied at temperature T is

$$f(W,T) = \{\exp[(W - E_F)/kT] + 1\}^{-1}, \tag{2}$$

where E_F is the Fermi energy (the thermodynamic electrochemical potential) determined by the electron density and equal to several electron volts for metals, k is the Boltzmann constant, $f(W,0) = 1$ when $W \leq E_F$, and $f(W,0) = 0$ when $W > E_F$. It means that no more than one electron can be in any of the allowed states. In a completely filled band, electrons cannot change the states of motion and cannot create conductivity. Only excitation to the allowed states of the next upper band can create electricity carriers, but it requires a high energy ΔE (the forbidden gap). If the highest energy band is empty and ΔE is high, we have an insulator (thermal excitation cannot create conductivity). If ΔE is low, we have a semiconductor, and rapid exponential increase of conductivity as temperature rises. If the highest energy band is not completely filled with electrons, as in Fig. 1(c), we have a metal.

The Fermi energy E_F is less than the potential-box depth W_0. The difference $\phi = W_0 - E_F$ is the work function (the evaporation energy), which is the analog of the ionization potential for atoms. This energy must be transmitted to the electron for its liberation from the Fermi level, where the electron density in phase space is high. For $T > 0$ the electron distribution is

$$\begin{aligned} N(W,T) &= g(W)f(W,T) \\ &= A'W^{1/2}/\{\exp[(W - E_F)/kT] + 1\}, \end{aligned} \tag{3}$$

and some electrons can occupy the levels with kinetic energy $W > E_F + \phi = W_0$, as is shown in Fig. 1(c). These electrons are able to escape from the solid (to evaporate) if their velocity v_z (normal to the surface) is high enough (normal kinetic energy $mv_z^2/2 > W_0$). The emission current density j_e is defined by the density of electron flux j_w (flux per unit area of solid–vacuum boundary) and the probability of penetrating the barrier, $D = 1 - R$, where R is the reflection coefficient:

$$j_w = e\int_0^\infty N(W,T)v_z dv_z; \tag{4}$$

$$j_e = e\int_0^\infty D(W)N(W,T)v_z dv_z. \tag{5}$$

For thermionic emission of electrons when the electric field applied to the surface of the emitter is weak but intense enough to extract emitted electrons onto the anode collector, $D = 0$ when $S < W_0$, and $D(W) > 0$ when $W > W_0$. In cylindrical coordinates $v_\perp$, v_z,

$$\begin{aligned} j_e &= eA' \int_{v_z>(2W_0/m)^{1/2}} \\ &\times \frac{D(v_z)\, 2\pi v_\perp dv_\perp v_z dv_z}{\exp[mv_\perp^2/2kT]\exp[(mv_z^2/2 - E_F)/kT] + 1} \\ &= BT^2 \int_{\phi/kT}^\infty dz \int_0^\infty \frac{dy}{e^y e^z + 1} \\ &= BT^2 \int_{\phi/kT}^\infty \ln(1 + e^{-z})\, dz \\ &\approx A'D_{ef}T^2 e^{-\phi/kT}. \end{aligned} \tag{6}$$

Equation (6), the Richardson equation, provides a proper description of thermionic emission of electrons. The constant $A' \sim 10^2$ A/cm² K² for metals. For pure surfaces with a smooth potential barrier, the effective transmission coefficient $D_{ef} \sim 1$; however, it falls to $D_{ef} \ll 1$ because of the absorption of impurity films on the surface of the emitter, which creates surface barriers with potential fluctuations. The work function ϕ is the most essential characteristic of an electron emitter. Higher emission current density is obtainable at lower temperature by the lowering of ϕ. Refractory metals such as tungsten or tantalum have ϕ from 4.5 to 4 eV, while the work function of some specially effective emitters may approach 1 eV. For the latter, $e^{-\phi/kT} \approx 0.01$–$0.1$ at $T \approx 10^3$ °C and the emission current density reaches values of 1–10 A/cm². For real emitters, the values of ϕ and D_{ef} vary greatly from one point to another, and therefore Eq. (6) should involve spatially averaged values.

The space charge of the emitted electrons induces an electric field that limits the emission current (Forrester, 1988). The density of the space-charge–limited current in a vacuum diode is given by the Child–Langmuir law:

$$j_{\mathrm{CL}} = (4\epsilon_0/9)(2e/m)^{1/2}U^{3/2}/d^2, \tag{7}$$

where d is the cathode–anode separation and U is the voltage difference between the flat cathode and the anode. The change of the current in the diode is dictated by this law if the emission current density in Eq. (6) exceeds j_{CL} of Eq. (7).

An increase of U causes the extraction of electrons onto the anode, and the limitation of emission by space charge is eliminated. This leads to saturation of the emission and the creation of fields on the surface of the cathode, intensifying the emission of electrons (Blakemore, 1985; Forrester, 1988).

If a strong electric field E is set up, the emission of electrons is intensified, and the surface-potential profile changes as is shown in Fig. 2. The superposition of the image potential $U(z) = -e^2/16\pi\epsilon_0 z$ and the uniform field potential $U_1(z) = -eEz$ has its maximum at $z = z_0 = (e/16\pi\epsilon_0 E)^{1/2}$. The surface-barrier height is lowered by an amount

$$\begin{aligned}\Delta\phi &= (e^3E/4\pi\epsilon_0)^{1/2} \\ &= (3.8 \times 10^{-5}\ \mathrm{eV\ m^{1/2}\ V^{-1/2}})E^{1/2}.\end{aligned} \tag{8}$$

This reduction of the work function results in an increase in emission that is referred to as the Schottky effect. The value of the emission current is defined by Eq. (6) when ϕ is replaced by $\phi - \Delta\phi$. This effect is more essential for low–work-function cathodes, functioning at low temperatures, and pointed cathodes with a very strong field.

As the electric field increases further (up to $E \approx 10^9$ V/m), another kind of emission, field emission (autoelectronic, tunnel, cold emission), rapidly increases (Blakemore, 1985). R. Wood was the first to observe field emission of electrons, in 1897. In 1992 Lilienfeld used the emission in a strong field inside an x-ray tube. Milliken and Lauritsen obtained the voltage–current characteristics of field emission for a wide range of parameters and confirmed the weak dependence of emission on temperature ($\ln j = A' - B/E$). In 1929, P. Fowler and L. Nordheim gave the theoretical explanation of field emission, which was based on the tunneling effect.

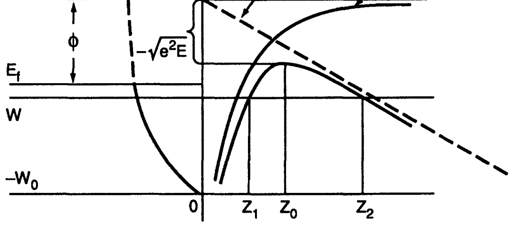

FIG. 2. The surface-potential profile including an external electric field **E**.

When field emission takes place, electrons penetrate the potential barrier at the boundary of the emitter by tunneling through it rather than passing over it as in the case of thermionic emission or photoemission. A strong electric field at the surface (Fig. 2) creates a potential well for electrons, into which they can penetrate from the occupied (filled) band in the emitter. It also makes the potential barrier lower and narrower and the probability of tunneling sufficiently higher.

To calculate the current density in the general equation [Eq. (5)], it is necessary to use the quantum-mechanical value of the transmission coefficient $D(W)$ at the potential of $U(z)$ when the energy level of the particle intersects the barrier line at the points z_1 and z_2 (Fig. 2):

$$\begin{aligned}D(W) &= \exp\left\{-\int_{z1}^{z2} [(8m/h^2)(U(z) - W)]^{1/2}dz\right\} \\ &= \exp\left\{-\int_{z1}^{z2} [(8m/h^2)(-eEz + |W| \right. \\ &\qquad \left. - e^2/16\pi\epsilon_0 z)]^{1/2}dz\right\},\end{aligned} \tag{9}$$

where

$$z_1 = |W|/2eE[1 - (1 - e^3E/W^2)^{1/2}],$$

$$z_2 = |W|/2eE[1 + (1 - e^3E/W^2)^{1/2}].$$

Integration similar to that performed in Eq. (6) gives the Fowler–Nordheim formula for metals:

$$j_{fc} = C_1E^2 \exp(-C_2/E), \tag{10}$$

where $C_1 = e^3/8\pi h t^2(y)\phi$, $C_2 = 8\pi(2m)^{1/2} \times \phi^{3/2}\vartheta(y)/3he$; t and ϑ are tabulated functions of $y = e^{3/2}\epsilon^{1/2}/\phi$; $t(y) \approx 1$, and $\vartheta(y) \approx 1 - y^2$. A good approximation to the exact formula is provided by the expression

$$j_{fe} \approx (1.4 \times 10^{-6}E^2/\phi) \times 10^a,$$

where

$$a = 4.4\phi^{-1/2} - 2.8 \times 10^7\phi^{3/2}/E, \tag{11}$$

where j is in units of A/cm^2, E in V/cm, and ϕ in eV. The Fowler–Nordheim formula agrees well with experiment at densities up to 10^{10} A/cm^2, as is illustrated in Fig. 3. Field emission produces a narrow energetic spectrum of electrons. The half-width ΔW of the energy distribution at $T = 0$ K is determined by the equation

$$\Delta W = 6.7 \times 10^{-9}E/\phi^{1/2}t(y). \tag{12}$$

When $\phi = 4.4$ eV, $j = 1 \times 10^7$ A/cm^2, and ΔW varies from 0.08 to 0.2 eV, while at $T = 300$ K, $\Delta W = 0.17$–0.3 eV. The adsorption of impurity films complicates the emission and distorts the energy spectra.

At low temperatures, field emission causes the emitter to heat because the energy of the electrons emitted from the occupied part of the band is $<E_F$, and the energy of the incoming conduction electrons is $>E_F$ (Nottinheim effect). At higher temperatures, the emission of hard electrons increases, and cooling of the emitter prevails.

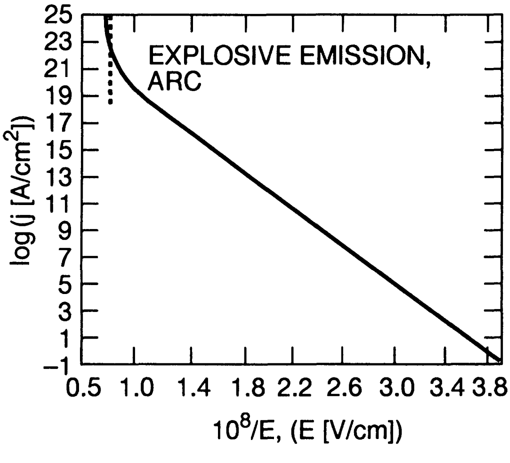

FIG. 3. Graph showing agreement of the Fowler–Nordheim formula with experiment at densities up to 10^{10} A/cm^2.

Field emission from semiconductors possesses some characteristic features (Blakemore, 1985):

1. An electric field penetrates deep into a semiconductor, which results in the displacement of the energetic bands and in the concentration of charge carriers and their spectrum.
2. When the density of electrons is much lower, j_{fe} becomes limited and greatly sensitive to the influences of light, temperature, etc.
3. Field emission depends on surface states.
4. Voltage–current characteristics and energy spectra are determined by the band structure of semiconductors.
5. The current in the emitter substantially redistributes the potential and changes the spectra of the electrons.

All the previously mentioned facts require many effects to be taken into account, which complicates the calculations and makes the interpretation of the results more difficult, but at the same time the said phenomena provide the basis for many important applications.

A gradual increase in the tunneling current up to the level of 10^{10} A/cm^2, together with a voltage increase, usually gives rise to the impulse of explosive emission (Bystritskiy and Didenko, 1989). The consequent development of vacuum breakdown and arc discharge leads to the destruction of the emitter.

Photoelectric emission is caused by the transmission of energy from photons to electrons. For the photoemission of an electron to occur, it must receive energy from a photon $h\omega > \phi = h\omega_0$ (Fig. 1), where ω_0 is the threshold frequency of light and $\lambda = 2\pi c/\omega_0$ is the threshold wavelength. Some electrons possessing this energy, which is greater than that of electrons above the barrier in vacuum, will move toward the surface of the emitter and may be emitted into the vacuum (or another medium). While moving toward the surface, the high-energy electron transmits energy to the conduction electrons and loses energy with high probability before reaching the surface of the emitter. The basic characteristic of photoelectric emission is the quantum yield Y, representing the number of emitted electrons per photon falling onto the photoemitter surface. The value of

Y depends on the surface state of the emitter, the energy, the angle of incidence, and the polarization of the photon.

For pure surfaces of most metals, $\phi > 3$ eV, and so photoemission from metals is observed when $\lambda < 0.4$ μm. Photoemission from alkali metals and barium can be caused by visible light, and from other metals only by ultraviolet radiation. For most metals, $Y \approx 10^{-4}$ electron per photon near the threshold. This light penetrates into the metal 10^{-7} cm and is absorbed there, but high-energy electrons are not able to escape from this depth because of the intense interaction with the conduction electrons. The electrons that have received sufficient energy from the photons at the depth of 10^{-9} cm from the surface are emitted with high probability. However, the probability of getting sufficient energy is low. The more tangent the light falling on the surface, the higher the probability of reflection of the photons. As the energy of the photons becomes higher, Y increases ($Y_{\mathrm{Bi}} = 4 \times 10^{-2}$, $Y_{\mathrm{Al}} = 1.5 \times 10^{-2}$ when $h\omega = 12$ eV). When $h\omega > 15$ eV, the absorption of photons rapidly increases (the reflection coefficient R falls to 5%) and Y rises to 0.1–0.2. On adsorption of admixtures, ϕ becomes less, and Y becomes greater because of the photoemission threshold being displaced into the visible region of the spectrum. Submonolayer films of alkali and alkaline-earth (electropositive) elements improve the effect of photoemission best of all.

In semiconductors and dielectrics, photoemission is provided by the excitation of electrons so that they get to the upper region of the conduction band (to the part of the band above the barrier) from the occupied valence band or from impurity levels [the donor band at the bottom of the conduction band or the acceptor band at the top of the valence band (Blakemore, 1985)]. In this case, the threshold energy $h\omega = \Delta E + \chi$ includes the width of the forbidden band ΔE, the electron affinity χ, and the height of the potential barrier above the bottom of the conduction band (the analog of the work function ϕ). In emitters with low density of electrons in the conduction band and with $\chi > \Delta E$, the electrons spend their energy on collision ionization of the valence-band levels to form free electrons in the conduction band and vacancies in the valence band. As a result of this process, the depth from which electrons can escape is lowered to 10^{-9} m, while photons can excite electrons at distances of no more than 10^{-6} m from the surface. Only a small number of excited electrons escapes into the vacuum ($Y \approx 10^{-6}$–10^{-4}). In substances with $\chi < \Delta E$, the energy of the photoelectrons is transmitted to the lattice oscillations (phonons) in small portions (10^{-2} eV); the probability Y for the electrons to escape into the vacuum increases and when $\chi > 1$ eV ($Y \approx 10^{-2}$) remains low.

The special treatment of p-type semiconductors using the adsorption of cesium and oxygen layers in an alloy is used in the manufacture of emitters with a negative electron affinity, from which most electrons excited by photons into the conduction band are emitted into the vacuum. In this process Y goes from 0.1 to 0.5 right above the threshold for photoemission. Initiation of photoemission by circularly polarized light enables one to obtain bunches of polarized electrons.

The emission of electrons into a vacuum is also initiated by other mechanisms of transmission of energy in a solid—for example, by electron or ion bombardment or by bombardment with excited (metastable) and accelerated atoms and molecules. We can observe a higher yield of electrons due to a greater concentration of energy release at the surface of the emitter.

2. TECHNOLOGY OF EFFICIENT ELECTRON SOURCES

Electron sources are most commonly used to obtain electron beams of limited transverse size. Gas-discharge electron sources were used for high-voltage installations such as x-ray generators. In recent years, new kinds of plasma sources have been developed for accelerators, especially for pulsed high-current accelerators. Thermionic cathodes became mass produced as the components of electron tubes and, later, in a great number of other products of emission electronics. After tubes were replaced by semiconductor devices, the electron-beam devices with thermionic cathodes became most widespread.

The simplest electron source is a tungsten filament heated to a high temperature T by

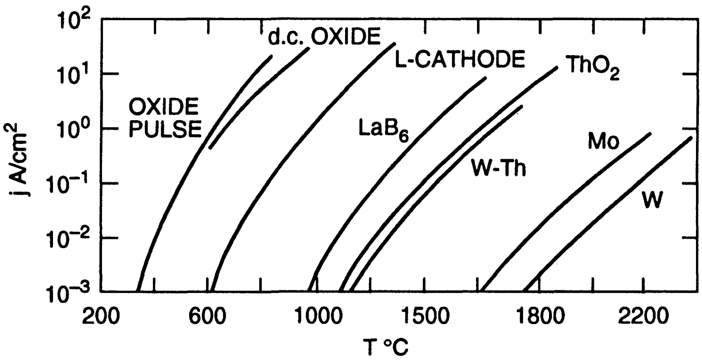

FIG. 4. The comparative characteristics of various thermoelectric emitters.

applying a certain voltage to it. At $T \approx 2600$ K, specific emission may reach $j \approx 0.5$ A/cm^2, the lifetime being as long as 10^4 h under good vacuum conditions (Kuznetsov, 1994; Forrester, 1988). Tantalum possesses similar characteristics at $T \approx 2400$ K. Other pure metals evaporate too quickly at the temperatures that provide proper emission of electrons. Admixtures, especially of rhenium, improve mechanical properties of tungsten and its longevity, and they prevent it from brittle destruction resulting from recrystallization. Directly heated tungsten cathodes in the form of studs are still being widely used for sources of bright electron beams in electron microscopes, and in the form of loops or various spirals in gas-discharge devices and ion sources, among others. Pure tungsten has a work function of $\phi = 4.5$ eV, causing a rather low efficiency of emission. Nevertheless, pure tungsten withstands ion bombardment and poisoning with residual gases and admixtures; it is easy to manufacture and can be used with demountable devices. The comparative characteristics of various thermoelectron emitters are given in Fig. 4.

Optimal lowering of the work function and a substantial increase in thermionic emission are achieved by covering the surfaces of emitters with thin films of electropositive elements (with lower ionization potentials) (Kuznetsov, 1994; Forrester, 1988). The typical dependence of the work function on the atomic density of cesium film on tungsten is shown in Fig. 5. The work function reaches its minimum when the atomic density is less than one monolayer. The film can sustain the emission temperature, and its slow evaporation may be balanced by atoms arriving by means of diffusion from the bulk of the substance or migration through pores. Thus, for example, if optimal conditions hold, the addition of thorium oxide to tungsten makes the work function ϕ as low as 2.63 eV. Although the beam brightness A' goes down to 3 A/cm^2 K^2, the emission current density, $j = 3$ A/cm^2, holds at the temperature of only 2000 K and at a low rate of thorium evaporation. At $T = 1800$ to 1900 K and the specific emission $j \approx 0.3$–0.8 A/cm^2, the efficiency is 35–50 mA/W. Carbonizing (carbon saturation) improves the characteristics of these cathodes, which are used in high-voltage devices. At present, highly tolerant thermionic emitters are being made of alloys of noble metals (platinum, iridium, os-

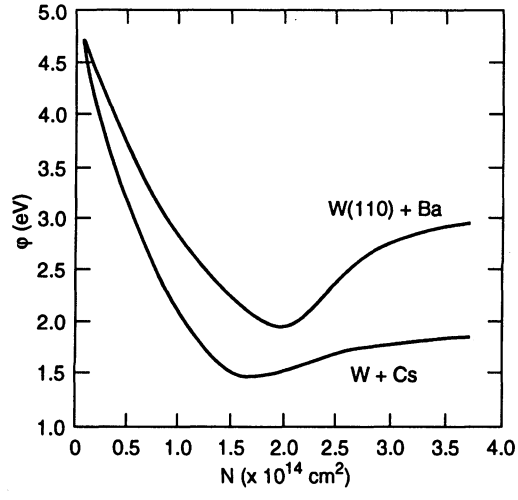

FIG. 5. Typical dependence of the work function on the atomic density of cesium film on tungsten. The work function reaches its minimum when the atomic density is less than one monolayer.

mium, etc.) with rare-earth elements (lanthanum, yttrium, scandium, etc.). Activation by means of optimization of coverings turns these alloys into efficient emitters (Kuznetsov, 1994).

Thermionic emitters with lower temperatures (<1800 K) are manufactured mainly in the form of knots with indirect heating. Tungsten spirals with high-temperature ceramic insulation serve as heaters. The usual form of emitters is a cap at one end with emitting surface at the opposite end (for electron-beam devices) or on the side surface (for electronic tubes, magnetrons, etc.). The heater is inside the cap. Power is transmitted to the emitter by irradiation or through heat conductivity. Screens are put against the nonemitting surfaces to minimize losses from irradiation. Optimal barium film on tungsten lowers the work function to ϕ = 1.66 eV. Under these conditions, $A' \approx 2$ A/cm^2 K^2, j = 3–50 A/cm^2 at T = 1320–1540 K, and the evaporation rate is 4×10^{-10} g/cm^2 s. The evaporation of the active substance is counterbalanced by the barium (oxide, aluminate, etc.) from the reserve designed into the cathode. In L cathodes, barium migrates onto the emitting surface through a porous wafer of baked tungsten powder from a hollow that contains a reserve of the active substance. In the initial state, it contains a mixture of barium and strontium carbonates. When activated in a vacuum, these carbonates decompose to form BaO, SrO, and CO_2, which is pumped out during this process. Then in the process of the reaction $6BaO + W \rightarrow Ba_3WO_6 + 3Ba$, free barium is formed. At $T \approx 950$ °C, j = 1.3 A/cm^2, and the lifetime is up to 8000 h. The L cathode is tolerant of adverse conditions, but evaporation of barium is rather substantial. By the use of the more regular structure of clutched and baked tungsten filaments (bundle cathode) instead of the porous wafer, it is possible to improve the characteristics of emitters (Le Duff, 1990; Kuznetsov, 1994).

The impregnated cathode consists of a porous wafer impregnated with an active substance (barium aluminate). Such a structure improves its manufacturability in comparison with L cathodes. For the former, it is typical to have ϕ = 1.67 eV, A' = 1.25 A/cm^2 K^2, and j = 1.5 A/cm^2 at T = 1020 °C. Pressed cathodes are produced by means of pressing mixed barium carbonates or aluminates together with molybdenum and tungsten powder with addition of restoring agents (WC, ZrH, TiH). At T = 1000 °C, j = 1 A/cm^2 and t = 5000 h, while t = 300 h at T = 1070 °C, and j = 3 A/cm^2. These cathodes are tolerant of ion bombardment and of gas poisoning even in bad vacuum conditions, $\approx 10^{-4}$ Torr. They also serve as good electron sources for gas discharges in hydrogen and noble gases.

Impregnated (dispenser) cathodes have operating times of 10 h at an operating temperature of 1100 °C. Many versions of impregnated cathodes have been developed during the last decades of investigation. The B-type cathode has been the most widely used in electron guns for commercial equipment since 1957. It consists of porous tungsten impregnated with BaO and Al_2O_3. These mixtures react chemically to liberate free barium atoms. CaO is also added to the impregnate. It reduces the barium sublimation rate and enhances emission properties. The names of B-type cathodes reflect the relative chemical compositions of the various compounds. As in high-temperature superconductors, a 532-type cathode contains five parts of BaO to three parts of CaO and two parts of Al_2O_3, and a 411-type cathode is $4BaO + CaO + Al_2O_3$.

The M-type cathode is a B-type cathode with the deposition of a thin film of ruthenium–osmium on the emission surface. The film must be very thin to permit the passage of barium. The possible film thickness is 0.1–1 μm. For a given temperature, the presence of a surface layer has increased the emission current density by a factor of 2. The M cathodes have a longer operation time relative to the B type since they have lower temperature for the same emission property. But damage to the thin film by ion bombardment leads to degradation of its emission characteristics.

A scandate cathode has a ScO admixture to the standard impregnation compound of a B-type cathode. The current density of a scandate cathode is almost identical to that of an M-type cathode. Since the scandate cathode does not rely on a thin surface film, and it is not as susceptible to mechanical damage and poisoning, it has some distinct advantages over the M type. Until now, scandate cathodes have not been used in long-term operating equipment.

Oxide cathodes consisting of thick (30–

200 μm) layers of the oxides BaO, SrO, and CaO on nickel or tungsten backing have become the most widespread. In the initial state, a mixture of the carbonates in suspension with organic compounds as a binder is applied to the base by spraying or by means of cataphoresis.

An oxide cathode is activated by heating at T = 800–1100 °C so that the carbonates decompose to form oxides while CO_2 is pumped out. Maintaining 1000 °C with the current removed leads to a partial restoration of barium and, as a consequence, to the transformation of an insulating mixture of oxides into an electronic semiconductor with donor barium admixture with levels near the bottom of the conduction band. The position of its Fermi level is between the bottom of the conduction band and the donor level. The optimized work function of an oxide cathode is ϕ = 1–1.2 eV, $A' = 10^1$–10^{-3} A/cm^2 K^2. At T = 800 °C, j = 0.5 A/cm^2, and t = 500 h; when j = 5–10 mA/cm^2, $t \approx 10^5$–10^6 h. In the impulse regime, j is 150 A/cm^2 at T = 1100 K. Oxide cathodes are 25 times as efficient as tungsten cathodes. The emission of electrons takes the major part of the power expenditure. To obtain high-brightness beams, it is necessary that emitters have smooth and uniform surfaces. For emitters without strong restrictions implied on their geometry, backings with developed surfaces are used, namely sponges, grids, sets of tubes, and bars.

Hexaborides of rare-earth elements are used as efficient cathodes. LaB_6 with, typically, ϕ = 2.66 eV and A' = 29 A/cm^2 K^2 (melting temperature 2210 °C) is most commonly used. LaB_6 is a polycrystalline substance or monocrystals of high hardness. Warming up and degassing at T = 1500–1600 °C leads to quick degasification and activation. At T = 1680 K, j = 1 A/cm^2, and $t \approx 10^4$ h; the evaporation rate is 10^{-9}–10^{-11} g/cm^2 s. Boron diffuses rapidly from LaB_6 into tungsten and molybdenum, which are in surface contact with it, the diffusion into tantalum being slower. To prevent boron diffusion, $MoSi_2$ is used. It is preferable to use graphite holders for fixing emitters made of LaB_6. Cathodes made of LaB_6 are most commonly used in dismountable systems such as accelerators, welding guns, etc. Pointed emitters in the form of straight-channel "studs" with the pointed end of the filament loop made of monocrystalline LaB_6 are used as thermoemitters in electron microscopes and electron-beam lithography.

More sophisticated configurations of thermionic emitters are in use: hollow cathodes in the form of hollow spheres or cylinders with a higher intensity of emission from the edges of the outlet aperture, and ribbon and circular cathodes.

In thermionic emission converters and other applications, the work function of tungsten emitters (and colder anode collectors) is lowered by the adsorption of cesium. In the presence of oxygen or fluorine, the optimal cesium film on refractory metals makes the work function as low as ϕ = 0.75–1 eV, and $j \approx 10$ A/cm^2 at $T \approx 1200$ K. These systems are used for sustaining the discharges in ion sources and gas lasers (Forrester, 1988; Dudnikov, 1992).

The class of cold cathodes includes autoelectronic (field) emitters, film-coated cathodes with a strong electric field in dielectric layers that are close to the surface, and secondary cathodes where emission is provided by interaction with gas-discharge plasma. To provide stable field emission in autoelectronic emitters, it is necessary to apply a stable electric field of $E \approx 5 \times 10^6$ to 5×10^7 V/cm to its surface and to provide high stability of the form and the work function. The latter is particularly hard to carry out because of the strong influence of the electric field and ion bombardment on the migration processes of surface atoms and on their adsorption–desorption.

At moderate voltages of $U \approx 1$–10 kV, the field strength on the surface of a field-emission cathode reaches its highest values on the points, with small radii of curvature $r \approx 10^{-4}$–10^{-5} cm. Such cathodes are pointed emitters with high-brightness beams. The emission current density $j \approx 10^7$ A/cm^2 dc, and j is up to 10^8 A/cm^2 in the pulse regime. The full current range is $I \approx 10^{-3}$ to 10^3 A. The stability and uniformity of the emission zone are provided by selective adsorption of substances lowering the work function toward the end of the point (barium on tungsten, zirconium on tungsten). Monocrystalline emitters with a certain stable face of the crystal sticking out of the point are commonly used. Ultrahigh vacuum, degassing, and higher temperature are used to reduce the effect of adsorption. Tungsten points function reliably in a vacuum of 10^{-9} Torr and ZrC with LaB_6 at 10^{-7} Torr. Functioning in the regime of thermal field emission is more stable at higher temperature but with a brightness higher than that of thermionic cathodes.

Recently, matrix field emitters have been developed with densely packed microemitters. The gap between the emitter and the anode being small ($d \approx 10^{-4}$ cm), the voltage $U \approx 10^2$ V is enough to cause field emission, and the average current density is $j \approx 1$ A/cm² dc. Because of the specific configuration of the unit (Fig. 6), ion bombardment of the point is excluded.

Although the interaction of electrons in a beam of high density increases the angular and energetic spread, with autoelectronic emitters it is possible to obtain beams of record brightness that are applicable mainly in high-speed electron lithography.

A strong electric field can accelerate electrons in a solid and thus cause some to escape into the vacuum (the emission of "hot" electrons). Favorable conditions for the emission of "hot" electrons may appear in thin dielectric films on conductive backings that have either "conductor–dielectric" or "conductor–dielectric–conductor" structure.

A strong electric field is created either by applying a positive charge to the vacuum surface of the dielectric film (by means of bombardment with slow ions or the removal of electrons from the surface in the process of secondary emission or photoemission) or by applying positive voltage to the very thin conductive film covering the dielectric. It induces field emission of electrons from the conductor into the dielectric film. Free electrons accelerate in the dielectric film and get sufficient energy for avalanche-type multiplication and for escaping into the vacuum. Some electrons penetrate the potential barriers and pass through the layers of the substance into the vacuum. The dissipation of energy being rather low because of the small film thickness, the emission of electrons is not accompanied by a considerable rise in temperature, but is usually accompanied by luminescence resulting from the free-carrier recombination. In producing "cold" sources of "hot" electrons, a metal backing (e.g., nickel with a dead surface) is coated with a thin dielectric film (MgO, 10 μm, often porous), then degassed in vacuum and subjected to heating in oxygen at $t \approx 850$ °C for 10 min. Self-maintained emission is excited by electron, ion, and photon impulse irradiation, the emitted electrons being extracted by 200 to 300 V at the collector. Average current density is 10 mA/cm², the effective temperature of the "hot" electrons is $T \approx 10$ eV, and the lifetime is 10 h.

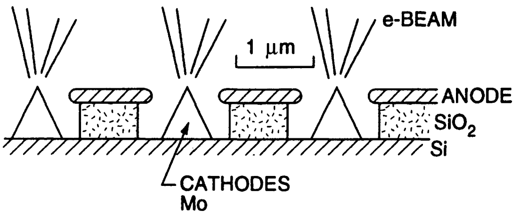

FIG. 6. Multipoint autoelectronic field emitters for high-speed electronic lithography applications.

After the deposition of a very thin conductive film (Au, ≈100 °A, islandlike films), transparent for the "hot" electrons, over the dielectric film, the controlled emission is initiated by applying 100–200 V to this film relative to the backing. In the impulse regime, higher voltage excites emission of high current density without inertia.

The emission of electrons from the surface of ferroelectrics is excited in a similar way. In a polarized plate of a ferroelectric, the polarization field is balanced by the surface charges. After the quick application of an inverse voltage to the surface electrodes (one of which is transparent to electrons), there is an unbalanced surface charge left on the surface of the ferroelectric, which induces a strong electric field and initiates the emission of electrons into the vacuum.

In recent years, efficient photocathodes subjected to laser irradiation have become important sources of electrons (Le Duff, 1990). Photocathodes with negative electron affinity made of p-type semiconductors having epitaxial layers (GaAsP, GaAs, InAsP + Cs, O) and activated by multilayer structures of cesium and oxygen are in common use. Values of $Y \approx 0.2$–0.5 of quantum efficiency of these photocathodes are reached at the minimum excess of photon energy over the threshold. It enables intense electron beams to be obtained with minimum spread of energy. Quick modulation of laser irradiation (up to 10^{-10} s) provides electron-beam modulation at the same rate, which is important for the generation of superhigh-frequency radiation, for free-electron lasers, and for carrying out a series of unique experiments. Application of circularly polarized radiation provides the photoemission of electrons with a definite spin orientation (obtaining polarized electrons).

Other ways of obtaining polarized electrons are based on the polarization of atoms in a magnetic field by circularly polarized radiation (optical pumping) and further ionization of polarized atoms with polarized electrons being freed. It is efficient to use metastable helium atoms in the 2^3S state with forbidden optical transition to the ground state. With optical pumping, it is possible to achieve a high density of polarized metastable helium atoms that can generate free polarized electrons in collisions with other molecules through Penning ionization (the expenditure of the energy of excitation of the metastable state on ionization).

Polarized electrons are pulled out of the plasma by the extracting voltage through the emission aperture.

The most generally used source of electrons is the electron projector, which produces the narrow electron beam in electron-beam (cathode-ray) tubes. The typical design of the electron projector is shown in Fig. 7. It comprises the heating cathode K, the Venelt electrode B, the first anode A_1, and the second anode A_2 connected with the conductive bulb coating. The oxide cathode applied to the end of the cap emits electrons. The size of the emitting zone and beam intensity are regulated by a rather low negative potential on the Venelt electrode, which creates a short-focus lens for the emitted electrons. The next electrodes accelerate and shape the beam, producing an image of the beam crossover formed at the cathode. A similar design is used for the electron sources in electron microscopes, but the emitter used is either a small spot on a straight-channel tungsten "stud" or the point of an autoelectronic or field emitter.

In the electron guns of electron-beam microwave generators (klystrons, traveling-wave tubes, inverse-wave tubes, generators of diffraction radiation, etc.), electron beams of high current density are formed by Pierce electrodes establishing the distribution of the potential at the beam boundary, which is close to the distribution of the potential in beams with space charge in flat, cylindrical, or spherical diodes. Typical configurations of electrodes are shown in Fig. 8. Indirectly heated cathodes, namely oxide cathode, L cathode, impregnated cathode, etc., are used as emitters. Computer simulation enables the optimization of the configurations of electrodes to derive the required beam parameters and to work out electron sources possessing the required characteristics. The example of an electron gun with a real beam compression of up to 3000 times is given in Fig. 9.

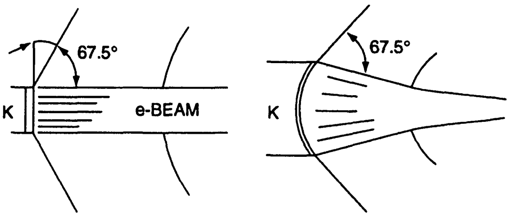

FIG. 8. Typical configurations of electrodes for a highly compressed electron-beam source.

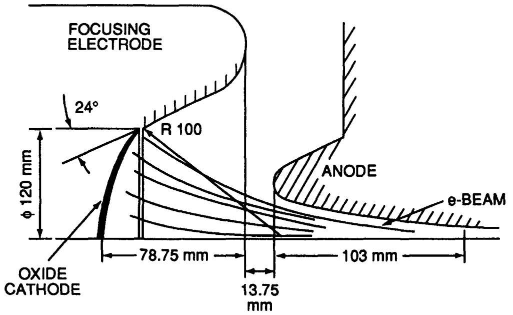

FIG. 9. An example of an electron gun with a real beam compression of up to 3000 times.

Plasma sources of electrons with the design close to that of plasma ion sources, but with changed extractor voltage polarity, are used for technological applications.

Impulse electron beams (5–10 μs) with intensities up to 10^6 A are obtained in sources of explosive emission (Bystritskiy and Didenko, 1989). Rapidly rising voltage (10^5 to 10^6 V) is set up between a flat cathode and an anode made of thin metal foil. High electric field strength at the cathode micropoints initiates field emission with rapid heating and explosion of the micropoints, which produces dense plasma on the surface. Electrons are extracted from this plasma, accelerate in the gap, and pass through the foil into the drift space. To maintain uniform emission, a high density of microscopic whiskers is achieved on the cathode. Stable emission is produced by cathodes made of graphite or carbon material, velvet, and velvetlike materials. The magnetic field of the electron flux focuses the electrons on the center into a small spot, and the space charge of the electrons suppresses the emission from the central part of the cathode. To maintain uniform emission on the entire surface of the cathode and to form a parallel electron beam, a strong longitudinal magnetic field is applied (0.1–1 T). The length of electron impulse is limited by the time necessary for the cathode plasma to reach the anode, and it is 10 μs when the gap width is $d \approx 20$ cm.

3. PHYSICAL PRINCIPLES OF ION PRODUCTION

3.1 Positive-Ion Production

The method of electron ionization of atoms and molecules in the gaseous phase still remains the basic one for positive-ion production. The ion flux coming through holes in a gas-discharge tube cathode (canal rays) was described by E. Goldstein in 1886. Atomic and molecular electron ionization cross sections increase as the energy of electrons W rises from the threshold of the ionization potential I up to $W \approx (3\text{–}4)I$. The magnitude of the cross section reaches a maximum value of $\sigma \approx 10^{-16}\text{–}10^{-14}$ cm^2 and then decreases as W^{-1} after the maximum point. At a gas pressure of 1 Torr, an electron produces up to 1 ion per cm in He, up to 10 ions in N_2 or O_2, and up to 20 ions in Hg. Electrons may be captured by ions in collisions with atoms and molecules; thus they experience charge exchange. The charge-exchange cross sections are very large (up to 10^{-14} cm^2) for resonant charge exchange of the same atom and ion at low collision energies (Green, 1984; Forrester, 1988).

Ions disappear (recombine) when they capture free electrons, electrons of negative ions, or electrons in solids. In the process of recombination, the energy expended upon ionization is released again by emission of a photon, transmission of energy to other particles, or excitation. In a plasma with an electron velocity distribution $f(v)$, the rate of ion production is proportional to the gas density n, the electron density $n_e = n_i$, and the ionization rate

$$\langle \sigma v \rangle = \int_0^\infty \sigma(v) f(v) v dv. \tag{13}$$

The last increases as the temperature of the electrons, T_e, rises. The electron and ion formation rate is in equilibrium with recombination in wall collisions. To suppress this effect, a magnetic field and special electrode configurations are used, namely electron and ion traps. To extract ions or electrons and form beams, a potential difference $U_0 \approx 1\text{–}10^2$ kV accelerating ions toward the extractor is established. This potential is established between the region of ion generation and the extractor (an electrode with an aperture that lets beams through). To sustain a strong electric field within this gap d without breakdown, the gas density in the gap should be low enough ($p < 10^{-4}$ Torr). This circumstance limits the maximum gas density n in the ion source. In ion sources for mass spectrometers, the gas is ionized by the electron beam generated by an ion gun ($I \approx 1$ mA, $W \approx 10^2$ eV).

In more powerful ion sources, the gas discharge produces a dense plasma, $n \approx 10^{10}\text{–}10^{14}$ cm^{-3}. In sources containing a hot cathode but no gas, the flow of electrons from the cathode is limited by space charge to a low level. With gas being delivered, the charge of the formed ions and the space charge of the electrons compensate each other, and inside the source a quasineutral plasma is formed. The ion flux with mass M coming onto the electrode with negative potential U_0 in the plasma is determined by the ion density $n_i = n_e$ and the temperature T_e of the electrons according to the Bohm formula,

$$j^+ = 0.4 n_i e (kT_e/M)^{1/2}. \tag{14}$$

The variation of thickness of the space-charge sheet with the directional flux j^+ is determined by the formula

$$d = (2/3)(2e/M)^{1/2}(\epsilon_0 U_0^3/j^+)^{1/2}. \tag{15}$$

If we make an opening $2r < d$ in size, we will have the elementary scheme of ion-beam production. Equations (14) and (15) provide elementary estimations of the beam production characteristics: the emission current density j, the plasma density n_i, the extraction voltage U_0, the extraction gap d, and the size r of apertures in the plasma electrode, which separates the extractor and the reservoir of the source with high gas density inside. An elementary scheme of an ion source with extractor is shown in Fig. 10.

Improved extracting systems included several electrodes that provide beam production with minimum divergence and aberrations. An example of such a system is shown in Fig. 11. Computer simulation using the Vlasov equation and the particle method enables one to design perfect systems (Whealton, 1981; Whealton *et al.*, 1988, 1989). The local divergence (angular width) of a beam, $\Delta\alpha$, is determined by the temperature of the ions, $T_i \approx 1$ eV, and the accelerating voltage U_0 $[\Delta\alpha \approx (T_i/eU_0)^{1/2}]$, the minimum beam emittance (the measure of the volume in phase space occupied by the beam) being close to $\epsilon = \pi r \Delta\alpha$ and the normalized emittance $\epsilon_n = \epsilon\beta = \epsilon v/c$.

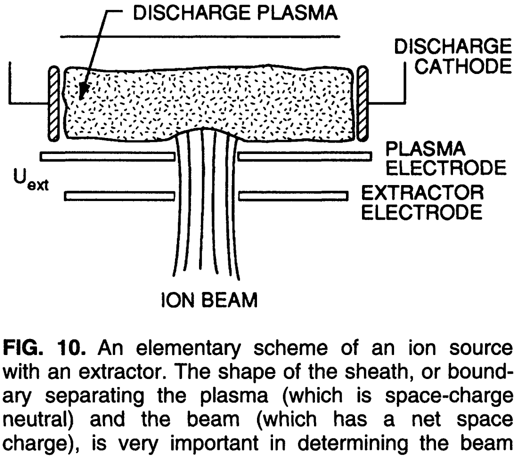

FIG. 10. An elementary scheme of an ion source with an extractor. The shape of the sheath, or boundary separating the plasma (which is space-charge neutral) and the beam (which has a net space charge), is very important in determining the beam properties.

The emission of electrons from the cathode is determined by the ion current in the direction of the cathode. In discharges with only a cold cathode, secondary emission of electrons is initiated by bombardment with ions, $j_e = \gamma j^+$, and characterized by the generalized ion–electron emission coefficient γ. For pure metals when the energy of the ions is as much as 10^3 eV, $\gamma \approx 0.1$ to 0.01. For materials covered by insulator films, such as Al_2O_3 and MgO, secondary emission significantly increases as a result of the strong electric fields within the film. The efficiency of secondary emission (caused by bombardment with ions, atoms, electrons, and photons) is provided by the activation of the cathode surface by alkali-metal and alkaline-earth elements. The space charge begins to limit the electron current from the cathode at the level $j_e \approx j^+(M/m)^{1/2}$. Efficient thermionic emitters are capable of emitting such a current; they are equivalent to cold cathodes having $\gamma \approx (M/m)^{1/2}$. The discharge voltage is determined by the following condition: Having been emitted from the cathode, an electron with energy eU_d should make γ^{-1} ions return to the cathode in the discharge and cause a new electron to be emitted into the discharge. The minimum energetic cost of ion production in the discharge is $p \approx 3I$. For discharges with cold cathodes, $\gamma^{-1} \approx 10$–10^2 and $U_d \approx 10^3$ V; for discharges in thermionic emitters, $U_d \approx 10^2$ V. In ion sources using electron oscillation, the electrons remain in the reservoir until they expend their energy on ionization and excitation, ions being efficiently returned onto the cathode by the magnetic field. The discharge voltage U_d is weakly dependent on the discharge current I_d. In efficient ion sources, a significant portion of the ions (~10%) is extracted and forms the beam. In plasma sources having high beam intensity $I^+ \approx 1$–100 A, the characteristic energy expense is $p \approx 1$–10 kW/A; these expenses are substantially higher in sources with lower intensity.

ions is performed in the ion sources with efficient confinement of ions in the magnetic field and high energy of electrons. The charge Z is determined by the electron current density j_e and the ion lifetime in the source, τ. In the latest sources with $j_e \approx 10^3$ A/cm^2 and $\tau = 1$ s, ions having $Z = 80$ may be obtained, but the intensity of such beams is not high.

Alkali metals have an ionization potential I less than the work function of pure metals ($\phi \approx 5$ eV). During the adsorption of an atom having $I < \phi$, a valence electron tunnels into the metal to the Fermi level and the particle resides on the surface in the form of a positive ion. If the temperature rises, these particles will evaporate in the form of ions, because the evaporation heat of atoms, l_0, exceeds that of ions, l_+, by $\phi - I$. The surface ionization is characterized by the degree of surface ionization α^+, the ratio of the density of the flux of evaporated ions to that of the flux of evaporated atoms. This flux is given by the Saha–Langmuir formula,

$$\alpha^+ = j^+/j_0 = A_+ \exp[(\phi - 1)/kT], \qquad (16)$$

where $A_+ = \gamma^+/\gamma_0$, the ratio of the statistical weights of ions and atoms at temperature T. The ionization coefficient $\beta^+ = \alpha^+/(1 + \alpha^+) = j^+/(j^+ + j_0)$ is also used.

At low temperatures, the adsorption of alkali metals reduces the work function ϕ to $\phi < I$, the fraction of the evaporated ions being small. If the temperature exceeds the threshold (usually $T \gtrsim 10^3$ K), the atom's lifetime on the surface and the thickness of the adsorbate lessens, while the work function goes up to $\phi > I$ and the surface ionization coefficient discretely increases to $\beta^+ \approx 1$. On the surface of W with $\phi = 4.3$–5.3 eV, we obtain surface ionization with $\beta^+ \approx 1$ for Cs ($I = 3.89$ eV) or Rb ($I = 4.18$ eV). Significant surface ionization is observed for K, Na, Mg, Ca, Sr, Ba, Al, In, Tl, U, Th, etc. For efficient ionization, it is necessary that the evaporated ions be removed by an electric field so that the space charge should not hamper the evaporation of ions.

When the electric field E at the surface of the emitter becomes higher, it leads to a decrease in the ion's evaporation energy according to the Schottky formula, Eq. (8). Also it causes an increase in surface ionization at E from 10^4 to 10^7 V/cm,

$$\alpha_E^+ = \alpha_0^+ \exp[e(eE/4\pi\epsilon_0)^{1/2}/kt], \qquad (17)$$

and a lowering of the threshold temperature at which surface ionization is initiated.

When very high fields are applied, the ion evaporation becomes considerable at low temperatures (field evaporation) because of the tunneling of ions from the adsorptional states on the surface into the potential well of the external field, $U(z) = -eEz$ (see FIELD EMISSION AND FIELD IONIZATION). Cesium ions on the surface of tungsten evaporate at room temperature in the field $E \approx 10^7$ V/cm. Stronger fields are created at points with a very small radius of curvature, $r \approx 10^{-7}$–10^{-8} cm, to achieve ion evaporation with high ionization potential. However, such points grow dull quickly because of field evaporation of the substance. Self-sharpening points having such extremely small radii of curvature are formed when a liquid film, either on a solid point or in a capillary in the presence of a very high electric field, becomes electrohydrodynamically unstable. When the field strength is $E \approx 10^8$ V/cm, the ion field evaporation produces an ion flux with current density reaching up to 10^8 A/cm^2 dc. The flow of the liquid in the film offsets the loss of the substance in the form of ions. Comparatively low temperatures of the liquid point make it possible to obtain a beam of very high brightness (Orloff, 1993; Prewett and Mair, 1991). Collective processes in such dense beams raise the temperature of the ions to 10 eV. But among all the sources developed, such electrohydrodynamic (EHD) emitters made of liquid metals, semiconductors, or alloys and dielectrics remain brightest (Belchenko *et al.*, 1990; Dudnikov and Shabalin, 1992). EHD sources have a beam current up to 10^{-3} A; but when the intensity is $I \approx 10^{-4}$ A, instabilities appear that substantially worsen the beam characteristics. Ions of hydrogen and noble gases are produced in the same way as a result of field ionization at a cryogenic needle. The intensity of such beams is significantly lower, but the brightness may be very high.

Valence electrons in atoms that are closer to the surface have higher energy levels, and so for the adsorbed particles the condition $I < \phi$ is easier to satisfy than for the free particles. The degree of positive ionization of the adsorbate is usually higher than could be expected if we used the Saha–Langmuir formula. Because of the quick nonequilibrium desorption initiated by the impact of ions, photons, and electrons we can observe the emission of particles having higher degrees of ionization. Previously this process was used to diagnose the surface composition.

Illumination of the surface by strong laser radiation fluxes and intense electron and ion beams initiates intense ion emission.

For production of nuclear polarized positive- and negative-ion beams, various processes are being used (Schiemenz, 1992):

1. Nuclear polarized atoms are produced by means of sextupole focusing of slow atoms with one projection of electron spin; conversion of electron polarization into a nuclear one by radio-frequency transition or Sona field reversal; transformation of nuclear polarized atoms into negative or positive ions; focusing them into a beam and accelerating. Slow atoms with electron polarization may be obtained by some other methods: by accumulation in liquid helium film in the presence of a strong magnetic field, by chemical polarization of nuclei, by optical pumping, and by spin exchange with optically polarized atoms of alkali metals. The transformation of polarized atoms into ions is performed in electron-beam ionizers, in rf and microwave discharge ionizers, and by charge exchange with atom and ion beams. The beams of highest intensity (6 mA of H^+ ions and 1 mA of H^-) are obtained by means of resonant charge exchange on positive and negative ions.

2. In sources using the Lamb shift, a beam of metastable hydrogen atoms in the 2*S* state is formed through charge exchange in the proton beam (deuteron beam) passing through a target of cesium vapor. The binding energy of an electron in cesium is close to that in hydrogen and deuterium in the 2*S* state. When the proton energy is $W = 0.4$ keV, the yield of the 2*S* state reaches its maximum. In a transverse electric field, the particles with one electron-spin projection make the transition from the 2*S* state to the 2*P* state and immediately emit photons. By a quick change of the direction of the accompanying magnetic field, the electron polarization is converted into the nuclear one. After that, the metastable nuclear polarized atoms transform selectively into positive or negative ions in iodine or argon vapor targets. These sources are small in size and have much power economy, but their intensity is not high (10^{-6}–10^{-4} A). The methods of selective lasing and ionization of metastable atoms by means of resonant laser irradiation, creating no limits for intensity, are very promising.
3. Beams of accelerated atoms with electron polarization are obtained by means of proton charge exchange in polarized targets. Polarization of atoms in an alkali-metal target is achieved by optical pumping by means of circularly polarized laser radiation in a magnetic field. A high magnetic field helps to keep a high degree of polarization. Then the electron polarization is converted into the nuclear one by magnetic field reversal. After that, atoms having nuclear polarization turn into positive ions in the process of charge exchange in helium or into negative ions in alkali-metal targets (cesium or sodium).

3.2 Negative-Ion Production

Active research on techniques for negative-ion production is one of the directions for source development. An electron has a low binding energy in a negative ion ($S = 0.75$ eV in H^-), which therefore dissociates easily in collisions with electrons, ions, or neutral particles. Positive ions, however, neutralize only in wall collisions. The high destruction probability for negative ions makes it very difficult to produce them. Negative ions are formed in collisions of electrons with molecules. As a rule, an electron is bound by a molecule temporarily to form an autoionized molecular negative ion that later falls apart in different ways (Green, 1984; Forrester, 1988):

$$H_2 + e \rightarrow H_2^- \rightarrow \begin{cases} H_2(v,J) + e & \text{(vibrational–rotational excitation)} \\ H^- + H & \text{(dissociative attachment)} \\ H^- + H^+ + e & \text{(polar dissociation)} \end{cases}$$

The cross section for negative-ion formation from the ground molecular state is 10^{-20} cm^2, increasing to 10^{-16} cm^2 in collisions of electrons with molecules excited by vibration and rotation ($v > 6$, $J > 6$).

The cross section for negative ions recombining with positive ions is large: $\sigma_r \approx 10^{-14}$ cm^2. The cross section for H^- destruction by electrons is $\sigma_e \approx 10^{-14}$ cm^2 with a broad maximum close to $W \approx 10$ eV and a threshold at $W = 0.75$ eV. The vibrational–rotational excitation of molecules decreases the energy of those electrons that form negative ions efficiently, at the same time causing a decrease in the rate of negative-ion destruction. Even when optimal electron-energy distributions are used, the cross section for negative-ion formation is much smaller than that for their destruction. In plasma H^-

sources, the emission current density is 0.01–0.1 A/cm^2. Up to 3% of the gas delivered may be transformed into H$^-$ ions. A considerable problem with negative-ion sources concerns the extraction of the large beams of accompanying electrons and negative-ion destruction in the gas coming from the source.

Previously great attention was paid to the charge-exchange method for negative-ion-beam production that involves the capture of two electrons by a positive ion. This method is most universal. At present it is used when other methods lack efficiency. In charge-exchange sources in the initial state, a positive-ion beam possessing the required energy and intensity is generated. In the next stage, positive ions are passed through an appropriate target, attaching two electrons and turning into negative ions (Green, 1984; Forrester, 1988; Belchenko *et al.*, 1990).

The optimal negative-ion yield, F^-, is determined by the ratio of their formation and destruction cross sections. For protons in hydrogen, $F^- = 0.02$ at the energy of $W = 10$ keV; in sodium, $f^- = 0.1$ at $W = 10$ keV; in cesium, $F^- = 0.5$ at $W = 0.4$ keV. Helium atoms produce He$^-$ ions when in the metastable 2S state; only the charge-exchange method can provide efficient He$^-$ ion production. Beam charge exchange is used for the production of positive and negative ions with nuclear spin polarization.

On surfaces with lowered work function ϕ, the particles having high electron affinity S are adsorbed in the form of negative ions (the work function increases during this process). Such particles evaporate in the form of negative ions. Negative surface ionization is characterized by the degree of surface ionization α^-, which is the ratio of the negative-ion current density to the atom flux. In equilibrium conditions, α^- is determined by the Saha–Langmuir formula,

$$\alpha^- = A_- \exp[(S - \phi)/kT], \tag{18}$$

where A_- is the ratio of the statistical sums of negative ions and atoms.

Only halogens can be ionized with considerable efficiency on the surfaces of refractory metals ($\phi \approx 4.3$ eV). High ionization efficiency is achieved for many substances on the surface of LaB$_6$, which has $\phi = 2.6$ eV and is highly tolerant of poisoning. On the surfaces of tungsten or molybdenum coated with cesium in optimal concentration, the formation of H$^-$ and D$^-$ is observed. As a particle approaches the surface, the level of its electron affinity lowers by $\Delta S = e^2/16\pi\epsilon_0 z$; therefore, $S + \Delta S > \phi$ for many substances on surfaces with low work function, and the electrons from the solid fill up the electron-affinity levels. However, when the particle moves away slowly, the electron affinity rises above the Fermi level again, and electrons once more tunnel into the solid body. Finally, only an exponentially small portion of the particles is evaporated in the form of negative ions according to the Saha–Langmuir formula.

On the other hand, quick removal of the particles from the surface by sputtering, reflection, or stimulated desorption with electrons or photons may leave no time for an electron to tunnel into the metal, and therefore it is "carried away" from the surface onto the electron-affinity level at the expense of the initial kinetic energy of the particle $W_\perp = mv_\perp^2/2$. The negative ionization coefficient b is defined by the expression

$$\beta^- = \frac{j^-}{j^{\mp}j_0} = \exp\left[-\int_{z0}^{\infty} \frac{w(z)dz}{v_\perp(z)}\right], \tag{19}$$

where $w(z)$ is the frequency of electron tunneling from the electron-affinity level at the distance z from the surface. The probability $\beta^-(v)$ of the fast particles being negatively ionized rapidly increases for particles with energy higher than the threshold energy $W_\perp > \phi - S$ and with the ability to escape from the surface in the form of negative ions (Belchenko *et al.*, 1990; Dudnikov, 1992). For sputtered and reflected hydrogen particles, the capture of the surface electrons intensifies dramatically as ϕ decreases to $\phi < 1.5$ eV through the adsorption of optimally concentrated cesium on the surface. Other alkali-metal and alkaline-earth admixtures catalyze negative-ion production this same way; however, cesium catalysis is much more efficient (Dudnikov, 1992).

In the sources using sputtering, a target having a specific form is subjected to cesium-ion beam bombardment with the energy of 1–10 keV and a current of 1 mA. To minimize the work function, cesium is deposited on the surface. Desorbed and sputtered negative ions with a current up to 10^{-3}–10^{-4} A are accelerated by the extracting voltage and focused into a beam. The sources with sputtering allow us to obtain a wide set of atomic and molecular negative ions (Alton, 1993).

Significant improvement of ion-source characteristics and the enhancement of negative-ion production efficiency have been achieved in surface-plasma sources in which cesium catalysis is used for negative-ion production (as discovered by Dudnikov in 1971). In surface-plasma sources, an electrode with negative potential is immersed into a plasma, and then the cesium admixture is delivered. Cesium ions are adsorbed on the surface, lowering the work function, and the extraction of ions from the plasma provides intense bombardment of the electrode surface, initiating the emission of intense negative-ion fluxes.

Because the space charge is canceled out, the limitations for the negative-ion beam intensities are eliminated, while rapid acceleration in the layer close to the electrode minimizes the negative ions' destruction when they move through the plasma toward the emission aperture. Fast negative ions coming from the electrode may be converted into cold negative ions as a result of resonant charge exchange with cold atoms. It enables beams of high brightness to be obtained. The emission current density for H^- ions reaches the level of 8 A/cm^2 dc.

Intense laser and electron irradiation of the surfaces with minimized work function initiates the negative-ion emission. Accompanying electron fluxes are suppressed by using specific configurations of extracting systems and a magnetic field (Dudnikov, 1992).

Self-consistent ion-extraction optics are very important for the production of the brightest beams. Such calculations are difficult because of the high degree of nonlinearity of the formulation, and the large number of dimensions that needs to be considered (Whealton, 1981). For negative-ion modeling, the situation is exacerbated by the determination of a formulation that is both reasonably self-consistent and tractable (Whealton *et al.*, 1988, 1989).

When applied to the surface, a high electric field causes an increase in the probability of particle desorption in the form of negative ions. In practice, such a process is performed in self-sharpening EHD emitters with the points covered by films of ion salt melts (Dudnikov and Shabalin, 1992). The surface-plasma sources are used as ionizers in the production of negative ions with nuclear polarization.

4. ACTUAL ION SOURCES

4.1 Positive-Ion Sources

The considered principles of ion production are used for the creation of ion sources with required characteristics: beam intensity I and ion energy W, composition of ions, required emittance $\epsilon = \Delta r \Delta \alpha$ and brightness $B = 2I/\epsilon^2 = j/T_i$, acceptable energy ($I/P$) and gas ($I/Q$) efficiency, required operational time and reliability. The achievement of these necessary characteristics is a result of ingenuity and deep optimization.

In real ion sources, efficient ionization must take place in a condition of low gas density, when the ionization free path length of electrons significantly exceeds the dimension of the gas-discharge chamber. The classical solution of this problem is an electron-oscillation gas discharge (PIG, from its origin in the Penning ion gauge), in which the electrons are oscillated along the magnetic field inside an anode tube with reflection from the opposite cathode plates at negative potential.

In a strong magnetic field, it is possible to initiate a gas discharge with a cold cathode and low gas density, but for the discharge transformation to the low-voltage, high-current mode (to the superdense glow discharge) with $U_d = 0.4$ kV and $I = 1$–100 A, a gas pressure of 10^{-2} Torr is required. The ion beam can be extracted from the gas-discharge plasma through a hole in the cathode plate along the magnetic field or through a slit in the anode tube perpendicular to the magnetic field. The use of a thermionic cathode is enhanced by the transition into the low-voltage ($U_d = 50$ V) discharge with low gas density and with an acceptably long operational time. The structures of Penning ion sources are extremely multifarious (Alton, 1993; Kutner, 1994). They have various electrode configurations and materials, extraction systems, and gas-injection systems. Some versions have electromagnets; others have permanent magnets. An example of a Penning-discharge ion source with self-heated LaB cathodes is presented in Fig. 12. The distinctive features of this source are low U_d = 80 V, with I_d = 0.8 A and j^+ = 0.6 A/cm^2, high proton content (up to 60%), high gas efficiency (up to 60%), and long operational time (10^2 h).

Another famous version of an ion source with electron oscillation is the Calutron, developed for high-productivity isotope separation. The scheme of this source is shown in Fig. 13. A thin plasma column is created by a thermionic cathode discharge in a strong magnetic field. The electron oscillation is provided by reflection of electrons from an oppositely located anticathode (a reserved cathode). As a thermocathode is used, a dc-heated pin from a tungsten or tantalum filament or massive tungsten block is heated by electron flux. An ion beam is then extracted through a slit (up to 1 × 20 cm^2) in the graphite or metallic body of the source anode. A three-electrode extraction accelera-

tion–deceleration system with specific profiles of electrodes is used for forming a good ribbon beam convenient for separation in a magnetic field (Forrester, 1988; Kutner, 1994).

Gases of separated elements, compound vapors, and sputtered solids are used as working substances. A sputtered electrode is immersed into the plasma column opposite the extraction slit and biased negatively with hundreds of volts. Ion sources can be heated up to high temperature, (1–2) × 10^3 °C, for creating the required density of a working-substance vapor. Emission current density is 0.1 A/cm^2 for a light ion and decreases as $M^{-1/2}$ for heavy ions. An increase of the magnetic field enhances the efficiency of ion generation, but this increases the fluctuation of the plasma parameters and increases beam emittance. Several versions of Calutrons have been developed for many applications including use in ion implantation (Alton, 1993; Kutner, 1994).

A successful structure of an ion source with magnetron electrode configuration was proposed and developed by Freeman in 1947. The layout of the Freeman ion source is shown in Fig. 14. A heated cathode of tungsten or tantalum wire located along a magnetic field inside the anode cylinder is used. The magnetic field is not too high, B = 10–30 mT. Freeman source characteristics are close to those of Calutrons, but the discharge is really noiseless. This is very important for precise beam formation and for good separation of the beam from impurities. The Freeman source is widely used for ion implantation (Chivers, 1992).

Very high efficiencies of ion generation have been reached in a duoplasmatron, having many applications (Forrester, 1988; Alton, 1993). In a duoplasmatron, discharge between a heated cathode and a small anode with an emission hole is used. The discharge column is compressed by a hole in a floating-potential (isolated) intermediate electrode and a strong magnetic field between this electrode and the anode (Fig. 15). The compressing of the discharge by the intermediate electrode and the magnetic field is created by a double sheath with a spherical surface; accelerated and focused electrons are near the emission hole. The magnetic field is compressed by the plasma and iso-

lates it from the wall. Axial extraction of ions is used. It is important to use a nonmagnetic anode insert with an emission hole. Through the emission hole of 0.1 to 1 mm diameter, a plasma jet with very high density (up to 10^{-14} cm^{-3}) is emitted. An ion beam is formed from an expanded plasma flux with lower density and adjusted for beam extraction by a high-voltage electric field. Some duoplasmatrons are operated with a cold hollow-cathode arc discharge or a superdense glow discharge. The energy spread of ions is 6 to 8 eV when ions are extracted from the expander and up to 60 eV for ion extraction from the anode hole. In a duoplasmatron with a strong magnetic field, the ion generation is efficient, but the discharge fluctuation is very high. High levels of fluctuation decrease the brightness B to

$$j/T_{ef} \sim 10^{-2}\ \text{A/cm}^2\ \text{eV} \quad (T_{ef} \sim 5\text{–}10\ \text{eV}). \qquad (20)$$

By the addition of an additional anode between the intermediate electrode and the electrode with the emission hole, a duoplasmatron with electron oscillation is created. By this transformation, increased aperture can be used for intense beam generation. This modified DuoPIGatron with a multiaperture extraction system has intensities up to 70 A. Versions with a multicusp magnetic field near the cylindrical wall have low-noise plasma and better ion-beam characteristics than versions with longitudinal magnetic field in the plasma.

Also, for generation of intense ion beams (50 to 100 A), periplasmatron modification of the duoplasmatron with radial injection of plasma from the hot-cathode toroidal chamber to the central chamber, with a multiaperture four-electrode extraction system, is used (Green, 1984; Forrester, 1988).

After 1978, ion sources were developed with a hot-cathode discharge chamber with a periphery multicusp magnetic wall for suppression of plasma loss. dc-heated tungsten filaments are used as cathodes for the discharge, and the chamber wall or special electrodes as anodes. Good homogeneity of the plasma can be reached on the big surface of the multiaperture four-electrode extraction system. The typical emission current density *j* is 0.25 A/cm², and *I* is 100 A in long (up to 100 s) pulses. Small multicusp sources with *I* ~ 0.1 A have been developed for industrial application. This ion source has a low level of fluctuations and high beam quality (Green, 1984; Forrester, 1988).

In the ion sources considered, the operation time is limited by destruction of the hot cathode to about 10 to 50 h (Forrester, 1988). For overcoming this defect, electrodeless rf and microwave discharges have been developed. In a widely used version of rf sources, the discharge is initiated in a quartz or Pyrex vessel in gas at a pressure of 10^{-2} to 10^{-3} Torr. A capacitor connection with the discharge is used with rf voltage between two rings around the vessel. An inductive connection uses an rf coil of copper tube around an insulating vessel immersed into a metallic chamber. The weak magnetic field (3–10 mT) is optimized by the plasma-generating rf of 2–10 MHz, and power of 10^2–10^3 W is used for plasma production. In the rf source with ion extraction along the inductance coil or capacitor discharge, the energy spread is very large (up to 10^2 eV). Better energy distributions have been produced with a perpendicular inductance coil and extraction along the magnetic field (Fig. 16). It is convenient to use a moving permanent magnet for resonant magnetic field production. By special processing of the vessel wall,

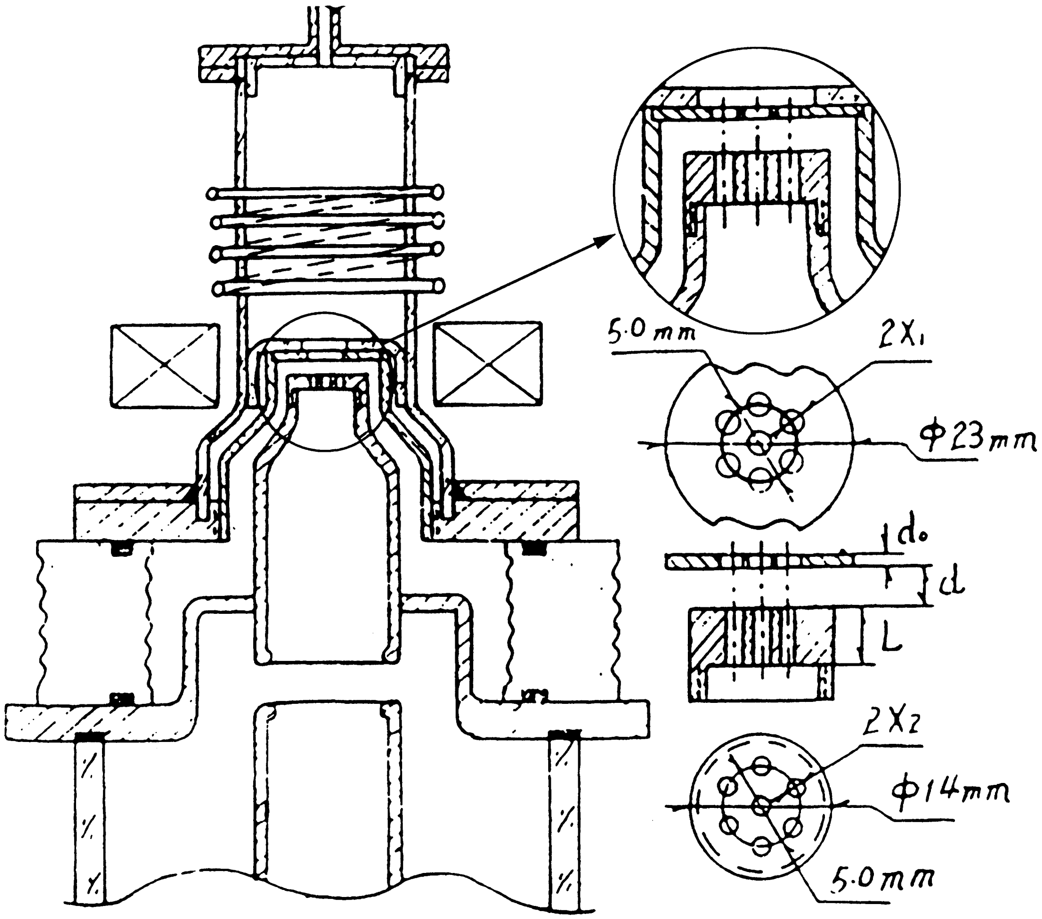

FIG. 16. rf ion source. The inductive connection uses a rf coil of copper tubing around an insulating vessel immersed in a metallic chamber. The weak magnetic field (3–10 mT) is optimized by the plasma-generating rf of 2–100 MHz, and power of 10^2–10^3 W is used for plasma production.

it is possible to reduce the recombination of the atoms and have a high atomic percentage (up to 80%) with low discharge power. Similar rf generators are used for atomic-flow production in polarized sources. The ions escape from the plasma through a hole at the plasma electrode. In a source with probe extraction, a thin positively biased probe is immersed in the plasma. By this probe, the plasma is biased positively relative to the plasma electrode, and ions are extracted and accelerated to the plasma electrode by a potential difference $U = 1$–10 kV. The screening of the plasma electrode by a dielectric diaphragm allows the ion flux to be focused on the emission holes and formed into a beam. Multiaperture probing extraction systems can be used also.

In rf sources with the usual extraction system, the plasma has a potential close to that of the plasma electrode, and a high potential difference has been applied between the plasma electrode and the extractor. Three- and four-electrode extraction systems can be used also.

In recent times, highly efficient plasma generation has been reached in rf discharges with a helical antenna having powerful resonance in strong magnetic fields (10–40 mT).

Microwave sources with electron-cyclotron resonance (ECR) have very high-efficiency plasma generation but a complex power supply (Alton, 1993). For widely used microwave generators with a frequency of 2.45 GHz, the ECR needs a magnetic field of 80 mT. The microwave power is guided into the discharge-chamber cavity by a waveguide and ceramic window and has created high-density plasma near the emission holes. For the production of H^+ of 0.1 A with a current density of 0.3 A/cm^2, ECR power of 0.5 kW is required.

Ion beams of different elements are generated in ECR sources for implantation. A slit extraction system is used for separation of beam components. A dielectric inert material such as BN is used for coating the wall of the discharge-chamber cavity. It is very important for long-term operation.

An improved version of ECR source with enhanced plasma electron confinement is used for high-charge ion production. A magnetic mirror trap with a high mirror ratio ($R = 3$ to 6) and an octupole or sextupole minimum-B system from strong permanent magnets has improved the stability of the plasma and increased the plasma lifetime. Krypton ions with charge Z up to 25 and thorium to 35 are formed in an ECR source ($I \sim 10^{-7}$ A) by increasing the ECR frequency to 16 GHz.

Successful generation of ions was obtained in a high-current arc discharge with a cold cathode (Belchenko *et al.*, 1990). By use of a freely expanding plasma jet and a precise multiaperture extraction system, intense beams of H^+ with very high brightness can be produced. The scheme of this arc-discharge source is shown in Fig. 17. Some fea-

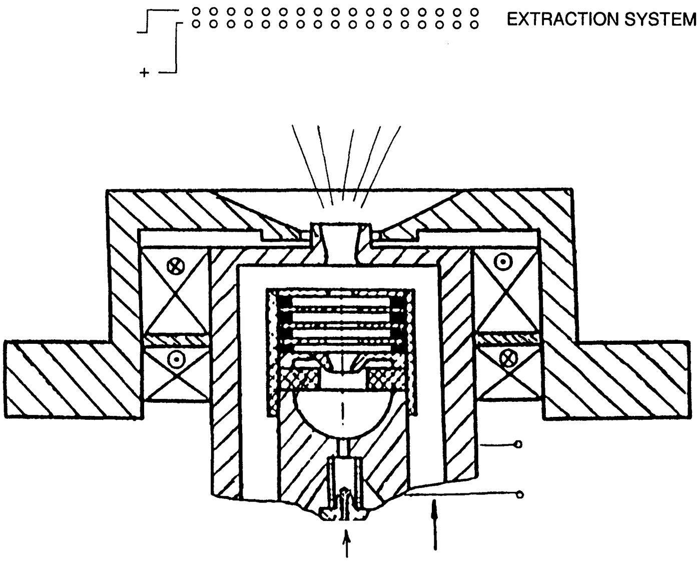

FIG. 17. Dimov arc-discharge ion source.

tures of the source are very high current density in a washed channel, $j = 3 \times 10^3$ A/cm^2; this helps to reach a high ionization coefficient (99.9%) and very high proton percent (95%). A plasma flux with a proton current up to 100 A can be reached. Plasma-jet expansion decreases the local transverse-ion temperature to the level of $T = 0.1$ eV. Normalized brightness $B = 3$ A/mm^2 mrad^2 was reached in an intense beam with energy $W = 1$–30 keV.

Intense generation of ions in the cathode spot of a vacuum arc is the basis for the metal vapor vacuum arc source (MEVVA; Brown, 1989). In the cathode spot with a diameter 10^{-3} mm and an arc current $I_d = 10^2$ A, the electron flux with a current density of $j = 10^8$ A/cm^2 produces intense ionization of the high-density cloud of vapor near the spot. The high-density cloud of plasma has a potential distribution with a maximum at the same place as the maximum of plasma density. By this potential distribution, part of the ions are accelerated to the cathode spot but another part to the anode. The anode flux of ions is formed into a beam by a multiaperture extraction system. The vacuum arc is ignited by the breakdown of an insulator surface and is supported in the vacuum during a pulse of 0.1–1 ms. Many modifications of MEVVA have been developed for industrial applications (Wolf, 1994).

Ions with charge of more than 1 ($Z = 2,3$) are formed in almost all plasma sources; but for generation of ions with significantly higher Z, it is necessary to have plasma electrons with higher energy (some tens of keV) and a long ion lifetime in the electron flux. Ions with $Z = 5,6,7$ are created in ion sources with electron oscillation by increasing the discharge voltage and by reducing the gas density (Kutner, 1994). It is easier to have higher Z in a pulsed discharge. In the electron beam ion source (EBIS), the electron beam from a thermocathode in a strong homogeneous magnetic field, with a current density $j \sim 10^3$ A/cm^2, is used for high-charge ion formation (Drentje, 1994). An ultrahigh vacuum (10^{-10} Torr), the proper quantity of ion injection into the electron beam, and programmable potential barriers near the cathode and near the exit of the electron beam to the recuperator help to retain ions for the stripping of the 35 electrons from krypton. By eliminating the potential barrier near the recuperator, multicharged ions are extracted from the EBIS. The cooling of ions by the addition of light ions improves the ionization level. In multicharged ion sources with ECR, an increase of charge is attained at the end of pulses.

Irradiation of a solid surface by a powerful laser pulse is used for multicharged ion production. Ions with $Z \sim 10$ to 15 are formed in the laser plasma jet. An ion beam is formed by a multiaperture extraction system from the plasma jet. For a CO_2 laser (10.6 μm) and pulse of 0.1 μs, an ion pulse up to 10 μs and a current of 1 A can be produced.

The brightest ion beam is produced in an EHD or liquid-metal ion source by field evaporation of ions ($E \sim 10^8$ V/cm, $j \sim 10^8$ A/cm^2) (Orloff, 1993; Prewett and Mair, 1991). For strong evaporation field formation, a sharp needle with a film of melted substance is used, and positive voltage of 3–15 kV is applied between the needle and extractor plate, which has a hole for the extracted beam. A typical distance for a needle spot-extractor is 1 mm. In simple EHD sources, the needle is welded to the filament pin and heated by dc, and a drop of melt is kept there by surface tension. The ion current is emitted after the threshold level of voltage is reached and after the melting of the working substance.

In an improved version of EHD sources, a special container for the working substance is used, and melted film flows through a small slit between the needle and the container wall (Dudnikov and Shabalin, 1992). This design can be used with a working substance of high vapor pressure and with a melted dielectric with ionic conductivity. The container-type EHD source is shown in Fig. 18. Needles from porous impregnated materials or from filaments are used for EHD ion-beam production. Ion beams from an EHD source can be focused to 0.1–0.03-μm diameter with a current density up to 5 A/cm^2. Full intensity from 0.1 to 1 mA can be reached, but ion-optic aberration for a wide-angle beam is large.

Ion sources with surface ionization evaporate as ions up to 100% of Cs, Rb, and K; up to 20% of Li; about 1% of Sr and In; and about 0.1% of Al, Ga, Tl, and Ca. For beam production, an electrode configuration similar to an electron gun is used. The ionizing vapor of elements or salts is guided to the

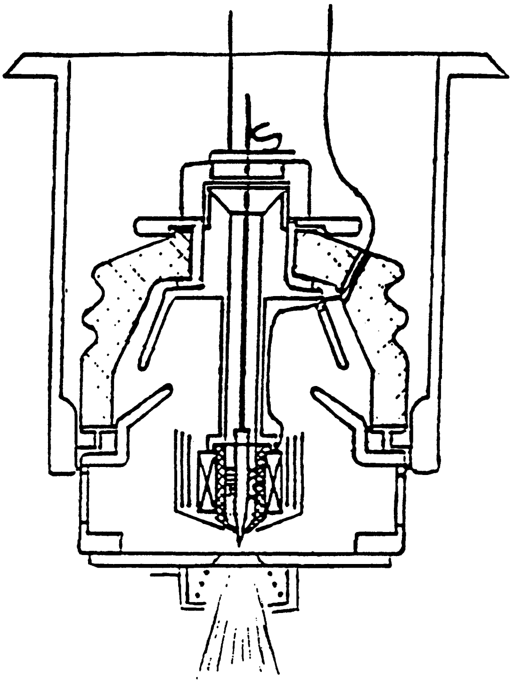

FIG. 18. Container-type EHD source showing the needles from porous impregnated materials or from filaments.

hot (>1000 °C) emitter surface of W, Ta, Mo, Ni, Rt, or Ir. Emitters of porous impregnated materials are used (Forrester, 1988; Alton, 1993).

In the emitters of aluminosilicates of alkali-metal or alkaline-earth elements, the functions of ionizer and source of ionizing substance are combined. Emission current density up to 10 mA/cm^2 and a long operation time can be reached in sources with surface ionization. Beam brightness increases with increasing current density, but operation with a strong electric field on the emitter surface increases the angular spread through the nonhomogeneity of the surface.

4.2 Negative-Ion Sources

Beams of negative ions (H^-, O^-) were registered on the first parabolic mass spectrograms of canal rays produced by J. J. Thomson in 1911. The negative ions were formed by charge exchange of positive ions, accelerated in the near-cathode potential drop of the gas discharge. The purposeful development of negative-ion sources began after a proposal by L. Alvarez in 1951 to use negative ions for multistage acceleration with charge exchange in tandem accelerators. Since that time, many versions of charge-exchange negative-ion sources with double-electron capture by positive ions have been developed; for example, see Fig. 19. As sources of positive ions are used, the following versions of sources have been modified for this application: rf and microwave, duoplasmatron, Penning-type, arc discharges, etc. As charge-exchange targets, tubes are used and a supersonic flow of gas or metallic vapor. The gas or vapor is condensed and recirculated.

In the first versions of negative-ion sources (1956), intensities were reported as high as 1–2 μA. Now the best charge-exchange sources have an H^- beam, acceptable for accelerators, with dc intensity up to 1 mA. The energy of a primary ion optimal for conversion into a negative ion is low (0.3–10 keV). For this reason, sources of primary beams with high perveance (a measure of the ratio of current to transverse space-charge–limit current) have been developed. With an arc-discharge source and a high-perveance multislit extraction system (Fig. 17), pulsed (0.2-ms) beams of H^- up to 15 mA (charge exchange in H_2, 1968) or 0.1 A (charge exchange in Na, 1972), or of He up to 10 mA (in Na) with high beam quality have been produced (Belchenko *et al.*, 1990). Later by use of a wide-aperture neutral-beam injector, H^- and D^- beams up to 10 A and He up to 1 A were obtained, but the current density of these beams is low.

Now charge-exchange ion sources are used for production of positive and negative ions with nuclear spin polarization (Schiemenz, 1992). The capture of polarized electrons from an atomic target by positive ions is used. The electron polarization of an alkali-metal atom target is produced by optical orientation (optical pumping), using circularly polarized resonant light in a strong magnetic field. The electron polarization of an accelerated atomic beam is converted into nuclear polarization by rf transition and by fast reversal of a longitudinal magnetic field (Sona transition). Nuclear polarized fast atoms are converted into negative ions by the capture of a second electron in a second target. The efficiency of conversion of H^+ into polarized H^- is $<10^{-2}$. For high-quality po-

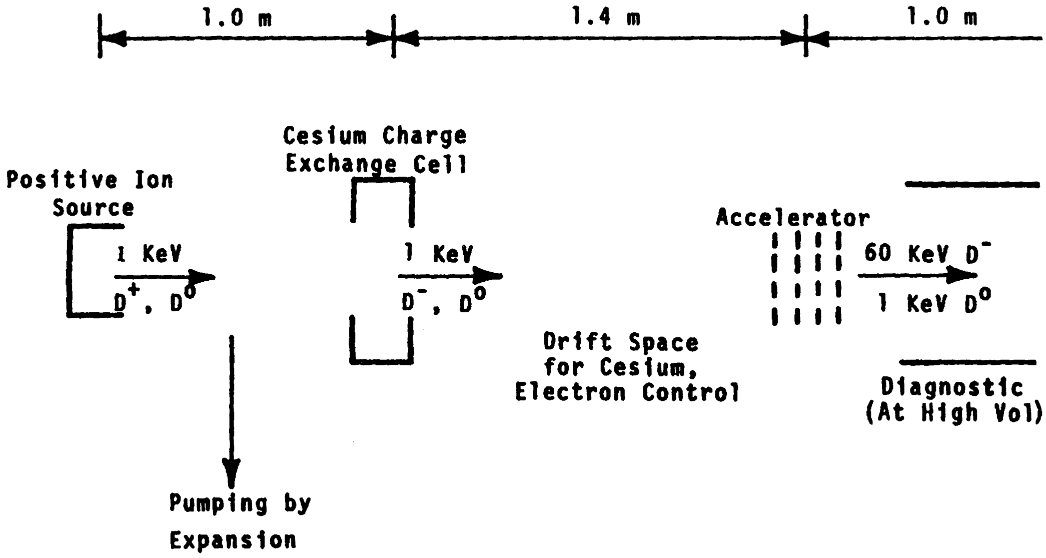

FIG. 19. Double–charge-exchange negative-ion source.

larized H^- beam production, it is necessary to have very high brightness of the primary H^+ beam.

In a plasma source, the negative ions are formed on the periphery of the discharge with reduced electron temperature (Green, 1984; Forrester, 1988). This reduces the negative-ion destruction significantly. In electron-oscillation sources, the emission slit is located a longer distance from the discharge column than in positive-ion sources. Higher gas density is required for increased negative-ion production (Forrester, 1988). Extraction perpendicular to the magnetic field is used to separate negative ions from electrons and to help reduce the escort electron flux. From a Calutron modified by K. Ehlers in 1965, up to 5 mA of H^- with $j^- \sim 20$ mA/cm² were produced. Later the H^- intensity was increased to 40 mA.

In earlier versions of a duoplasmatron, the enhancement of negative-ion generation has been achieved by a shift of the emission hole to the periphery of the discharge (I^- up to 0.2 mA, $i_e \sim 15$ mA). A further development of this idea uses a tubelike discharge around an emission hole (up to 17 mA of H^-).

Modifications of multicusp ion sources with a peripheral magnetic field are used for negative-ion production. A dipole magnetic barrier is created near the extraction system for reflection of energetic electrons from the hot-cathode discharge. This magnetic field helps to reduce the flux of escort electrons. The deflection magnetic field is created in a multiaperture, multielectrode extraction system for reducing the electron flux. From a big multicusp plasma source, up to 3 A of H^- with $j \sim 10$ mA/cm² have been extracted. The destruction of extracted negative ions in collisions with gas escaping from the source is a problem of plasma sources.

Surface ionization of negative-ion sources is similar to that for positive-ion sources, but a material with low work function ϕ, such as LaB_6, is used for negative surface ionization (Alton, 1993). The flux of the working substance is guided to the high-temperature (1000–1500 °C) ionizer surface with a low work function. The evaporated negative ions are extracted by an electric field. A magnetic field parallel to the ionization surface is used for deflection of the escort electrons to a low-potential electrode. The halogens, halides, and other elements and compounds with a high electron affinity S have been converted to negative ions by surface-ionization sources with good efficiency if $S > \phi$. The typical construction of a surface-ionization negative-ion source is shown in Fig. 20. The increase of surface electric field is enhanced by the ionization coefficient. In an EHD source with a very strong electric field

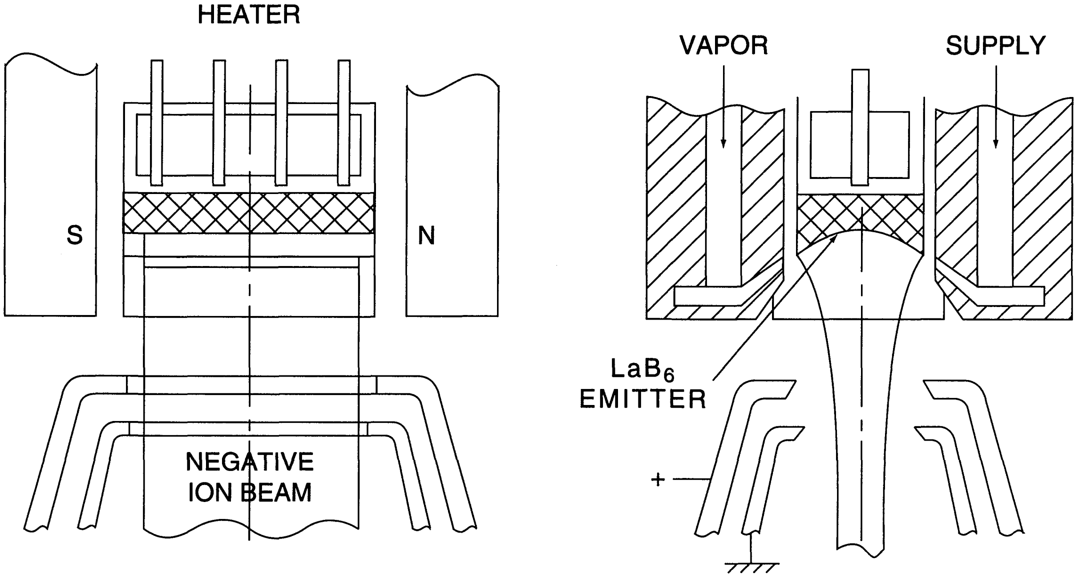

FIG. 20. Typical construction of surface-ionization negative-ion source, in two orthogonal transverse views, the left having the magnetic field in the plane of the drawing and the right having it perpendicular to the paper.

(10^8 V/cm), high–current-density negative-ion beams have been extracted from a low-melting eutectic halide compound (Dudnikov and Shabalin, 1992).

In the more universal sputtering ion sources, the emitter surface with the working substance is bombarded by ion beams of 1–5 mA and energy 5–20 keV (Alton, 1993). Bombardment by Cs^+ ions is convenient, because a compact surface-ionization Cs^+ source is commonly used. The sputtered negative ions are extracted by an electric field and focused by an emitter surface and an ion-optic system. The negative ionization of sputtered particles is catalyzed by optimal cesium deposition on the emitter surface. A large variety of sputtering negative-ion sources has been developed for application in tandem accelerators with intensity of 0.1 mA. Negative ions of almost all elements and compounds with electron affinity are produced in sputtered sources.

The most efficient negative-ion production has been achieved in surface plasma sources (SPS) with cesium catalysis (Dudnikov, 1992). The addition of a small admixture of cesium or other substances with low ionization potential decreases the surface work function and increases significantly the negative-ion emission from all types of plasma sources. But the highest efficiencies have been reached in surface-plasma sources with an electrode configuration optimized for surface-plasma production of negative ions.

The planotron (flat magnetron) was the first version of surface-plasma source (Institute for Nuclear Physics, Novosibirsk, 1971), and it is still used for accelerators and other applications. Figure 21 shows distinctive features of the planotron. This SPS consists of a spool-like cathode and racetrack anode with a small (up to 0.5 mm) gap. A magnetic field is created by magnetic poles along the gap. Plasma is generated by a glow discharge in crossed fields. Along the magnetic field, electron motion is limited by cathode reflectors. Plasma density up to 10^{14} cm^{-3} can be achieved in long-pulse discharges. The emission slit in the anode is oriented perpendicular to the magnetic field and separated from the plasma column by a gap. Cylindrical focusing of emitted negative ions by the concave surface of the cathode is used with a slit extractor, and spherical focusing is used with a circular extraction aperture. A small admixture of cesium increases the negative-ion emission up to 100 times through the reduction of the work function. An emission current density of 5 A/cm^2 was reached. Different versions of the planotron have been developed at Fermi National Laboratory, Brookhaven National Laboratory, SSCL, Ar-

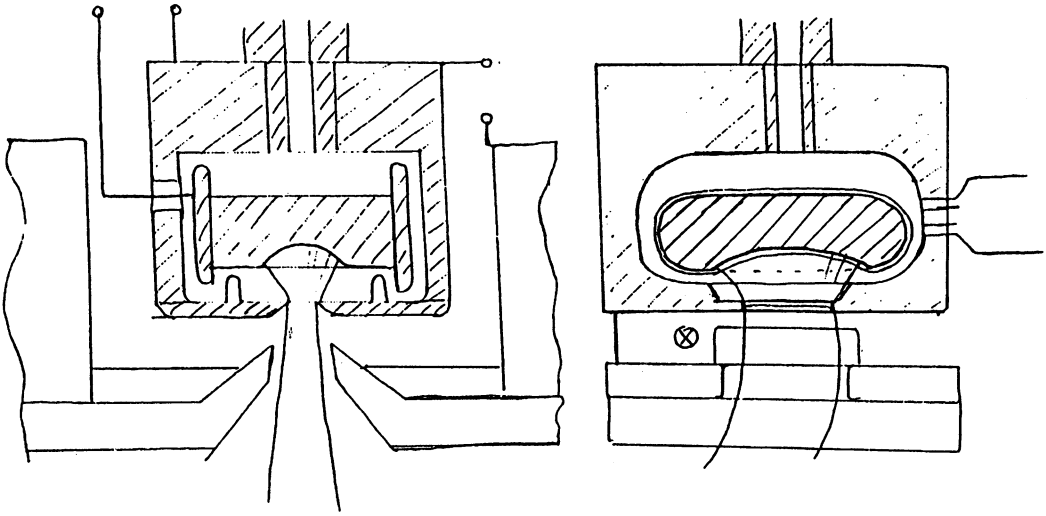

FIG. 21. The planotron (flat magnetron) showing a spool-like cathode and racetrack anode with a small (up to 0.5 mm) gap and a magnetic field created by poles along the gap, and a plasma generated by the glow discharge in crossed fields.

gonne National Laboratory, Deutsches Elektronen-Synchrotron Laborator, and others. It is important to use a high-speed gas valve for pulsed SPS operation. Precisely controlled cesium admixing is very important for long-term reproducible operation. An H^- beam of 80 mA and $\epsilon_{n(90)} = \pi$ mm mrad (normalized emittance of 90% of the beam) can be delivered to a preaccelerator by a planotron.

Another modification of the SPS, the semiplanotron (Fig. 22), is very similar to the planotron, but it uses only the front part of the discharge where plasma is drifted between the concave cathode and the part of the anode with the emission slit. Features of the semiplanotron are increased efficiency of negative-ion production and convenient cathode cooling. The semiplanotron is very good for intense, high-brightness, high–duty-factor negative-ion production.

The Penning SPS (Dudnikov-type SPS) is produced from a planotron by removal of the central plate of the spool-like cathode. A glow discharge, in a crossed field between cathode reflectors and anode, is used for plasma production. Primary negative ions are formed by secondary emission from the cathode surface bombarded by plasma particles. Thermal negative ions are extracted

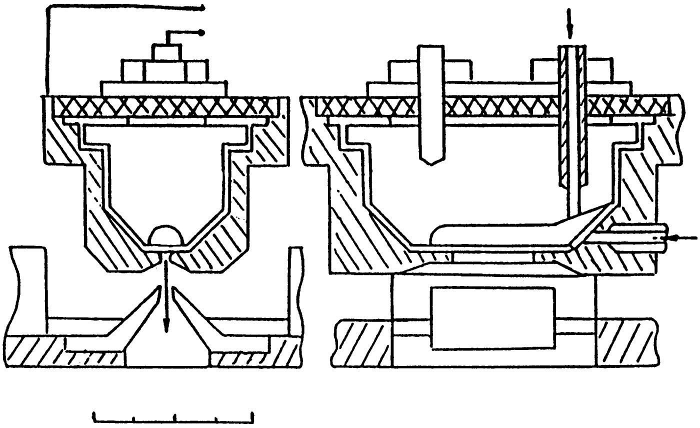

FIG. 22. A modification of the SPS-semiplasmatron, which is very similar to the planotron but uses only the front part of the discharge, where plasma is drifted between the concave cathode and the part of the anode with the emission slit.

through an emission slit after resonant charge exchange of fast negative ions with thermal atoms near the emission aperture. By this process, the negative ions are cooled to a very low temperature (less than 1 eV), and high enhancement of beam brightness can be achieved. In the Penning SPS and semiplanotron, an SPS noiseless mode of discharge can be achieved. It is very important for good negative-ion–beam space-charge compensation and high-brightness preservation during transport.

An independently developed embodiment of the cesium catalysis principle was made in 1977 by W. L. Stirling of Oak Ridge National Laboratory. It ran a $\frac{1}{2}$-A negative hydrogen beam for 30 s. This embodiment is a variant of the Calutron ion source mentioned above.

Many variants of the Penning SPS and semiplanotron with multiaperture slits and circular-hole extractor systems have been developed for production of negative-ion beams with intensity up to 11 A. Small-scale sources with spherical geometrical focusing and hollow-cathode discharge have been developed for long-term dc operation. Negative-ion beams with $j^- = 0.3$ A/cm^2 ($I = 3$ mA) were extracted during 10 h of operation.

A multicusp magnetic-wall SPS was developed at Lawrence Berkeley Laboratory (1982). This large-volume, low-pressure SPS can operate at high duty factor or dc. The source chamber is a large box or cylinder (~20 cm) with alternating polarity of permanent magnetic dipoles on the wall surface to produce a multicusp magnetic field. A negatively biased (~0.3–0.6 kV) emitter convertor is immersed in plasma. Under bombardment by plasma particles, negative ions are formed and emitted from the emitter surface. The emitter surface is curved to give geometrical focusing of negative ions to the extraction aperture. Negative-ion beams with intensity up to 1 A and $j^- \sim 10$ mA/cm^2 can be extracted from this type of SPS with emitter–extractor gap $d = 8$ cm. Cesium admixture is used for catalysis of negative-ion formation. A barium emitter surface has been used for this purpose, but with less efficiency.

A smaller version multicusp SPS has been adapted for 20-mA negative-ion–beam formation for an accelerator. This version of the SPS (Fig. 22) was optimized for heavy negative-ion production. For this application, the emitter surface must have material of heavy negative ions and heavy gas, such as Xe, Kr, or Ar, used for discharge support. Heavy negative-ion beams of up to 0.1 A in pulses and up to 0.01 A dc can be extracted. Different negative ions of elements and compounds can be produced.

Different versions of gas-discharge ion sources can be used for negative-ion production with good efficiency after any modification and addition of cesium admixture for catalysis of surface-plasma formation of negative ions.

Like an intense pulsed electron beam, an intense positive or negative pulsed ion beam can be generated by the application of a fast-rising high-voltage (near 1 MV) pulse to a diode (Bystritskiy and Didenko, 1989). For ion acceleration, a strong magnetic field is used for magnetic insulation, which inhibits the movement of electrons across the magnetic field. The first explosive emission of electrons from the cathode is initiated by electron field emission from small whiskers and evaporation of whiskers. Positive ions are emitted by the anode plasma layer, which is generated by electron bombardment of the anode. The negative-ion emission is initiated by bombardment of the cathode surface by ions from the diode gap. A prepulse is used for the generation of ions in the gap. Ion intensity up to 10^6 A with current density $(0.5–5) \times 10^3$ A/cm^2 can be reached in a pulse of 10^{-7} s.

5. CONCLUSION

The first hundred years since the discovery of the electron have witnessed a significant development in electron and ion sources. The growth of sources and beam parameters has been very active and accelerating during this time. Unexpected discoveries and inventions have opened new possibilities for improvement of electron- and ion-beam characteristics and for new applications of beams. Real nanofabrication and manipulation of single atoms are now coming into practice. The highest concentration of power densities has been achieved by use of ion and electron beams. Further development of this activity will do much to make the presently impossible become a reality.

GLOSSARY

Brightness: The specific current of particles emitted by unit surface into unit solid angle.

Brillouin Zone: The polyhedron in reciprocal space over which the electron wave vector $\mathbf{k} = \mathbf{p}/\hbar$ is allowed to vary.

Calutron: A powerful plasma ion source with hot cathodes, gas discharge with electron oscillation in a strong magnetic field, and transverse extraction of the ion beam, developed by Lawrence for isotope separation.

Cathode Rays: The flux of electrons emitted from the cathode in low-pressure discharges.

Cesium Catalysis: The significant enhancement of negative-ion formation in gas discharges by the addition of a small admixture of cesium or other substances with low ionization potential, decreasing the electrode work function.

Child–Langmuir Law: The equation for space-charge–limited current density in a vacuum diode.

Cluster: A compound particle consisting of several atoms or molecules weakly bonded together.

Electron Affinity: The binding energy of the additional electron in a negative ion.

Electron Cyclotron Resonance (ECR): Resonance absorption of electromagnetic radiation by electrons in a static magnetic field when the electromagnetic frequency is equal to the cyclotron frequency of the electrons. It is a most powerful method of heating electrons to a high temperature.

Emittance: A measure of the volume in phase space occupied by a beam, indicative of the reciprocal of the quality of the beam.

Explosive Emission: The emission of a high-density electron flux from a high-density plasma layer generated by whisker explosion through field emission in a strong electric field.

Fermi Level, Fermi Energy: The value of the energy that separates occupied from empty states in the conduction zone in the limit as $T = 0$.

Fermi Surface: The surface of constant energy in electron momentum space, corresponding to the Fermi level in a crystal.

Field Emission (Autoelectronic Emission, Tunneling Emission, Cold Emission, Field Evaporation): The emission of charged particles by tunneling from the solid surface to the potential well created by a strong electric field.

Forbidden Zone (Gap): The difference in energy between the top of the occupied band and the bottom of the conduction (partially occupied or empty) band.

Ionization Potential: The smallest potential difference necessary for electron acceleration to produce atom or molecule ionization. Equal to the binding energy of an electron in the atom or molecule.

Optical Pumping: The transfer of spin polarization from circularly polarized photons to the electrons in atoms or a solid.

Oxide Cathodes: The most widely used cathodes, consisting of thick layers of oxides—BaO, CrO, or CaO—on a nickel base.

Penning Discharge: A low-pressure gas discharge with oscillation of electrons along the anode tube in a magnetic field between two cold cathodes.

Perveance: Beam current divided by $\frac{3}{2}$ power of acceleration potential; used as a measure of the ratio of current to the transverse space-charge–limited current.

Photoelectric Emission (Photoeffect): The emission of electrons initiated by the absorption of photons.

Polarized Electrons, Polarized Atoms or Ions: Particles with an increased probability of electron or nuclear spin projection along a particular direction.

Quantum Yield: The average number of photoelectrons emitted on absorption of one photon.

Schottky Effect: The increase of thermionic electron or ion emission by a strong electric field at the surface of the emitter.

Secondary Emission: The emission of electrons or ions initiated by bombardment with electrons, ions, excited or fast atoms, etc.

Surface-Plasma Sources (SPS): Ion sources with negative-ion formation by the interaction of plasma particles with electrode surfaces in gas discharges.

Thermionic Emission: The emission of electrons or ions from a solid heated to a high temperature, taking place by the "evaporation" of the particles.

Thermionic Emission Converter: A power supply for conversion of heat into electricity by emission of electrons from a cathode with higher work function and collection of them by an anode with lower work function.

Work Function: The energy difference between the vacuum energy level of an electron and the Fermi level in a solid; the evaporation energy of an electron.

INTRODUCTION

In the modern world, science and technology have developed a symbiotic relationship with one another. It is usually assumed that all scientific discoveries will eventually lead to some new or improved technologies. It is also commonly assumed that the successful development of technology requires a knowledge of science and mathematics. There is also some awareness that developments in technology have led to new advances in science. But this continual interaction between science and technology, which has come to characterize the modern industrial world, is of relatively recent origin, dating back only some two hundred and fifty years.

Throughout most of history, science and technology followed different social and intellectual traditions and, with a few exceptions, had little impact on each other (Layton, 1974). Since classical times, science was closely associated with philosophy. As a form of natural philosophy, science was concerned with asking and answering philosophical questions such as, what is the ultimate nature of reality? With the goal of generating new knowledge about the world, science put little or no emphasis on using such knowledge to solve practical problems. Scientists used mathematical, geometrical, and other rational methods in order to idealize problems so that their solutions could be universally applied to the description of nature as a whole. Scientific knowledge, the result of contemplation, was also associated with the elite, and after the establishment of universities during the Middle Ages, most scientists had university educations. Finally, knowledge of science was gained and disseminated through a written tradition of treatises, textbooks, and journals.

Historically, technology was practical ac-

tivity concerned with asking and answering questions about what should be done in particular situations. The goal of technology was to develop workable solutions to practical problems. Engineers traditionally used cut-and-try empiricism and rule-of-thumb techniques that, while applicable to specific situations, could not be generalized to a wide class of problems. Before the late eighteenth century, few mechanics or engineers had formalized educations or university training; technology was the province of an artisan class. Knowledge of technology, which resulted from observation and experience, was gained through an apprenticeship system and disseminated through direct contacts between master and pupil. Very little technological knowledge was written down.

During the eighteenth and nineteenth centuries, new research and pedagogy arose in such areas as applied mechanics, the strength of materials, the theory of machines, thermodynamics, heat transfer, hydrodynamics, electromagnetism, and optics. This led to a new scientific approach to technology that could not be easily classified in terms of the traditional categories of science/technology or theory/practice. By the nineteenth century, this new research and pedagogy had become institutionalized in engineering schools, technical institutes, research laboratories, and professional societies, and by the second half of the century, it was becoming more and more common to refer to this range of activities under the terms engineering science or applied physics.

1. EARLY INTERACTIONS BETWEEN SCIENCE AND TECHNOLOGY

1.1 Greek Mechanics

Although a sustained and institutionalized scientific approach to technology dates back only some two hundred and fifty years, there was a long but sporadic history of interactions between science and technology that would pave the way for the emergence of engineering science and applied physics (Clagett, 1963). While the Greeks' interest in ideal philosophies, such as that of Plato, and their dependence on slavery led them to emphasize the creation of scientific and mathematical theories over the practical development of technology, the Greeks did make some important contributions in applying their scientific knowledge to technology. Beginning as early as the fourth century B.C. the Greeks were undertaking a systematic study of mechanics based on mathematical principles. Such studies would establish a scientific basis for understanding technology. The pseudo-Aristotelian work *Mechanical Problems* (ca. 280 B.C.) described the law of the lever and used the law to explain such practical things as rowing a ship and throwing a rock from a sling. There is also evidence that Euclid provided one of the earliest geometrical proofs of the law of the lever in his *Treatise on the Balance* (ca. 300 B.C.). He also conducted some early studies on optics, dealing with the problem of perspective.

Some of the most important work in the application of science to technology was done by Archimedes, who combined an interest in mathematics with a background as a practical inventor (Drachmann, 1962). Through his mathematical studies of the lever, including the case of unequal arms, his work determining the centers of gravity of plane and solid figures, and his geometric study *On Floating Bodies* (ca. 250 B.C.), which led to the famous "principle of Archimedes" concerning the weight of submerged bodies, he provided a new understanding of the basic theory of machines by reducing statics and hydrostatics to rigorous propositional disciplines. He also conducted some studies on optics and mirrors.

During the Hellenistic period, work on applied mechanics continued (Drachmann, 1948). Ctesibius experimented with air and water pressure, leading to his inventions of a forced pump, a water organ, and a water clock. Philo of Byzantium developed empirical ballistics formulas for artillery and described an early thermoscope that could represent differences in temperature of a fluid. The most extensive treatises on applied mechanics were produced by Hero of Alexandria, who probably derived many of his ideas from Ctesibius and Philo. In his book *Mechanics* (first century A.D.), Hero analyzed the five simple machines (wheel and axle, lever, pulley, wedge, and screw) in terms of a given weight moved by a given force. Hero's book *Pneumatics* described a number of inventions and devices operated by water, air, or steam (Hall, 1973). Most of these devices were simple playthings or automata, but they were based on a rather sophisticated theory that argued that small portions of vacuum could be interspersed between small pieces of matter. In a book entitled *On the Dioptra,* Hero described a surveying instrument combining elements of the theodolite and the level, and he showed how it could be used in engineering problems such as boring a tunnel.

1.2 Chinese and Muslim Mechanics

Both the Chinese and the Muslims made important contributions to the advancement of science and technology. While in most cases the two areas were independent of one another, there were some instances where the barriers between theoretical and empirical studies were overcome. During the Warring States period in China (480–221 B.C.), the philosophy of Mo Ti led his followers to conduct experimental studies that led to empirical rules concerning the reflection of light from concave and convex mirrors and rules concerning the functioning of levers and pulleys. Chinese interest in alchemy may have contributed to the casting of iron, studies of the magnet, and the invention of paper during the Han dynasty (202 B.C.–220 A.D.), as well as the creation of gunpowder during the Thang dynasty (618–906 A.D.). Studies of astronomy undoubtedly led to Su Song's creation of one of the earliest astronomical clocks in the 1080s (Needham, 1954, 1970).

The Muslim world benefited from contacts with both Greece and China. Arab scholars in Baghdad translated and extended Greek and Hindu scientific and philosophical works and made significant advancements in the area of mathematics (Nasr, 1968). Research into pneumatics, stimulated by the translation of Hero's works, probably contributed to the development of various mechanical devices such as fountains and automata. The astronomical work of Ptolemy influenced the development of astronomical clocks about the same time as they were developed in China, althought it is unclear if there was any direct connection between the two inventions (Hill, 1984).

1.3 Medieval Mechanics

During the Middle Ages, much more emphasis was placed on technological development than had been during the period of the Greeks. But the bulk of the Greek science and mathematics that had been taken over and extended by Islamic scholars only began to become available to the Latin West after the twelfth century. With the translation of Greek scientific and philosophical texts, particularly the works of Aristotle, science began to play more of a role in technological development (Clagett, 1959). Aristotle had argued that nature and *techne* function in similar ways. In fact, he believed that nature provided the forms that technology was to imitate.

In the first half of the twelfth century, there were attempts to connect the practical arts with the seven liberal arts. Hugh of St. Victor, Director of the School of St. Victor in Paris, argued that there were seven mechanical arts—weaving, weapon foundry, navigation, agriculture, hunting, medicine, and acting—that paralleled the seven liberal arts of grammar, dialectic, rhetoric, arithmetic, geometry, astronomy, and music.

The translation of Greek science from Arabic and the establishment of universities led to a new spirit of experimentation. At Oxford, Robert Grosseteste argued that natural philosophy had to be based on mathematics and experimentation. His treatise on optics suggested that lenses could be used to magnify small objects. Roger Bacon, who was Grosseteste's successor, continued the experimental tradition. He conducted experiments on the magnifying effects of lenses and the optical properties of parabolic mirrors. His experimental studies led Bacon to suggest that telescopes, self-propelled boats, submarines, and flying machines could be constructed.

One of the leading experimenters of the thirteenth century was Pierre de Maricourt, who argued that manual skill was important in order to correct errors, which could not be done with a knowledge of natural philosophy alone (Gimpel, 1976). In his *Epistolae de Magnete,* he described an experimental study of the magnet and suggested several practical applications. This work paralleled work that had been done earlier in China, but it is unclear if Maricourt knew of such work, either directly or indirectly. Using a spherical lodestone and small iron wires, he discovered magnetic meridians, and he described the use of a compass to find directions. He also noted the laws of magnetic attraction and repulsion and used that knowledge to attempt the construction of a perpetual motion machine in which a magnetic arm would be forced to revolve in a circular path through the alternate attraction and repulsion of other magnets.

The combination of an experimental with a rational spirit could also be seen in two major technological achievements of the Middle Ages—the Gothic cathedral and the weight-driven mechanical clock. Beginning in the twelfth century with the building of St. Denis near Paris, the new Gothic style of cathedral began to spread throughout Europe (Mark, 1982). The application of rational and experimental techniques in these buildings can be seen in the notebooks of the thirteenth century engineer-architect Villard de Honnecourt, who outlined a practical geometry for stone cutting, carpentry, surveying, construction, and bridge building. During the thirteenth and fourteenth centuries, the development of a weight-driven mechanical clock, indirectly influenced by earlier Chinese and Muslim devices, by such people as Giovanni di Dondi and Richard of Wallingford reflected a desire to imitate the motion of the heavens by mechanical means (Price, 1964).

2. THE EARLY MODERN PERIOD

2.1 The Renaissance

Although there were examples of the interaction between science and technology during the medieval period, these instances were limited by the small amount of Greek science that had been translated into Latin, the dogmatic position of the medieval Catholic Church when it came to conflicts between faith and reason, and the rather rigid social distinctions that existed between the scholar and the craftsman that arose from barriers between the universities and the guild systems. During the period of the Renaissance in the fifteenth and sixteenth centuries, many of these limitations on the interaction of science and technology began to disappear. New translations of Greek texts, including the works of Plato, Euclid, Archimedes, and the Greek atomists, began to appear. The Protestant Reformation began to undermine the authority of the Catholic Church, and the barriers between the scholarly and craft traditions began to break down.

Renaissance artist-architect-engineers provided new connections between theory and practice. For example Filippo Brunelleschi, the designer of the dome on Santa Maria del Fiore in Florence, combined interests in hydraulics, mechanics, construction, gold smithing, sculpture, and perspective (Prager and Scaglia, 1970). Leon Battista Alberti, who helped to introduce fixed-point perspective into painting, developed a theory of construction that combined the use of mathematical proportion with experimentation (Ferguson, 1977). He showed that in designing bridges, floating material could be used to determine what parts of the river flowed most swiftly so that the piers could avoid those locations. Franceso di Giorgio Martini, another well-known artist, conducted experiments on guns and cannons to discover the relationship between the amount of gunpowder and the weight of the projectile (Reti, 1963). One of the most important artist-engineers was Leonardo da Vinci who used both theory and experiment in his study of engineering. He conducted experiments on small-scale structures in order to discover formulas that connected the strength of pillars and beams with their thickness and length. The recent discovery of the *Madrid Codices* of Leonardo indicates that he was attempting a systematic study of machines by distinguishing and analyzing the function of individual mechanisms within different types of machines, rather than treating each different machine as unique (Reti, 1974).

2.2 The Scientific Revolution

During the period of the Scientific Revolution in the sixteenth and seventeenth centuries, new scientific theories and discoveries led to further interactions between science and technology (Hall, 1983; Jacob, 1988; Lindberg and Westman, 1990). In universities such as Padua, the medical faculty came into a position of dominance over the divinity faculty, and with this change more attention was paid to the scientific works of Aristotle rather than his logical works. This led to a new interest in observation, experimentation, and practical applications of science. On the other hand, the translation of Plato during the fifteenth century contributed to a new interest in the development of mathematical theories of science and technology. These two different approaches were brought together in the emergence of a magical or Hermetic approach to nature (Yates, 1979). Although rejected by most scientists and engineers today, Hermeticism strongly influenced many people such as Copernicus, Kepler, and Newton. This approach to nature led to the view that knowledge in general, and science in particular, was a tool that could be used to manipulate the forces of nature for some practical purpose. For example, in his preface to the first English translation of Euclid, John Dee, a possible model for Shakespeare's Prospero, argued that science and such practical activities as architecture, hydraulics, mechanics, and navigation were all governed by principles of geometry, which he saw as a form of mathematical magic (Dee, 1975). Giambattista della Porta, author of *Natural Magick* (1658), saw magic as explaining both scientific and practical activities. His book included discussions of astrology, alchemy, distillations, optics, metallurgy, magnetism, and mechanics.

The recognition of a new relationship between science and technology was put forward in the seventeenth century by Francis Bacon, who argued that the goal of science was not just knowledge, but knowledge that would allow humans to exert power and control over nature (Rossi, 1970). Bacon foresaw a new technological form of science. In his *New Atlantis* (1628), he described an institution called Solomon's House in which group research was conducted and aimed at improving engines, machines, cannons, clocks, ships, and other elements of technology. Although Bacon's goal of a technological science was not realized in his lifetime, his view influenced the founding of the Royal Society of London in 1662, and it foreshadowed the emergence of the industrial research laboratory in the twentieth century.

While some new theories emphasized how science could be applied to practice, other theories focused on how technology could be used to explain science. In the sixteenth century, beginning with René Descartes and continuing with Pierre Gassendi, Thomas Hobbes, Robert Boyle, G.W. Leibniz, and Isaac Newton, there emerged a mechanical philosophy in which all of nature was seen to function like a gigantic machine or clockwork mechanism. This encouraged scientists to turn their attention to technology if they were to understand how the natural world functioned (Dijksterhius, 1961).

2.2.1 Mechanics These new mathematical-experimental theories led to some significant interactions between science and technology (Drake and Drabkin, 1969). One of the most important was in the area of mechanics. During the sixteenth century, following on the work of some artist-engineers, Nicola Tartaglia showed how impetus and gravity acted together on a projectile causing it to follow a curved path. He was also able to show, through a mixture of experiment and mathematics, that the maximum range of a cannon would take place when it was elevated at an angle of 45°. Another leading contributor to the science of mechanics was Simon Stevin, who was one of the earliest people to discover the resultant action of two noncollinear or nonparallel forces. He also contributed to a new understanding in ship building by extending Archimedes's principle of buoyancy, showing that the center of gravity of a floating body was in the same line as the center of gravity of the displaced fluid.

One of the leading figures in the creation of modern mechanics and its connection to the practical arts was Galileo Galilei, who studied at the University of Padua and gained practical experience in the Venetian Arsenal. Although best known for his support of the Copernican system and his subsequent trial, Galileo (1633) also helped to establish modern mechanics in his work *Discourses on Two New Sciences*. Galileo began this work with a discussion of the scale effect by showing that if a machine were doubled in size by simply doubling all of its dimensions, it was likely to fail since its weight would increase eight times while the strength of the individual parts would increase only four times. He continued with a discussion of how to calculate the load that a beam fixed at one end could support, if loaded at the other end. Following Tartaglia, Galileo was able to show that a projectile fired from a cannon would follow a parabolic path.

Galileo also conducted experimental and mathematical studies of the pendulum and suggested that a clock regulated by a pendulum would be more precise than clocks regulated by the verge and foliot. A few years later, Christian Huygens, working with a clockmaker, constructed the first pendulum clock. Through his work on the pendulum, Huygens was able to deduce the law of centripetal force. Such a law played a significant role in Isaac Newton's formulation of a universal theory of gravitation (Westfall, 1980), in his *Principia Mathematica* (1687). Although Newton's work was primarily theoretical, his formulation of mechanics, based on his mathematical definition of force, provided the basis for a rational study of technology during the eighteenth century.

2.2.2 Pneumatics and Steam A second area in which there was a significant interaction between science and technology during the Scientific Revolution was pneumatics, which was stimulated by a renewed interest in the work of Hero of Alexandria and the practical problem of pumping water from mines. Miners had noted for some time that there was a limit to the distance that water could be raised by suction. Such figures as Giambattista della Porta, Giovanni Branca, and Salomon de Caus wrote books on pneumatics describing pumps, fountains, and steam-powered devices. In the middle of the seventeenth century, Gasparo Berti, Evangelista Torricelli, and Blaise Pascal conducted experiments with columns of water and mercury that established that the weight of the atmosphere exerted a pressure that could support a column of mercury. About the same time, Otto von Guericke in Germany began a series of experiments using his newly invented air pump to create a vacuum (Guericke, 1962). By creating a vacuum in a cylinder fitted with a piston, he was able to show that the pressure of the atmosphere could do mechanical work by moving the piston to the bottom of the cylinder.

Guericke's work influenced work in England where Robert Boyle and Robert Hooke made improvements on the air pump and used it to determine that the pressure of a given amount of air varied inversely with its volume. In Paris, the Dutch scientist Christian Huygens and his assistant Denis Papin constructed an apparatus similar to von Guericke's, but instead of an air pump it used a small amount of gunpowder in an attempt to force air out of the cylinder. Later Papin moved to England where he served for a time as Boyle's assistant. While in England, Papin experimented with steam and suggested that condensing steam could be used to create a vacuum in a cylinder. Using a small apparatus he was able to demonstrate that steam at high pressure could be used to raise a piston while condensing steam could lower it again. By the beginning of the eighteenth century these ideas would come together in the invention of the steam engine.

2.2.3 Optics The third area in which there was a significant interaction of science and technology during the Scientific Revolution was in the field of optics (Lindberg, 1976). Renaissance artists' use of perspective had encouraged a study of optical phenomena. At the beginning of the seventeenth century lens makers in Holland, such as Hans Lippershey and Zacharias Jansen, began to develop more powerful instruments by combining lenses in order to form telescopes and microscopes. The telescope became famous as an astronomical instrument after Galileo used it to observe the sun and planets providing him with empirical evidence to support the Copernican theory. Galileo also used a microscope to study insects. This work was followed by Robert Hooke in England and by Antoni Leeuwenhoek in Holland.

The invention of the telescope and microscope led to new theoretical and experimental studies in the area of optics. Johann Kepler, who designed some telescopes, conducted experimental studies on the laws of refraction. A mathematical formulation of the law of refraction was put forward by Willebrord Snell in 1621. During the seventeenth century, different theories were put forward concerning the nature of light. Descartes believed that light consisted of small particles, while Huygens put forward a wave theory of light. The experimental and theoretical studies on light culminated in the work of Isaac Newton and the publication of his *Opticks* (1704). Defects with telescopes led him to begin a study of optics that resulted in his design of a reflecting telescope and later to experiments with prisms in which he was able to resolve white light into the spectrum. Newton adopted a corpuscular theory of light, but he also maintained some aspects of a wave theory by assuming that moving particles of light could cause vibrations in the surrounding aether.

3. THE EIGHTEENTH CENTURY

3.1 The Industrial Revolution

During the eighteenth century, there were significant advances in the development of technology, particularly in Great Britain, that have been called the Industrial Revolution. The production of iron using coke rather than charcoal, the invention of the steam engine, the mechanization of the production of textiles, the expansion of the network of canals, and the centralization of production in the factory system dramatically transformed eighteenth-century society. Although most of the technological advances that contributed to the Industrial Revolution owed little dependence to science, there were an increasing number of interactions between science and technology that set the stage for a formalized relationship between the two areas.

Developments that had taken place during the Scientific Revolution did have some impact on eighteenth-century technology. At the very end of the seventeenth century, Thomas Savery of Dartmouth, England, designed a steam-powered pump based on an idea put forward by della Porta. The so-called miner's friend used condensing steam to create a vacuum that raised water from a mine by suction. By 1712, Thomas Newcomen, an English ironmonger and blacksmith, brought together the ideas of von Guericke, Huygens, and Papin to construct the first workable steam engine, which used condensing steam to raise and lower a piston (Cardwell, 1963). There is still considerable debate concerning how much Newcomen's invention owed to science, but it does seem possible that he knew of Papin's work and that he was in correspondence with Robert Hooke.

3.2 Rationalism and Experimentalism

The greatest impact of science on eighteenth-century technology was in the emergence of a rationalistic–experimental approach that drew heavily on the scientific method. In France, Antoine Parent developed a theory of the efficiency of machines through the use of Galilean mechanics, and he was one of the first to apply differential calculus to engineering problems (Parent, 1700). Although his application of his theory to an analysis of waterwheels contained several errors, it stimulated a new approach to the study of machines.

3.2.1 Waterwheels The new approach to machines was continued in England by John Smeaton, who has been called by some the first modern engineer. He was influenced by Newton's *Principia* and combined its rules of reasoning with an experimental approach to technology. Smeaton's most famous work was his study of waterwheels. With the increasing demands for water power brought about by the growth of the textile industry, there was a debate concerning whether the overshot or undershot waterwheel was more efficient (Reynolds, 1983). During the middle of the century, Smeaton constructed a small model waterwheel that could function as either an overshot or an undershot wheel. By varying the speed of the water and the speed of the wheel, he was able to show that an overshot wheel was the most efficient.

At the same time, several scientists, such as Jean and Daniel Bernoulli and Jean d'Alembert, began to develop a theory of hydrostatics and hydrodynamics and applied these theories to practical problems. Bernard Forest de Bélidor, in his widely influential *Architecture hydraulique* (1737–1753), attempted to calculate the efficiency of waterwheels but wrongly concluded that undershot wheels were more efficient. Not long after, Johann Albrecht Euler theoretically established, through the use of rational mechanics and the use of *vis viva* (mv^2), that the overshot wheel was more efficient than the undershot (Euler, 1754). Many of these same scientists, such as Daniel and Jean Bernoulli, Pierre Bouger, Henri-Louis Duhamel du Monceau and Leonhard Euler applied mechanics and higher mathematics to the study of ship design, propulsion, and stability (Prichard, 1987).

3.2.2 The Steam Engine The new rationalistic–experimental approach to technology also led to significant improvements in the steam engine during the second half of the eighteenth century (Cardwell, 1971). After his work on the waterwheel, Smeaton conducted an experimental study of the Newcomen engine by building small model engines in which he could vary different factors such as the size of the cylinder, the size of the boiler, and the number of strokes per minute. Through these tests, he was able to improve dramatically the efficiency of the engine.

The most significant improvements in the steam engine were made by James Watt. As instrument maker at the University of Glasgow, he began a study of the inefficiencies of a small model Newcomen engine. Through a series of experiments on the engine and on the properties of steam, he realized that for the engine to work efficiently the cylinder had to be hot when the steam entered and cold when the steam was condensed. It was not efficient for one cylinder to be at two temperatures but if a second cylinder were added, a separate condenser, the engine would be much more efficient (Channell, 1974). There has been much speculation that Joseph Black's concept of latent heat was crucial in the improvement of the steam engine, but Watt, although a friend of Black's, denied that his work played any important role. Most historians now agree that it was Watt's broad knowledge of the laws of heat and his use of the scientific method, rather than the concept of latent heat, that led to the improvement of the steam engine.

3.2.3 Electricity The design of new devices and instruments led to scientific and technological advances in the area of electricity (Heilbron, 1979). In the seventeenth century, Otto von Guericke constructed a revolving sulfur globe that would build up a static electrical charge when it rubbed against a dry hand or piece of cloth. Static electrical machines were improved during the eighteenth century, using disks of glass revolving between carpetlike material. The study of static electricity advanced when the Dutch scientist Pieter van Musschenbroek invented the Leyden jar, which served as a condenser for static electricity.

Using these new devices, Benjamin Franklin, in colonial America, began a series of electrical experiments that led him to reject the old notion that there were two different types of electrical fluid and to argue instead for a single fluid in which an excess of fluid would result in a positive charge and a deficit of fluid would result in a negative charge (the exact opposite of the modern definition). One of Franklin's most significant accomplishments was his famous kite experiment in 1752 that demonstrated that atmospheric lightning was an electrical phenomenon. This knowledge led Franklin to the important invention of the lightning rod, which was able to protect structures against destruction from lightning.

During the middle of the eighteenth century John Mitchell at Cambridge used a magnet suspended from a string to show that magnetic repulsion obeyed an inverse square law. A few years later Joseph Priestley concluded that electrical force followed an inverse square law, on the basis of the fact that a charge inside a cavity was not affected by an electrical charge on the outside of the hollowed body. Between 1785 and 1789 Charles A. de Coulomb used a torsion balance to show that the attractive and repulsive forces of electricity and magnetism followed an inverse square law and were similar to Newton's gravitational force.

3.3 Institutions

One of the most important developments in the interaction between science and technology was the emergence of the idea that a scientific approach to technology could be institutionalized in a new form of scientific and technical education (Artz, 1966). As early as the seventeenth century, Jean-Baptiste Colbert, chief finance minister to Louis XIV, argued that French manufacturers and mercantilists would benefit from educational reform. At a time when higher education emphasized theology and the classics, Colbert proposed establishing a number of academies to teach the scientific and mathematical basis of such practical subjects as road and bridge building, fortification, design, navigation, and manufacturing. Although few of his plans were actually realized during his lifetime, the establishment of the *Académie des Sciences* being one of the few exceptions, his ideal continued and came to fruition in the eighteenth century.

Throughout Europe during the eighteenth century, government involvement in mercantile and military projects led to the establishment of new schools to provide engineers for the state. In France, the *Corps des Ponts et*

Chaussées was created in 1716 and led to the establishment of the *École des Ponts et Chaussées* in 1747, as a school to train engineers for the Corps (Brunot and Coquand, 1982). At about the same time, military schools at La Fère and Mézières were established as was the *École des Mines,* all of which taught engineering subjects. In Hungary, the state helped to create a mining school at Schemnitz in 1735, which later became the Royal Hungarian Mining Academy, while in Saxony the *Bergakademie* at Freiberg was established in 1765. These schools combined practical studies in technology with courses on chemistry and geology, Freiberg becoming particularly well-known because of the geology lectures of Abraham Werner. Although England lagged behind the Continent in establishing engineering education in the eighteenth century, John Smeaton, concerned over the developments in France, helped to form the Society of Civil Engineers in 1771 in order to give some formal structure to the training of engineers. Also in England, industrialists and scientists, such as James Watt and Joseph Priestley, came together in the Lunar Society of Birmingham in order to exchange ideas (Schofield, 1963).

These institutions reflected an attempt to develop a new scientific approach to technology. In France, Bernard Forest de Bélidor, a professor at the artillery school at La Fère, published a book entitled *La science de ingénieures* (1729), which was notable as one of the first uses of the term engineering science. It was in the engineering schools of France that some of the first elements of what would be called engineering science emerged. Jean Rodolphe Perronet, director of the the *École des Ponts et Chaussées,* pioneered a scientific approach to bridge building by designing a testing machine in order to determine the strength of stone for use in bridges (Perronet, 1782–1789). A short time later, Charles de Coulomb, a graduate of the military school at Mézières, used mathematical studies of maxima and minima to solve problems of bending beams, the construction of vaults, and the pressure against earthwork walls (Heyman, 1972). These experimental and theoretical studies culminated in Pierre-Simon Girard's *Traité analytique de la résistance des solides* (1798), which was one of the first texts on the subject. Also at the same time the mathematician Gaspard Monge, while teaching at Mézières, developed his system of descriptive geometry, which allowed for the graphic solution to a wide range of engineering problems (Monge, 1799). Many of the graduates of these engineering schools, such as Jean Charles Borda, Lazare Carnot, and J. V. Poncelet, would make significant contributions to science and technology during the nineteenth century.

4. THE NINETEENTH CENTURY

4.1 The Rise of Engineering Science

Although an important and institutionalized interaction between science and technology began to emerge in the second half of the eighteenth century, it did not have a significant impact until the nineteenth century. Much of the technology that contributed to the Industrial Revolution was, for the most part, based on traditional skills and craftsmanship rather than on engineering science. But the new technologies, and the increased scale of traditional technologies, that resulted from the Industrial Revolution helped to establish engineering science as a necessary part of scientific and technological development, and in the process helped to bring about its autonomy from pure science (Layton, 1971).

With the development of the steam engine, railroads, ocean-going iron-hulled ships, large-scale suspension bridges, and the electrical telegraph, it became impractical and uneconomical for engineers to rely on traditional rule of thumb or trial and error. At the same time scientists, who were interested in the practical applications of science, were beginning to discover—what most engineers had already known—that many of the laws of science were not directly applicable to technology. Newtonian mechanics might explain the forces acting between two atoms but it did not help to determine how an iron beam might act under a complex load. Boyle's law explained the relationship between pressure and volume in an ideal gas but was of little use in describing how steam acted in a working steam engine. The Bernoulli equation or the Navier-Stokes equations of classical hydrodynamics had limited application in describing real fluids undergoing nonlaminar flow. Finally, Ohm's law or Maxwell's equations, in their scientific form, were of limited use in the study of real electrical circuits, telegraph cables, and dynamos.

One of the most important developments in the emergence of engineering science took place at the end of the eighteenth century with the establishment in Paris of the *École polytechnique* in 1794–1795 (Fourcy, 1987; Shinn, 1980). The school, designed to train both military and civil engineers, represented a new recognition that these two branches of engineering rested on the same principles. At the *École polytechnique,* all areas of technology were based on a core curriculum of geometry, trigonometry, physics, chemistry, mechanics, laboratory, and shop work. Some of the most famous mathematicians, scientists, and engineers, including J. L. Lagrange, Simon Laplace, A. L. Cauchy, G. Coriolis, J. M. C. Duhamel, G. Lamé, G. Monge, C. L. M. H. Navier, S. Poisson, J. V. Poncelet, G. de Prony, and Lazare Carnot, taught at the school. Through their work, a theoretical approach to technology emerged based on mathematical techniques and a scientific methodology that could be formalized in written treatises and articles.

The *École polytechnique,* by providing a new model for scientific and engineering education, helped to spread a scientific approach to technology to other countries. The school's organization and curriculum influenced Austrian polytechnics at Vienna and Prague, and German polytechnic schools at Karlsruhe, Munich, Dresden, Stuttgart, and Hanover. In the United States, the Military Academy at West Point and Rensselaer Polytechnic Institute, two of the earliest American engineering schools, introduced methods and textbooks that had originated at the *École polytechnique.* Many of the leading engineer-scientists of the nineteenth century, including Ferdinand Redtenbacher, Otto Mohr, Franz Grashof, Friedrich Clebsch, August Föppl, and Ludwig Prandtl, were associated with these polytechnics.

4.2 Applied Mechanics

4.2.1 Strength of Materials

During the nineteenth century, the development of engineering science led to significant new interactions between science and technology. In the area of applied mechanics, a great deal of new work was done in the strength of materials (Timoshenko, 1953; Todhunter, 1886–1893). In England, Peter Barlow and Thomas Tredgold conducted experimental tests on timber. The introduction of cast and wrought iron as building materials stimulated more experimental studies. In order to test iron, new machines capable of larger loads had to be designed. In 1833, the Royal Navy installed a one-hundred-ton machine at the dockyard at Woolwich that was used to test iron chains. Barlow used this machine to conduct tests on iron rails. About the same time, William Fairbairn and Eaton Hodgkinson constructed a testing machine to do compression tests on full-size cast-iron pillars. On the Continent, Johann Bauschinger created one of the earliest university materials testing laboratories at the Polytechnic Institute of Munich. While in America, Robert Thurston founded laboratories at Stevens Institute of Technology and Cornell University.

While material testing was undergoing development in England, Germany, and America, there were important advancements in the theory of elasticity, especially in France. The work of Augustin Cauchy, Gabriel Lamé, C. L. M. H. Navier, Siméon Poisson, and Adhemar Barré de Saint-Venant led to a new theoretical understanding of elasticity. Particularly important was Cauchy's formulation in 1822 of the concept of stress. In Germany, Johann Bauschinger and Hermann Zimmermann extended the theory with the application of graphical methods to stress analysis.

4.2.2 Structures

Applied mechanics also led to new experimental and theoretical analyses of structures, particularly in response to demands created by the construction of railroad bridges and suspension bridges (Billington, 1983). In England, William Fairbairn, Eaton Hodgkinson, and Robert Stephenson conducted experimental studies that contributed to the design of the Conway and Britannia tubular railway bridges (Vincenti and Rosenberg, 1978), while W. J. M. Rankine and James Clerk Maxwell developed theoretical techniques of parallel projection and reciprocal figures, which allowed new ways to study the forces acting in a structure (Maxwell, 1864). In

America, Squire Whipple discovered graphical and mathematical methods for the analysis of truss bridges, which could not be analyzed by other methods. In France, C. L. M. H. Navier published a mathematical study of suspension bridges while Jean V. Poncelet developed a mathematical study of the stability of revetments and their foundations.

4.2.3 Machines The development of applied mechanics also resulted in new theoretical approaches to the study of machines. At the end of the eighteenth century and beginning of the nineteenth century, Lazare Carnot, C. L. M. H. Navier, J. V. Poncelet, and Baron Prony generalized the concept of *vis viva* (mv^2) and applied it to the study of machines. Later, G. G. Coriolis, William Whewell, and Henry Moseley employed the idea of work to treat a machine as a device in which transmitted work was divided into useful and wasteful work. This functional approach to a machine provided a new method to measure efficiency.

During the nineteenth century, a theory of machines began to focus on a study of the kinematics of mechanisms (Ferguson, 1962; Hartenberg and Denavit, 1964). Jean Nicolas Pierre Hâchette, Agustin de Betancourt, and Phillipe Lanz, using a program outlined by Gaspard Monge, created a system of classification of mechanism based on the conversion of one type of motion into another. André-Marie Ampère extended the work of Monge and Lanz and coined the term *cinématique* (Ampère, 1838–1843). By the middle of the century, Robert Willis, Jacksonian Professor at Cambridge, put forward a theory based on the relationship of motions created by a mechanism. By the second half of the century, Franz Reuleaux, director of the Royal Technical School at Charlottenburg, further extended the theory by moving away from isolated mechanisms and toward the idea of mechanisms as part of an integrated system in which a mechanism could be inverted into another mechanism (Reuleaux, 1895). Particularly important work was done in 1868 by James Clerk Maxwell in his analysis of mechanical governors, which led to the development of an early theory of feedback control (Maxwell, 1868; Mayr, 1970).

4.2.4 Hydrodynamics During the nineteenth century, applied mechanics led to new advances in hydrodynamics (Rouse and Ince, 1957). In the first half of the century, C. L. M. H. Navier and G. G. Stokes put forward mathematical theories on the motion of fluids. In 1842, Stokes introduced the concept of lines of motion, which was developed by W. J. M. Rankine in 1870 into a theory of stream lines. During the second half of the century, hydrodynamic theories were extended by Hermann von Helmholtz, Lord Kelvin, Lord Rayleigh, and Osborne Reynolds. Many of these theories led to improvements in naval architecture and hydraulic machines. At mid-century, John Scott Russell conducted experimental and theoretical studies on bodies moving through a liquid and concluded that objects shaped like a wave offered the least resistance (Emmerson, 1977). At the same time, William Froude and Edward James Reed conducted studies on the stability of ships. In 1834, Benoît Fourneyron, influenced by the work of Lazare Carnot, developed the Fourneyron water turbine. At mid-century, James B. Francis conducted experiments at Lowell, Massachusetts, that led to a set of design principles for water turbines (Layton, 1979).

4.3 Thermodynamics

The emergence of engineering science also led to significant interactions between science and technology in the area of thermodynamics (Cardwell, 1971). After the invention of the steam engine in the eighteenth century, there was a great deal of interest in the nature of heat. At the end of the eighteenth century, while superintendent at an arsenal in Munich, an American, Benjamin Thompson (Count Rumford), raised questions concerning the prevailing caloric theory of heat by showing that more heat was generated while boring a cannon with a blunt tool than with a sharp one. Although both Humphrey Davy and Thomas Young put forward mechanical theories of heat in the early part of the nineteenth century, such theories were not widely accepted until the second half of the century. But even the caloric theory led to significant developments. Jean Fourier in his *Théorie analytique de la chaleur* (1822) used the idea of caloric as the basis for a new mathematical analysis concerning the flow of heat through a material body. Sadi Carnot, an army engineer and son of Lazare, published his *Réflexions sur la* *puissance motrice du feu* (1824), in which he used an analogy between a waterwheel extracting work from falling water and a heat engine extracting work from heat falling from a higher to a lower temperature to analyze the factors that determined the production of work in a heat engine, and he put forward what has come to be known as the Carnot cycle. After Carnot's death, Emile Clapeyron rediscovered Watt's idea of an indicator (or *P-V*) diagram and introduced it into Carnot's theory (Clapeyron, 1834).

During the 1840s, several scientists, including Robert Mayer, James Prescott Joule, and Hermann von Helmholtz, began theoretical and experimental studies based on a mechanical theory of heat. This work led to the formulation of the conservation of energy (Elkana, 1974). The mechanical theory of heat was applied to the theory of heat engines by Rudolf Clausius in Germany, and Lord Kelvin and W. J. M. Rankine in Scotland. Through a study of transformations between heat energy and mechanical energy they were led to the concept of entropy and formulations of the second law of thermodynamics. During the second half of the century, the first and second laws of thermodynamics were interpreted in terms of an atomistic, kinetic theory of heat by Clausius, James Clerk Maxwell, and Ludwig Boltzmann. In order to treat the large number of particles in a gas, Maxwell and Boltzmann resorted to the use of probabilities, establishing the foundations for the creation of statistical mechanics.

Although most of the developments in thermodynamics in the nineteenth century were associated with the steam engine, there were advances associated with other heat engines. Both Joule and Rankine conducted studies of hot-air engines, a few of which were built by John Ericsson. In 1860, Étienne Lenoir constructed the first commercially successful engine powered by illuminating gas. This led to a new interest in the application of thermodynamics to internal combustion engines (Bryant, 1967). In 1862, Alphonse Beau de Rochas showed that air must be compressed to gain maximum efficiency and he set out the conditions that would become the four-stroke cycle. Although he did not know of Beau de Rochas's work, Nicolaus Otto produced a workable four-stroke engine in 1876 with the help of Franz Reuleaux's insight into the importance of compression. At about the same time, Rudolf Diesel, while a student at the Munich Technische Hochschule, realized that an engine could increase its efficiency if there was a very high compression at the beginning of the cycle (Thomas, 1987). Soon after, he published a book on his "rational heat-engine," but it was not until 1897 that he was able to build a workable engine.

4.4 Electricity and Magnetism

Some of the most significant developments in the interaction between science and technology took place in the area of electricity and magnetism. The discovery of current electricity by Luigi Galvani and Alessandro Volta at the end of the eighteenth century led to a new range of electrical experimentation and with it new scientific discoveries concerning the nature of electricity and magnetism. In 1820, Hans Christian Oersted, who had been searching for a connection between electricity and magnetism, discovered that an electric current generated a magnetic effect. Only a week after Oersted's discovery of electromagnetism, André-Marie Ampère suggested the possibility of creating an electrical telegraph. During the 1820s and 1830s, several scientists, including Pavel Schilling in Russia, Carl Gauss and Wilhelm Weber in Germany, Charles Wheatstone and William Cooke in England, and Joseph Henry in America, worked on various electrical telegraphs. The most successful telegraph was the system invented by Samuel F. B. Morse, whose code made his system more practical than many of the others. During the second half of the century, the idea of the telegraph was extended by Elisha Gray, who showed how several messages could be sent through one wire, by Alexander Graham Bell (Bruce, 1973), who showed how electricity could carry the human voice, thus inventing the telephone, and by Oliver Heaviside, who developed a theory that led to long-distance transmissions.

Oersted's discovery of electromagnetism led researchers to search for the possibility that magnetism could produce electrical effects. In 1831, Michael Faraday, in England, discovered that moving a coil of wires in the presence of a magnet could induct an electrical current in the coil (Williams, 1971). By the second half of the century, Faraday's discovery of electromagnetic induction served as the basis for the creation of electrical dynamos by William Siemens in 1856 and Z. T. Gramme in 1867. Early in the century, Humphrey Davy had discovered both arc and incandescent lighting, but dependence on batteries limited their use. During the 1870s and 1880s, new dynamos made possible Charles Brush's practical development of arc lighting and Thomas Edison's invention of incandescent lighting (Friedel and Isreal, 1986). Edison's development of an entire electrical lighting system at his laboratory in Menlo Park, New Jersey, reflected a new approach to invention—one based on systematic, planned research by an interdisciplinary team of scientists and engineers. His work would provide one model for the emergence of the industrial research laboratory in the twentieth century. The invention of the dynamo also led to improvements in the electrical motor. Both Michael Faraday and Joseph Henry built small electrical motors as part of their research, and several inventors succeeded in building direct-current motors (Molella, 1976). The development of electrical motors advanced in 1888 with Nikola Tesla's proposal for a motor powered by alternating current.

One of the most significant developments in the area of electricity and magnetism was the discovery that light was an electromagnetic wave (Buchwald, 1989). At the beginning of the nineteenth century, Thomas Young put forward a wave theory of light. This theory raised serious questions concerning the properties of the medium that was undergoing vibration, and different models were put forward by Augustin Fresnel, Siméon Poisson, George Stokes, James MacCullagh, Lord Kelvin, George Green, and Augustin Cauchy. The most successful approach began in 1846, when Michael Faraday suggested that light might be a vibration of electric and magnetic lines of force, on the basis of his experimental discovery that the plane of polarization of light could be affected by a strong magnetic field. Faraday's work led James Clerk Maxwell to put forward an electromagnetic theory of light in 1862. Using a mechanical model of the aether, Maxwell derived a set of laws that governed electricity and magnetism. By 1865, he abandoned his mechanical model and focused his attention on a set of equations that expressed how electric currents could give rise to magnetic fields and how changing magnetic fields could give rise to electrical fields.

Maxwell's theory predicted the existence of electromagnetic waves that would travel at the speed of light. Such waves were experimentally detected by Heinrich Hertz in 1888 (Buchwald, 1994). Between 1894 and 1896, Guglielmo Marconi, using some ideas of Oliver Lodge, demonstrated that Hertz's waves could be used to transmit wireless signals. By the beginning of the twentieth century, the creation of radio and Edison's observation of the "Edison effect" in the 1880s led to John Ambrose Fleming's invention of the diode and Lee DeForest's invention of the triode.

5. THE TWENTIETH CENTURY

5.1 Applied Physics and Industrial Research

At the end of the nineteenth century and beginning of the twentieth century, the interactions between science and technology brought about by the rise of engineering science contributed to what some people have called a second industrial revolution (Mumford, 1934). Unlike the first industrial revolution, this one was heavily dependent upon scientific advances, especially advances in physics. It was during the nineteenth century, particularly after 1870, that physics began to emerge as an autonomous discipline with its own journals, university departments, and research institutes (Jungnickel and McCormmach, 1986). More and more by the beginning of the twentieth century this new physics was becoming associated with industrial concerns.

One of the most important developments in the emergence of applied physics was the establishment of industrial multidisciplinary research laboratories, based on the idea of group research (Hughes, 1989). Although some industrial research evolved in the German chemical industry during the 1880s, it was not multidisciplinary and made limited use of group research. In America, Thomas Edison's Menlo Park Laboratory provided one model for industrial research. Here physicists, chemists, mathematicians, and engineers were brought together in teams to form an "invention factory." Another model for industrial research emerged at the beginning of the twentieth century in science-based companies such as American Bell Telephone and the General Electric Company. While the industrial research laboratories established by these companies had some similarities to Edison's laboratory, they emerged at a time when some of their fundamental patents were expiring, and their primary purpose was to maintain and defend the companies' dominance over a particular technology. Although the original intent of these laboratories was to block competition, they conducted a great deal of fundamental research, and in exploring all possible routes a competitor might follow, they made many discoveries that led to new commercial products. For example, the Bell Laboratories' focus on the control of long-distance telephony led George Campbell to develop the wave filter and Harold Arnold to perfect the triode (Brittain, 1970). The General Electric Laboratory's focus on the light bulb led to William Coolidge's development of the tungsten filament and development of the x-ray tube, and later to Irving Langmuir's Nobel Prize–winning work on atomic physics (Wise, 1985).

By the period of World War II, a great deal of applied physics research was being done in government-sponsored research laboratories. Although some work, such as aerodynamic studies of airplanes and chemical research for gas warfare, had been conducted during World War I, it was World War II that brought about what Dwight Eisenhower called the military-industrial complex. Particularly in the United States, Great Britain, Germany, and the Soviet Union, university, industrial, and governmental laboratories conducted wartime applied research directed and sponsored by the military. This work led to such developments as radar, sonar, computers, jet aircraft, rockets, operations research, and the atomic bomb. With the end of World War II, this model of research continued into the era of the Cold War and the Space Race, and still plays a significant role in applied research today.

5.2 Atomic Theory and Quantum Mechanics

During the twentieth century, the emergence of applied physics in university, industrial, and governmental research laboratories led to significant new developments in science and technology. Much of this work was based on the revolution that was taking place in physics at the end of the nineteenth century and beginning of the twentieth century. Of particular importance was the new model of the atom that emerged during this period. Since the time of the Greeks, it had been assumed that atoms were the smallest units of matter, indivisible, immutable, and eternal. But in the 1890s, experimental discoveries began to challenge this view. Scientists discovered that electricity applied to an evacuated tube produced cathode rays. In 1895, W. Roentgen discovered that when cathode rays struck a metal target, other rays, termed x rays, were produced. In 1897, J. J. Thomson proved that cathode rays were a stream of particles (later called electrons) whose weight was less than that of the smallest atom. At the same time, other scientists, including Henri Becquerel and Pierre and Marie Curie, discovered that certain elements, such as uranium and radium, emitted a type of radiation that indicated the change of an atom of one chemical substance into another.

At the same time that questions were being raised about the billiard-ball model of matter, scientists were also discovering problems with the idea of continuous fields. The difficulty centered on describing the nature of blackbody radiation (Kuhn, 1978). Theories predicted an infinite amount of radiation in the ultraviolet region, while experiments had shown radiation with a maximum wavelength below the ultraviolet region. The solution to this "ultraviolet catastrophe" was suggested by Max Planck in 1899, when he argued that radiation was not emitted and absorbed continuously but in discrete packets of energy, or quanta. In 1905, Albert Einstein extended Planck's theory and introduced the idea that light consisted of a stream of photons with their own energy and momentum.

During the first decades of the twentieth century, a new model of the atom was formulated. Ernest Rutherford developed a model of the atom in which electrons orbited around a nucleus (Wilson, 1983). His student, Niels Bohr, used quantum theory to extend the model by arguing that electrons were confined to certain discrete orbits (Moore, 1985). The Bohr model provided scientists with a new understanding of chemical combinations and the atomic spectrum of hydrogen, but it could not explain other spectra or the relative intensities of spectral lines. In 1925, Werner Heisenberg suggested abandoning mechanical models and using instead a matrix mechanics (Van der Waerden, 1967). About the same time, Erwin Schrödinger used Louis de Broglie's idea that matter could have wavelike properties to formulate a wave mechanics, which was shown to be equivalent to matrix mechanics. Heisenberg's and Schrödinger's formulation of quantum mechanics combined with the Bohr model of the atom provided the basis for some important new technological advances.

5.2.1 The Atomic Bomb One of the most significant developments of the twentieth century was the creation of nuclear weapons (Rhodes, 1986). The new atomic theory predicted that a great deal of energy was stored in the nucleus of an atom and might be released if a heavy atom was split into two smaller atoms. With the discovery of the neutron by James Chadwick in 1932, physicists had a possible way to split the atom. The next year, Leo Szilard speculated on the possibility that a chain reaction could release significant amounts of energy. In December of 1938, Otto Hahn and Fritz Strassmann in Germany conducted an experiment in which uranium nuclei were split by bombarding them with neutrons.

With the beginning of World War II, America, Great Britain, Germany, and the Soviet Union (Holloway, 1994) all began research in an attempt to exploit nuclear energy. By 1940, Otto Frisch and Rudolf Peierls in England had calculated that the critical mass needed to sustain a chain reaction was small enough to consider building a bomb. In December of 1942, a team of scientists led by Enrico Fermi at the University of Chicago succeeded in creating the first sustained nuclear reaction. During the next few years, the American atomic bomb project focused on the engineering problems associated with separating uranium-235 from uranium-238 and producing plutonium-239 from uranium-238 in order to create enough weapons-grade materials. Through the development of an electromagnetic separation by Eastman Kodak, gaseous diffusion by Union Carbide, and nuclear reactors by Dupont and Westinghouse, enough material was available to test the world's first atomic bomb on 16 July 1945 and for the bombs used a few weeks later against Japan.

5.3 Postwar Developments

5.3.1 Nuclear Weapons and Reactors After World War II, research continued on nuclear energy. Further development of nuclear weapons culminated in 1951–1952 with the creation of hydrogen bombs under the leadership of Stanislaw Ulam and Edward Teller in the United States and Andrei Sakharov in the Soviet Union. About the same time, work continued on the development of nuclear reactors for military and civilian purposes. Several experimental reactors were built during the late 1940s in the United States, England, France, and the Soviet Union. In 1946, Captain Hyman Rickover of the U.S. Navy began development of a nuclear reactor to power a submarine, in conjunction with Argonne National Laboratory, Westinghouse, and General Electric (Hewlett and Duncan, 1974). By the early 1950s, the nuclear-powered submarine Nautilus was launched and the first civilian nuclear power plant, using Rickover's designs, was built at Shippingport, Pennsylvania.

5.3.2 The Space Race World War II also stimulated interactions between science and technology in the area of aeronautics and space research (McDougall, 1985). While some work on rockets was done before World War II by Konstantin Tsiolovsky and Sergi Korolev in Russia and Robert H. Goddard in America, it was during the war that Germans under Wernher von Braun did significant research and development of rockets resulting in the V-1 and the first ballistic missile, the V-2. After World War II, the United States and the Soviet Union placed a great deal of effort into the development of missile technology both for military purposes and for the scientific exploration of space. Although Stalin's purges almost destroyed the Soviet rocket program, Korolev's and Valentin Glushko's work allowed the Soviets to launch the first earth-orbiting satellite, Sputnik I, on 4 October 1957. This was followed quickly by Sputnik 2, which placed a dog into orbit in November of 1957; Lunik I, which missed the moon but discovered the solar wind; Lunik II, which landed on the moon; and Lunik III, which photographed the dark side of the moon. The Soviet program culminated on 12 April 1959 with Yuri Gagarin becoming the first man to orbit the earth.

In America, Wernher von Braun, who was brought from Germany after the war, developed the Army's Redstone rocket and played a leading role in America's space program including the launching of Explorer I, the first U.S. satellite; the Mercury program, which led to John Glenn's being the first American to orbit the earth; and the Apollo program, which culminated with Neil Armstrong's and Edwin (Buzz) Aldrin's moon landing in July of 1969. At the same time, America sent several unmanned spacecraft on missions to Mars, Venus, and eventually Jupiter, Saturn, and Neptune, opening the era of the scientific exploration of space. These developments provided scientists with new ways to conduct both astronomical and geological observations and experiments, and at the same time they led to significant technological developments in the areas of communication and navigation.

5.3.3 Computers Another area of interaction between science and technology that was stimulated by World War II was the development of the computer (Goldstine, 1972). While some elements of the computer date back as far as the Greeks, and later several mathematicians, including Blaise Pascal and G. W. Leibniz, designed mechanical calculating machines, the basic aspects of the modern computer, including the ideas of a memory, central processing unit, and ability to be programmed, were put forward in the nineteenth century by the English mathematician Charles Babbage, but he was never able to build such a machine. By the end of the nineteenth century, Herman Hollerith designed a tabulating machine, incorporating elements of Boolean algebra, to process data from the 1890 U.S. Census, but these early machines were limited by mechanical problems and were not general programmable computers. The modern computer developed in response to the need to calculate ballistic equations that resulted from the introduction of much more powerful guns during World War I, and to the need to break enemy codes during World War II.

By the beginning of World War II, several projects were under way to develop a computer to carry out scientific calculations and to break the German Enigma code. One of the first successes, the Mark I, was created by a group at Harvard University and IBM led by Howard Aiken in 1944. Although it was electrically powered, it performed calculations through a series of essentially mechanical telephone relay switches. As early as 1937, John V. Atanasoff began work on a machine that used vacuum tubes, but other war duties prevented him from completing his work. The first truly electronic computer, known as ENIAC (Electronic Numerical Integrator and Computer) and using eighteen thousand radio tube switches, was created by a group under J. Presper Eckert and John Mauchly in 1946 at the University of Pennsylvania.

While computer hardware was being developed, there were also significant advancements in software. In 1936, the British mathematician Alan Turing had described an ideal computer known as a Turing machine. A year later, the American Claude Shannon demonstrated that a set of electronic switches could be used to express logical statements using Boolean Algebra. Beginning in 1945, a group, including mathematician John von Neumann, attempted to design an improved version of the ENIAC, called the EDVAC (Electronic Discrete Variable Calculator), by incorporating some of the ideas of Turing and Shannon. In his *First Draft of a Report on the EDVAC* von Neumann outlined the design for a general all-purpose computer, what has come to be called a von Neumann machine. The major advance of the EDVAC was its ability to store a program along with data. This allowed the computer to do a new set of tasks without having to rewire circuits physically as had been the case with the ENIAC, and it allowed the computer to modify its own program. The creation of the general programmable computer opened up research in new areas including the development of cybernetics by Norbert Wiener in 1948, the development of artificial intelligence by such people as John McCarthy, Marvin Minsky, Herbert Simon, and Allen Newell, the idea of parallel processing and neural networks by Warren McCullock, Walter Pitts, Donald Hebb, Frank Rosenblatt, Seymour Papert, and W. Daniel

Hillis, and the creation of artificial life by Fred Cohen and J. Doyne Farmer (Pratt, 1987). The computer has also revolutionized many fields of science by its ability to bridge the gap between theory and experiment with the concept of computer modeling.

5.3.4 Solid State The advancement of computer science and technology was stimulated by the postwar revolution in solid-state technology. On the basis of research that involved linkages between quantum mechanics and electrical engineering, William Shockley, Walter Brattain, and John Bardeen invented the transistor at Bell Laboratories on 19 December 1947 (Weiner, 1973). The success of the transistor led to further miniaturization when Jack Kilby of Texas Instruments and Robert Noyce of Fairchild Electronics each developed an integrated circuit in the late 1950s.

At the same time, the interaction between quantum mechanics and electrical engineering, stimulated by the scientific and military interest in short-wave radiation, led Joseph Weber and Charles Townes in the United States and N. G. Brasov and A. M. Prokhorov in Russia to conceive of the idea of microwave amplification by stimulated emission of radiation. By 1954, Townes and James P. Gordon had constructed a functioning ammonia-beam maser at Columbia University. This success led to the development of solid-state masers by a group at Bell Laboratories. These devices found almost immediate applications in the areas of military radar, communications, and radio astronomy.

By 1957, Townes at Columbia and Arthur Schawlow at Bell Laboratories had the idea of creating a similar device for light. At the same time, R. Gordon Gould, a Columbia graduate student, followed a somewhat independent line of research, which also led to the idea of a laser. In 1960, Theodore H. Maiman, of the Hughes Research Laboratories, created the first operating laser. The invention of the laser led to significant research into spectroscopy, chemistry, and semiconductors, and to a wide range of commercial applications in such areas as communications, material processing, and fusion (Bromberg, 1991). As with other postwar developments in the interaction of science and technology, the solid-state revolution reflected a symbiotic relationship in which knowledge was flowing as much from technology to science as it was flowing from science to technology.

INTRODUCTION

Experimental physics is heavily dependent on computers. It would be difficult to conceive of many modern experiments without computers, and computers are an indispensable and integral part of most experimental apparatus in physics. They are used in every stage of the experiment. Computer systems used for these applications range from simple microprocessors embedded in "smart instruments," to distributed processors able to acquire data at high speed, to supercomputers used to model experimental results.

It is nearly impossible to give a comprehensive picture of the myriad ways computers are used in physics experiments. Here the basic concepts involved in these applications are presented, and examples of their use in real-life experimental situations given, concentrating primarily on the role of computers in the experimental process as opposed to the details of the hardware and software used.

A typical physics experiment goes through several phases: physics design, apparatus design, construction, data acquisition, data reduction, data analysis, and, finally, presentation of results. In most experiments, computers are used in every phase. Although the same could be said for many other sciences, in physics there is a particularly close relationship between physical results and mathematical models, which has resulted in a central role for computers in experiments.

1. COMPUTERS AND THE REAL WORLD

The physical sciences describe the world in mathematical terms. Computers are designed to perform mathematical operations, and so it is natural that they are used to model and measure the physical world. Computers allow physicists to obtain quantitative values that would be impossible to calculate

digital Encyclopedia of Applied Physics

using traditional mathematical techniques. This capability has had a profound impact on physics. The precision to which values can be calculated using computers has resulted in much more stringent tests of theories.

Computers have also allowed experimental physicists to measure the real world more accurately and precisely. Computer-based data-acquisition systems allow experimentalists to run complicated experimental setups and to store extremely detailed data.

Despite the successes of computers in modeling and measuring the real world, there are important differences between computer calculations and reality (see, for example, Kent, 1978). One such difference is the distinction between *continuous* real-world values and *discrete* representations them.

Many physical quantities such as voltages, positions, times, etc., can take on any real value. A device that can produce any real value as the result of an operation is known as an *analog device* (Goldstine, 1972, pp. 140–147). Amplifiers, integrators, and filters are examples of analog devices. Analog computing devices exist; one example is a position computer that takes several inputs from a position-sensitive detector and produces voltages corresponding the position of a detected particle. However, analog computers are not flexible; they are usually designed for a single calculation. The vast majority of computing devices in use today are *binary digital computers*. These computers perform operations on numbers represented in base 2. This scheme allows general-purpose computational devices and much simpler input and output of results; however, the finite number of base-2 digits, or bits, used means that not every real value can be represented. For most practical purposes, this difference is negligible, but in some applications it can be critical.

Another difference between computer models of the real world and reality is the limited storage and speed of a computer. Real-world processes may be very complex, making their simulation impractical without simplifying assumptions. These assumptions often reduce the accuracy of a model in order to make it computationally tractable. Thus, the results of computer models and calculations often do not exactly correspond to reality.

2. DEVICES AND EQUIPMENT

The overwhelming majority of computers used in physics today are binary digital computers (Dasgupta, 1989). Most digital computers are built around at least one *central processing unit* (CPU). A CPU performs basic arithmetic and logical operations on binary data. It communicates with the rest of the computer via a *data bus*, an electronic path over which it sends and receives data. The data bus connects the CPU to memory and other devices, such as mass storage, keyboards, displays, and external communications (for more information, see COMPUTER HARDWARE).

Four primary computer configurations are used by experimental physicists today: single-primary-user *workstations*, multiple-user *mainframe computers*, *embedded processors*, and *distributed processors*. By far the majority of computers in use today are workstations, such as personal microcomputers or graphics workstations (Grubb and Borchers, 1991). The popularity of multiple-user mainframe computers has waned as the hardware costs of computers have plummeted in recent years; nonetheless, this configuration is still useful for applications requiring supercomputing power or shared resources, such as long-term storage. Many of the functions of traditional mainframe computers are being displaced by networks, in which individual workstations communicate and share resources.

Embedded processors are dedicated computers in instruments that control the instrument and allow communication with the outside world. These processors are usually not available for general-purpose computing, but they are an important part of many physics experiments.

More complex setups, such as high-energy physics detectors, may use a system of distributed processors to process huge amounts of data efficiently and quickly. These systems often use special-purpose processors to evaluate and preprocess the data in order to send only necessary information to a coordinating computer system.

An important computer configuration used by physicists is the wide-area network. Many experimental groups have members from widely scattered institutions. The use of a network (such as the Internet) for communication enables these groups to function efficiently, pass data back and forth, and even run experiments remotely. This use of computers is presently widespread in high-energy physics, and is becoming more so in other disciplines.

Many physics experiments require data communication between a computer and external measurement devices. These devices are frequently accessed by use of a standard communications bus, such as CAMAC, VME bus, Fastbus, or IEEE-488 (also known as the General Purpose Interface Bus or GPIB) (see BUS SYSTEMS AND COMPUTER INTERFACING). A wide array of devices for experimental control and data acquisition is available for these standard buses.

3. COMPUTERS IN EXPERIMENTS

A typical experiment goes through a variety of stages, from experimental design to presentation of results. Today, computers are commonly used in every stage (Matey, 1993).

3.1 Experimental Design

The first phase of any experiment is the design of the experiment itself, which usually incorporates several parts. First, the scientific problem the experiment is meant to address must be considered. Once an experimental method to address the scientific problem is devised, the apparatus is designed and an experimental protocol set. Specific predictions about the outcome of the experiment under various circumstances are often needed before it ever begins.

The physics design of any experiment requires a quantitative understanding of the physical effect the experimentalist wishes to study. While many of the necessary predictions may be calculated with theoretical models using computers (see SIMULATION AND MODELING USING COMPUTERS), experimental design involves a great deal more than predictions from a specific theory. For example, the strength and quality of the observed signal from the actual detectors must often be predicted, as must the noise or background signal in the same detectors. In this stage, the experimentalist may also use computer-based techniques such as *Monte-Carlo modeling* (see MONTE-CARLO METHODS) to design the experiment to optimize the statistical significance of the results.

Once the conceptual design of the experiment is complete, the apparatus itself must be designed. Here computers also play an important role, as they are widely used in computer-aided design (CAD), engineering (CAE), and machining (CAM) applications. In addition, computers are used extensively in the detailed design of the physical characteristics of the apparatus. For example, experimentalists may use a computer to calculate exact electric and magnetic fields in an experimental setup.

3.2 Experimental Control and Data Acquisition

Computers lend themselves ideally to the control of instruments, and to the task of collecting data for experiments. They are extensively used in both these roles in most physics experiments. Experimental physicists are able to draw upon a considerable industry in computer control and data-acquisition products for both these tasks. Computers control many devices in a typical physics laboratory such as power supplies, frequency synthesizers, stepping motors, valves, switches, timers, vacuum pumps, lasers, and, of course, other electronic devices. Using such devices, the computer can be programmed to operate virtually the entire experimental apparatus.

Today, most experimental data are acquired via computers. The most ubiquitous devices employed for this purpose are *analog-to-digital converters* (ADCs), which convert an analog voltage into a digital number, *time-to-digital converters* (TDCs), which convert a time interval into a digital number, and *scalers,* which count electronic pulses. These basic devices can be packaged in a variety of instruments, and communicate to the computer using a variety of communication standards. Experimental data often fall into one of the following categories.

3.2.1 Logged Values *Logged data* represent values that are recorded periodically, with a low recording frequency and fairly loose requirements on the exact times the values are recorded. For example, a record of the temperature of a device taken every few minutes would be logged data.

3.2.2 Wave Forms *Wave-form data* consist of values recorded at regular, precise intervals, generally at a high frequency. The result is a digitized representation of the variation of the values with time. A digital oscilloscope is the most common form of wave-form digitizer.

3.2.3 Scans A *scan* is formed by varying one parameter and recording the value of another. For example, varying the current to a device and recording its temperature at each current value would create a data scan.

3.2.4 Histograms A *histogram* is a plot of the frequency of detection of a signal as a function of some attribute of that signal. One common use of the histogram is in spectroscopy; an energy scale is divided into a number of bins, and the value of each bin represents the number of photons detected with the corresponding energy.

3.2.5 Event Data *Event data* consist of records of measurements taken by a number of instruments, often triggered by the detection of a signal in one or more of them. Each set of associated measurements is called an *event*. For example, a high-energy physics experiment may have many detectors looking at a target. When a particle hits the target, it gives off a shower of particles from the reaction in the target. The time of arrival and energy of each detected particle would comprise an event. The recording of individual events allows the data to be reconstructed and analyzed in detail after the experiment is over. It is especially useful for complex multiparameter experiments.

The above data types are not mutually exclusive; for example, a multichannel scaler, which records the number of detections observed as a function of time, is a mixture of wave-form and histogrammed data.

3.3 Data Reduction

The widespread use of computers in experiments has coincided with an explosion in the volume of data produced. These data must be managed and reduced to a comprehensible form during a phase of the experiment often called *data reduction*. Depending on the experiment, data reduction may occur at the same time as data acquisition, later during data analysis, or both. In the data-reduction phase, raw numbers collected during data acquisition are put into a form from which the data analysis may be performed. At this point of the experiment, the data are also usually archived in a computer-readable format for future reference.

A typical data-reduction task is the combination of spectra taken with different detectors into a single spectrum representing the experimental observations. Another might be the adjustment of several data sets to some common process so they can be directly compared. In the case of event data, data reduction usually involves calculating physically meaningful values from the data and applying constraints or *cuts* to the events to select only events of interest. For example, in a high-energy physics experiment, the paths of the detected particles might be reconstructed, and only those paths that converge on a selected point chosen for further analysis.

These data-reduction processes would be essentially impossible without modern computers, as they consist of huge numbers of repetitive tasks.

3.4 Data Analysis

Once the data have been reduced to a manageable size, the analysis begins. It is difficult to imagine the analysis and interpretation of any nontrivial data set today without the use of computers.

The final results of physics experiments are almost always quantitative values for physical parameters. Of those experiments that do not provide such parameters, most report either the observation or the nonobservation of a physical effect. Either way, the results of physics experiments must be presented in a quantitative manner. Computers are frequently indispensable tools in the determination of the results from the experimental data.

Data analysis takes as many forms as there are experimental designs. However, a number of techniques are widely used. Statistical determination of physical parameters from experimental data via *curve fitting,* in which the data are compared with a theoretical function, and *direct statistical estimation,* in which the values of parameters are directly determined from the statistical properties of the measurements, are two such techniques. Such analyses often require a large number of calculations, and are almost invariably performed by computer. Another technique often used in data analysis is the *Fourier transform,* by which the frequency components of a wave form are calculated. Yet another commonly used analysis technique is *Monte-Carlo* modeling. In this process, the results of a complicated experiment are modeled by simulating the measurements using random-number generators to determine the effects of complex physical processes. The modeled results produced via a number of assumptions are then compared with the actual experimental results.

3.5 Presentation of Results

The final step in the life of an experiment is the presentation of the results obtained from the data analysis. Physicists report these results mostly via published papers and talks. Computers are widely used in the preparation of both, and are beginning to be used in their presentation as well.

Many results are presented in graphical form; today, essentially all charts and graphs are computer generated. Papers are usually written using computer-based word processors, and can be submitted to journals electronically. Indeed, figures that once were hand-drawn for journals are now regularly generated on commonly available desktop printers.

4. COMPUTER REQUIREMENTS FOR EXPERIMENTAL APPLICATIONS

4.1 Hardware Requirements

The computer hardware requirements for all physics applications have generally placed physicists among the class of so-called "power users" who use all the computer power they can obtain and constantly demand more. This generalization applies to both experimental and theoretical physicists, although the specific hardware requirements are somewhat different for the two cases.

Some of the many computer hardware considerations for experimental physicists are the following.

4.1.1 Processing Speed The speed with which problems can be solved and calculations performed is, naturally, a prime consideration for experimental applications of computers. The complexity of calculations that can be performed in a reasonable time frame is directly related to the processing speed. In Monte-Carlo techniques, for example, the precision of the result is determined by the number of events that are simulated. Experimental physicists have an apparently insatiable appetite for computer processing speed; the greater the speed of the computer, the more data that can be analyzed and the more detailed the analysis can be.

4.1.2 Input/Output Speed Data-acquisition and experimental control applications often require very high data input and output rates. For example, a wave-form may be digitized at 500 MHz, or 2 ns per measurement, with each measurement consisting of an 8-bit number, for a total data rate of 4 billion bits per second. Typical data-transfer rates today in general-purpose computers are a few hundred million bits per second, lower by about a factor of 10 than the requirements for such a wave-form. Moving the data to and from the computer is often the primary bottleneck in the data-acquisition speed.

4.1.3 Memory As the number of data samples increases, the memory required to hold them also increases. Thus, the memory requirements for experimental applications increase as the available computing power and input/output speed increase. Additionally, event recording allows many-dimensional representations of the data, and calculations and displays of these representations require large amounts of available memory.

4.1.4 Mass Storage The considerations for mass storage are similar to those for memory. As the volume of data that can be processed increases, the requirements for mass storage to archive the data also increase. However, mass storage also involves a different consideration: that of retrieval speed for data.

Traditionally (that is, until a few years ago) physicists stored data primarily on magnetic tapes. This technology allowed relatively cheap, high-capacity storage, but the time required to access an individual piece of data could be extremely long. Tape technology has improved greatly, but new technologies, such as magnetic and optical disk drives, have arisen to challenge it. The time required to access data stored on an optical disk is several orders of magnitude smaller than that required to access data on a tape, and the time to access data on a magnetic disk is smaller still. However, new technologies allow tapes to record data at a much lower cost than optical disks. Tapes are primarily useful for voluminous data that do not need to be accessed in a random order, such as archival storage, while more compact data that need to be frequently accessed are stored on disks.

4.1.5 Display and Printing Capabilities The increasing complexity of physical data and the increasing use of computers for presentation of the data have resulted in increased demands upon the display and printing capabilities of computers. For example, the complexity of representations of data and results has led to an increased use of color in displays and printed articles. The display capabilities required for experimental applications, both resolution and color, have likewise increased.

4.2 Software Requirements

The evaluation of software requirements for experimental physicists is more difficult than that of hardware requirements. Many high-quality commercial programs exist that perform a wide variety of tasks; however, the market for experimental physics applications, which frequently require specialized features that can be found in no commercial product, is small, and many physicists must write their own programs to obtain the optimization and flexibility required.

Nonetheless, here is an enumeration of some of the software considerations that must be evaluated by the experimental physicist.

4.2.1 Operating System The *operating system* of a computer is the software that allows other programs access to the computer's resources. It determines the specific software packages that the experimentalist can use, because presently most software applications run under only one operating system. All hardware systems offer a limited selection of operating systems; many offer only one.

The determination of the best operating system to use for a specific application can be complex. For example, an experimentalist may want to make use of a multitasking operating system that can run more than one process at a time. Programming such a system for a real-time application, such as data acquisition, may be very difficult, however. Today many operating systems have *graphical user interfaces,* which produce more consistent displays to the user and are considered easier to use than *text-based interfaces.*

Multiuser operating systems are commonly used today, though their influence is much less than it once was. These operating systems offer several advantages in simultaneous use of shared resources, but have disadvantages stemming from limitations that must be imposed on each user.

4.2.2 User Interface The *interface* of a software product is the way the user interacts with it and how it displays information to the user. The interface often has a dramatic effect on the utility of the software (Card *et al.,* 1983). Physics applications have a miserable track record in this respect; many programs developed specifically for use in physics applications have horrendous user interfaces. Newer physics software has offered improvements, especially in the use of *graphical user interfaces,* or GUIs, but the quality of user interfaces in commercially available programs for physics applications still lags industry standards.

On the other hand, general-purpose software has undergone dramatic improvements in user interfaces in the past several years. General-purpose word-processing packages, for example, now routinely offer easy-to-use equation editors, enhancing their use for scientific publication.

4.2.3 Speed The power and speed of the software are, of course, important considerations in the choice of any program. In data-acquisition applications, speed may become critical, as it determines the maximum data rate that the system can handle.

4.2.4 Flexibility The *flexibility* of a software program is its utility in a variety of situations. For example, a program that can read and display data from a wide variety of possible formats is more flexible than one that requires data in a single format; a data-acquisition program that can acquire data from a wide variety of instruments is more flexible than one that acquires data from a specific configuration. Traditionally, it has been conceded that there generally exists a tradeoff between flexibility and ease of use. However, some new programs seem to be defying that rule.

4.2.5 Extensibility An *extensible* program is one to which the user can add new functions. Language compilers are the most extensible programs that exist, as they allow the user to make a new application. However, many more specialized programs now incorporate some degree of extensibility or programmability. In these situations, the display and interface may already be in place, allowing the physicist to concentrate on the physics alone.

5. EVALUATION OF COMPUTER USE IN EXPERIMENTAL PHYSICS

5.1 Advantages

The advantages of computers for experimental physics are clearly manifold. Without computers, it would have been impossible to obtain most of the significant experimental results of the last thirty years. Computers have made experimental physics more productive, more sensitive, and more comprehensive.

There are several specific but less obvious advantages that computers bring to experimental physics. First, computers allow the optimization of experimental design, both in equipment and in the design of the data-acquisition process itself. Such optimization can be used to obtain more from an existing apparatus or to design a new experiment to be more powerful for the same cost.

Second, experiments can now be automated to a great degree, significantly reducing the amount of time the experimentalist must spend monitoring the equipment.

These first two advantages can be combined into a third: Carefully designed experiments can now be carried out in a manner that minimizes the possibility that the experimentalist will introduce a bias into the results. If the entire data-acquisition phase of the experiment is planned ahead and automated, there is less tendency on the part of the scientist to abort a partially completed measurement in order to "optimize" some parameter based upon inadequate statistics.

Finally, computers have enabled scientists to search through enormous quantities of data for subtle effects, and to redo analyses of old data in the light of new discoveries. These capabilities may be important in the future, and may allow searches for experimental evidence of new effects without the need for new data.

5.2 Disadvantages

The disadvantages of computer use in experimental physics are more difficult to discern than the advantages. The most apparent is a tendency by many to hold the results of computer calculations above question. Much analysis of data requires a great deal of judgment; curve-fitting routines, for example, can often return incorrect results when not used judiciously. The same problem can plague modeling calculations.

The ability of computers to process data quickly can lead to the unwitting introduction of experimenter bias into results. If an experiment is not carefully planned and the data acquisition automated, a scientist may be tempted to modify the apparatus or the plan too quickly based on preliminary results produced as the experiment runs.

Another disadvantage arises because of the number of ways the same data can be analyzed. Statistical analysis programs exist that allow researchers to search through huge volumes of data for correlations. Unfortunately, the significance of a correlation discovered in this way is much less than that of a correlation hypothesized before the data were taken. For example, a gamma-ray spectrum might be searched for peaks corresponding to gamma-ray emission lines. The statistical significance of any lines found is quite dependent on whether the energies were known before the search was started. In short, it is important to understand statistics and probability well before using a computer to calculate probabilities despite the apparent simplicity of using the computer programs.

Finally, computer models are sometimes assigned a presumed accuracy that far exceeds their true accuracy. Great care must be used in applying computer models to the real world without a detailed understanding of the modeling process.

5.3 Example

A brief example of the use of computers throughout the experimental process is provided by a recent experiment (Knapp, 1995). Its purpose was the investigation of x-ray production from impacts between electrons and highly charged uranium ions, with particular emphasis on two processes: dielectronic recombination, a resonant process, and radiative recombination, a nonresonant process.

The experiment took place in an electron-beam ion trap (EBIT), a device that traps and strips ions in a high–current-density electron beam. The EBIT was designed using computer calculations and simulations. For example, the magnetic field along the electron-beam path had to be designed to very precise tolerances in order to achieve the required current density. For this, the magnetic field from a given magnet configuration was calculated. Then the electron trajectories in that magnetic field were calculated and analyzed, and a new magnet configuration produced that would give better results. The process was iterated many times before the optimal design was reached. The resulting optimized trajectories are shown in Fig. 1. Once the magnet configuration was optimized, the magnets themselves were designed by computer to correspond as closely as possible to the ideal magnets used in the optimization process. Finally, the mechanical parts and assembly were drawn using a CAD program.

The experiment was designed to measure the intensity of x rays produced by the two processes as a function of the electron-beam energy. It was performed by "sweeping" the electron-beam energy across the dielectronic recombination resonance energies. Both physical processes cause the ions to recombine with electrons, changing their ionization state. If the energy was not swept quickly enough, too many ions would recombine as data were obtained, making it difficult to interpret. If the energy was swept too quickly, the power supplies controlling it would be unable to keep up and it could not be measured properly. The rate at which the sweeps should be performed was estimated by fairly simple computer simulations.

The data-acquisition process consisted of recording the x-ray energy, electron-beam energy, and time for each observed x ray. The operation of the EBIT was computer controlled, and the electron-beam energy sweeps were generated by a programmable function generator with a built-in microprocessor, which communicated with the main computers over a GPIB bus. The data were taken using a CAMAC-based data-acquisition system with a total processing time of 20 μs per event. The events were stored on a read-write optical disk for later playback. They were also displayed on a computer screen so that the progress of the measurements could be followed. A total of about 50 million events were recorded in two weeks of running.

For data reduction, the data were replayed from the optical disk and displayed as a *scatter plot* of x-ray energy vs electron-beam energy, as shown in Fig. 2. Each event was displayed as a point on the screen, with the horizontal position determined by the electron-beam energy and the vertical position determined by the x-ray energy. As more events fell at the same point on the plot, the color of the displayed point was changed.

The resulting points formed patterns that allowed determination of the processes that gave rise to them. Radiative recombination resulted in x rays along angled bands, while dielectronic recombination gave rise to intense spots. The data reduction was continued by selecting only the events falling on the angled L_{12} radiative recombination band and projecting them onto the electron-beam energy axis, forming a histogram, as shown in Fig. 3. In this plot, the radiative recombination appears as a gently sloping continuum, while the dielectronic recombination produces sharp peaks.

To analyze the results, the histogrammed data were fitted by theoretical models using an iterative nonlinear maximum-likelihood algorithm running on a personal computer. The initial fit, shown in Fig. 4(a), was very poor; the theoretical curve did not match the data at all. Although the computer program that performed the fit worked well, it could

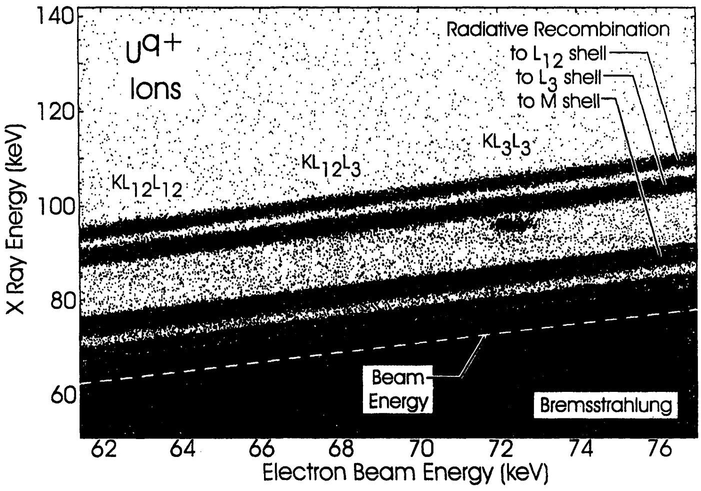

FIG. 2. Scatter plot of the data. Each point represents an event; the horizontal position corresponds to the electron-beam energy, and the vertical position to the x-ray energy. The angled bands are caused by radiative recombination, while the intense spots result from dielectronic recombination.

not reveal what was wrong. Analysis of the residuals [shown in Fig. 4(b) and defined in the caption] indicated that the shape of the peaks used in the fit was incorrect. The final fit, shown in Fig. 4(c), uses a theoretical model that includes quantum-mechanical interference between the two processes. The need to include the interference for this case was unexpected and very interesting.

A paper describing the experiment and the results was written and submitted electronically. The figures used in the paper were generated using computers.

Thus, computers were applied to this experiment from its inception through its publication. It illustrates many of the ways computers are used in physics experiments today.

6. FUTURE TRENDS

Predicting the future is always a difficult affair; however, the future role of computers in experimental physics is relatively easy to predict. As computers become cheaper and more powerful, they will become even more tightly integrated into experimental physics than they are today. More computer-controlled smart instruments that can communicate with a main controlling computer will become available.

The current trend of decentralization of computing resources is likely to continue, as individual processors are used for each task in an experimental environment. It seems likely that these individual processors will be networked to a greater degree than they are today. The use of wide-area networks for communications and data transfer will continue to increase, probably dramatically.

One particularly interesting trend is that of electronic and on-line publishing. The role of traditional print journals will certainly change in the next few years as the ability to post experimental results quickly to a wide audience grows.

The biggest problem today will likely continue into the near future; it is that of development of the specialized software required for experimental applications. Nonetheless, the sophistication and complexity of experimental physics software will continue to increase.

GLOSSARY

Analog-to-Digital Converter (ADC): Digital device that converts an analog voltage into a digital number.

Analog: A value represented by a continuous quantity, such as a voltage.

Binary: Numbers expressed in base 2: each binary digit (*bit*) can have a value of 0 or 1.

Bit: Binary digit.

Byte: Shortest binary number that a computer processes. In the vast majority of computers today, a byte is made up of 8 bits.

Central Processing Unit (CPU): A device in a computer that performs the basic arithmetic and logical operations for the computer.

Continuous: Describing a function or operation whose value can correspond to any real number.

Data Bus: The electronic data path via which components in a computer communicate with each other and with external devices.

Digital: A representation of numbers by digits in some base. For example, most numbers are commonly written in base 10, while computers primarily work with numbers in base 2. Both of these are digital representations of the numbers.

Discrete: Describing a function or operation whose value cannot correspond to any real number, but only to a set of separate numbers.

Embedded Processor: A computer processor that is integrated into an instrument or device.

Graphical User Interface: An interface consisting of graphical elements such as pictures.

Interface: The means by which a user interacts with a program running in a computer.

Mainframe: A large computer intended primarily to be accessed by many users simultaneously.

Monte Carlo: A technique for studying mathematical problems that consists of generating many random simulations of the problem.

Scaler: A device that counts events.

Text-Based User Interface: An interface consisting primarily of text, with few or no pictures.

Time-to-Digital Converter (TDC): A device that converts the value of a time interval into a digital number.

Workstation: A compact computer that is configured to be used primarily by one (or a few) users.

INTRODUCTION

Archaeology adds to our understanding of human society through the systematic excavation and analysis of material culture. Traditional archaeological methodology focuses on controlled excavation, classification of features and artifacts, social interpretation of what is found at a particular site, and integration of results from multiple sites into regional cultural frameworks.

The application of physics and other natural sciences to archaeology adds tremendous power to the archaeologist's toolkit. This multidisciplinary and interdisciplinary field of endeavor has been named *archaeometry*, or archaeological science. Archaeometric methods were initially used largely by scientists with an interest in archaeology (Leute, 1987, pp. 2–4; Craddock, 1991). In recent years, archaeometry has started to become more central in the education of the archaeologist and in the planning and execution of archaeological projects (Taylor and Payen, 1979; Olin, 1982).

The diverse methods of archaeometry are most easily classified according to the major problems they can help the archaeologist to solve: dating, prospecting, characterization, and paleoenvironment. Absolute or *chronometric* dating is necessary to examine contemporaneity and change within an individual site, within a culture region, or between culture areas. Geophysical prospecting is used to map out paleogeography favorable for site location, to locate sites, to delineate site boundaries or work areas, or to detect features and artifacts within a site. Characterization of features and artifacts is used to infer the sources (also called *provenances*) of raw materials or the technology that was used to manufacture artifacts. Paleoenvironmental studies suggest the landscape, climate, and biological (including dietary) resources that were available. It is impossible to review all archaeometric methods comprehensively herein, but general principles and applications are described for several of the most important techniques, with some bias in coverage toward the author's areas of expertise. References given are not in general to seminal articles but mostly to review articles and books. In addition to the references listed at the end of this paper, many articles concerning archaeometry can be found in the following journals: *Journal of Archaeological Science, Journal of Field Archaeology, Archaeometry, Archaeomaterials*, and *Geoarchaeology*.

1. DATING

Absolute, or chronometric, dating determines an age or interval of time in years, while relative dating assesses the contemporaneity or sequence of events. The full panoply of chronometric methods vary consider-

ably in the amount and type of material required, the range of archaeological time they can be used for, and the precision of the dates (Parkes, 1986; Aitken, 1990). Sternberg (1990) classifies these methods according to two dimensions:

1. whether they are "clocks" or involve matching of patterns, and
2. whether they are applicable globally or regionally/locally.

Dean (1978) provides a useful theoretical framework for chronometric dating, which clarifies the dependence of a meaningful date upon both proper laboratory work and consideration of archaeological context and relationships. The event being dated and the target cultural event of interest may be separated by an additional bridge of time, which must be archaeologically inferred.

1.1 Radiocarbon Dating

Radiocarbon (^{14}C) dating (Taylor, 1987) has had a more profound effect on the development of archaeology than any other archaeometric method. It has also played an important role in Quaternary geology, geochemistry, geophysics, hydrology, environmental studies, and medicine (Taylor *et al.*, 1992). The discovery of ^{14}C dating in the years after World War II by Libby (1955) earned him the Nobel Prize in chemistry in 1960.

Radiocarbon is formed in the upper atmosphere when neutrons generated by collisions of cosmic rays with atmospheric constituents are captured by nitrogen-14. The radioactive isotope beta decays back to ^{14}N with a half-life of 5730 years. However, the ^{14}C rapidly oxidizes to CO_2 and becomes distributed through the carbon geochemical system involving atmosphere, biosphere, and oceans. Modern carbon is about 98.9% ^{12}C (stable isotope), 1.1% ^{13}C (stable), and 1×10^{-10} % ^{14}C. Living objects will maintain the ambient ratio of $^{14}C/^{12}C$, but upon death, this ratio begins to decrease at a rate commensurate with the half-life. Thus, the radiocarbon age can be derived from the equation for radioactive decay,

$$A = A_0 e^{-t/\tau}, \tag{1}$$

where A is the present ^{14}C activity of the sample, A_0 is the initial activity of the sample at $t = 0$, t is the age in years, and τ is the mean life. The relation between mean life and half-life is

$$\tau = t_{1/2}/0.693, \tag{2}$$

which is equal to 8267 years for ^{14}C. Radiocarbon dating is an example of a "global clock" that "ticks" at a uniform rate anywhere in the world at any time. The technique is useful from historic times back to about 50 000 years ago, when the amount of ^{14}C becomes too low to measure.

For the first three decades of ^{14}C dating, activity was measured by counting the beta particles emitted by the decaying ^{14}C atoms. Libby's original method was to coat the inside of a Geiger counter with solid carbon. This was soon replaced by proportional gas counting by converting the ^{14}C back into CO_2 or a hydrocarbon gas, which is used as a counting gas within a proportional counter. Liquid-scintillation counting methods combine a liquid scintillator with a benzene solution that contains the radiocarbon. With these conventional methods, a few grams of carbon are typically needed. High-precision conventional dates can be as precise as ±20 years, but counting time may be several months. Common sources of error are background counts from sources other than the beta decay of ^{14}C and counting errors due to the random nature of the decay process.

Since 1980, a new measurement technique has emerged that has caused a revolution in ^{14}C dating: direct counting of ^{14}C atoms with an accelerator mass spectrometer (AMS), using either a cyclotron or an electrostatic accelerator. In the electrostatic accelerator, a negative-ion source and stripping of C^- ions to form C^{3+} ions separates ^{14}C from the more abundant but short-lived ^{14}N negative ions. The ions are accelerated in a tandem (two-stage) electrostatic accelerator. Mass spectrometry is used to separate and count ^{12}C, ^{13}C, and ^{14}C atoms. The ^{14}C ions are measured in a conventional counter while the more numerous stable isotopes are measured with a Faraday cup. The key impact of AMS dating is not in being able to date older material but in being able to date smaller amounts of material. Only milligrams of material are required, as opposed to the grams required by conventional methods. This allows more selectivity to be used in the choice of sample material. The actual counting time is also reduced from several days in beta counting to under an hour in direct counting.

In the late 1950s, it was first realized that there were secular changes in the amount of ^{14}C in the atmosphere and other geochemical reservoirs; in other words, the A_0 term in Eq. (1) is not a constant. It is now generally agreed that there is a long-term variation in the atmospheric radiocarbon concentration, with an amplitude of about ±5% and a period of 10 000 years, and short-term fluctuations with periods of decades and amplitudes of about ±1% (Olsson, 1970; Stuiver and Kra, 1986). The details of these variations, as shown in Fig. 1, have been deciphered by radiocarbon dating tree rings of known dendrochronological age. The long-term changes are probably geomagnetic in origin; when the earth's magnetic field is stronger (or conversely, weaker), fewer (more) cosmic rays can penetrate into the atmosphere and less (more) ^{14}C is produced. The short-term changes are probably heliomagnetic in origin; when the sun's magnetic field is stronger (weaker), fewer (more) cosmic rays can penetrate into the inner solar system. Climatic changes can also alter the carbon geochemical cycle and affect the radiocarbon concentration of the various reservoirs (Stuiver *et al.*, 1991). These changes necessitate the calibration of ^{14}C dates, which is the conversion of the laboratory-generated raw dates given in radiocarbon years to calibrated ages given in calendar years (Stuiver and Kra, 1986). During the past 10 000 years, the discrepancy between radiocarbon and calendar ages is as high as 1000 years, occurring ca. 5000 B.C.

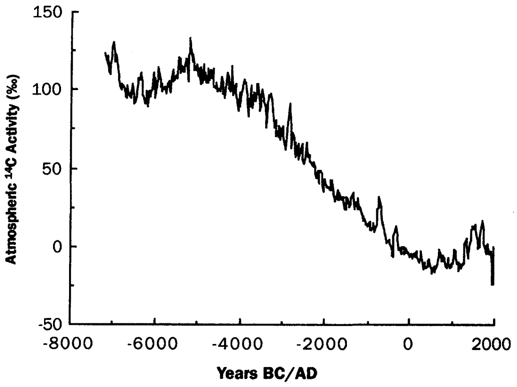

FIG. 1. Radiocarbon activity (per mil deviation from the standard) vs time, from measurements on dated tree-ring samples. Data from Stuiver and Reimer (1986).

Many materials have been used for radiocarbon dating, including wood and charcoal, plant materials, textiles, shells, and bone, involving a variety of sampling considerations and pretreatments. Dating of individual items occasionally attracts great public interest. Damon *et al.* (1989) describe the dating of the linen known as the *Shroud of Turin*, which many people believe was used to wrap the body of Jesus. This study was only made possible because of the small samples allowed by AMS dating. Three laboratories (Arizona, Oxford, Zurich) participated in the study, obtaining consistent results that yielded an overall calibrated calendar age of A.D. 1260–1390 at the 95% confidence level, demonstrating that the linen is medieval. Most problems involve a greater number of dates from an individual archaeological site or a group of sites. For example, Haynes (1992) reviews the contributions of radiocarbon dating to the continuing debate about when people entered the New World. Radiocarbon dating made it possible to first date North American Paleoindian sites by means other than association with glacially related geologic deposits. Radiocarbon dates from the Clovis Paleoindian culture in the American Southwest cluster from 11 200 to 10 900 years before present. Haynes claims that earlier ^{14}C dates from other sites, such as Meadowcroft Rockshelter in Pennsylvania (ca. 14 000 BP) and Monte Verde in Chile (ca. 12 800 BP), are as yet ambiguous, because of the possibilities of sample contamination, complicated stratigraphy, erroneous identification of human artifacts, and/or unclear associations between dated material and human artifacts. The controversy concerning the peopling of the New World is discussed by Marshall (1990). Other published applications of radiocarbon dating abound, especially in the proceedings of the triennial International Radiocarbon Conference, published in the journal *Radiocarbon.*

1.2 Other Radiometric Methods

Another conventional radioactive dating method useful in archaeology is the *potassium-argon* (K-Ar) method (Aitken, 1990).

The decay of ^{40}K to the gas ^{40}Ar with a half-life of 1250 million years still allows precision of ±1000 years for materials as young as 1000–30 000 years old if there is sufficient potassium. Volcanic rocks associated with archaeological sites are the actual materials dated; the thermal volcanic event releases the argon gas and resets the radiometric clock. The traditional approach determined potassium content chemically, but the newer argon-argon method converts some of the potassium into ^{39}Ar by neutron irradiation, after which it can be measured by mass spectrometry along with the ^{40}Ar. Potassium-argon dating is useful in studies of hominid evolution (Bishop and Miller, 1972), as discussed below for magnetic reversals.

The decay of the radioactive isotope ^{238}U provides the basis for *uranium-series dating* (Aitken, 1990). The chain of daughter radioisotopes includes three relatively long-lived isotopes: ^{238}U, ^{234}U, and ^{230}Th. The buildup of ^{230}Th is controlled by its 75 400-year half-life. Measurements in the conventional method are made by alpha spectrometry, following chemical extraction of the elements involved. The age range covered by this method is from 5000 to 350 000 years, again extending into the time frames of hominid development and the Paleolithic period. The materials that can be dated include material associated with archaeological sites—calcite in cave speleothems, and travertine deposits from springs—as well as archaeological materials of bone, teeth, coral, and shells.

Other dating methods are possible because of the effects of radiation. *Thermoluminescence dating* (Aitken, 1985; Aitken, 1990) has been useful as a method for directly dating the manufacture of pottery or the heating of other materials such as baked clay, burned flint and stones, volcanic rocks, slag, and glass. Certain minerals in pottery, mostly quartz and feldspar, will emit light in excess of the normal red-hot glow when heated above 350 °C. This extra light is the thermoluminescence (TL). The origin of the TL can be described via a four-step process:

1. Irradiation of the sample from radioactive sources within the soil and the sample itself will free electrons in the sample from their parent nuclei. Over archaeological time, the irradiation is constant, and the number of freed electrons is proportional to time.
2. These electrons can then become trapped in crystalline defects, the number of which remains constant in the sample over archaeological time.
3. Heating of the sample, in nature or in the laboratory, expels electrons from their traps.
4. Nearly instantaneous recombination of these electrons with ions at luminescence centers generates the thermoluminescence.

The age is determined by calibrating the natural TL against a TL generated by a known laboratory dose of radiation. The TL can be measured by a sufficiently sensitive photomultiplier to a precision of ±5% of the age. The age range for this method extends back beyond the origin of pottery, ca. 7000 B.C. in the Near East. TL is a "regional clock" in that it is sensitive to the radioactive environment at each site.

Besides dating *per se*, TL has also become important as a method of detecting forgeries. For example, forgery was successfully detected for a group of stylistically suspect ceramics from Haçilar, Turkey, by the Research Laboratory for Archaeology and the History of Art at Oxford (Jones, 1990). Authenticity dating differs from regular dating in two important respects: only a small sample size is normally possible, and the radiation history during the life of a museum piece is so variable that it is basically unknown.

Another technique related to TL is *electron-spin resonance* (ESR) dating, also known as electron paramagnetic resonance (EPR) (Ikeya and Miki, 1985; Aitken, 1990). This is another method of evaluating the dosage of radiation accumulated by a sample. With this method, electrons are not ejected from their traps. Instead, they are detected by their response to high-frequency electromagnetic radiation while also in the presence of a slowly varying dc magnetic field. At a given frequency, a condition of resonance is established for a certain magnetic field strength. The absorption of the electromagnetic radiation is proportional to the concentration of trapped electrons. The same materials used for TL dating are amenable to ESR; dating of speleothem calcite is the most common application, with an age range of about 10^4–10^6 years.

1.3 Archaeomagnetic Dating

Archaeomagnetism is a subfield of *paleomagnetism* that uses archaeological materials or materials that have been magnetized during archaeological time (Tarling, 1983; Eighmy and Sternberg, 1990). The materials most commonly used are baked clays from fireplaces, clays from floors or walls baked during conflagration, and ceramics. If the date of the magnetization is known, these materials can be used to construct the pattern for secular variation for a geographic region. Once this has been done, the pattern can be used as a master curve for absolute dating.

Two major phenomena are involved in archaeomagnetic dating. The first is that the geomagnetic field changes over time. This secular variation is due to fluid motions in the Earth's outer core, where the geomagnetic dynamo originates. Geomagnetic directions change at rates of typically 1° per 25 years, whereas the dipole moment of the magnetic field has decreased by about 5% since the time of Gauss, who first measured absolute field strength.

The other major phenomenon is the ability of certain minerals in rocks to acquire a permanent (remanent) magnetization. The most important such minerals are magnetite (ferrimagnetic) and hematite (antiferromagnetic). Rocks can become magnetized parallel to the magnetic field by several mechanisms, the most important occurring when they are heated above (or close to) the Curie temperature (580 °C for magnetite; 680 °C for hematite), thereby acquiring a thermoremanent magnetization (TRM). Even when the field changes, stably magnetized rocks can retain most of their remanence parallel to the direction of the ancient field. Archaeomagnetism, like TL, has an advantage over ^{14}C in that the event being dated, the firing of the clay feature, is usually a cultural event due to the activity of people living at a site.

Archaeomagnetic direction studies require samples oriented in the field. Samples of about 2 cm^3 are collected within an oriented plastic or plaster-of-paris cube. From 6 to 12 oriented specimens might be collected from a single feature, such as a hearth. In the laboratory, magnetic moments of these samples are measured with either a spinner or cryogenic magnetometer. Typical moments of magnetization are 3 A m^2. For studies of magnetic direction, the stability of magnetization must be assessed by demagnetizing the sample, using either thermal or alternating-field demagnetization. These analyses are used to remove unstable secondary components of magnetization in order to retrieve the primary magnetic direction of interest. Directions are analyzed using spherical statistics, which were originally developed largely for the analysis of paleomagnetic results.

Unoriented as well as oriented materials can be used for paleointensity studies, an advantage because potsherds are very abundant at many archaeological sites. Paleointensity studies have most often been done with samples carrying a TRM, which theory and experiment indicate is linearly proportional to the strength of the magnetizing field. Thus,

$$\mathrm{TRM}_{\mathrm{paleo}}/\mathrm{TRM}_{\mathrm{lab}} = B_{\mathrm{paleo}}/B_{\mathrm{lab}}, \qquad (3)$$

where $\mathrm{TRM}_{\mathrm{paleo}}$ is the strength of thermoremanent magnetization acquired in the paleomagnetic field having paleointensity B_{paleo} and $\mathrm{TRM}_{\mathrm{lab}}$ is the strength of magnetization acquired in the laboratory field B_{lab}.

If the secular variation pattern is not yet well established for a region, archaeomagnetism can be useful as a relative dating method. A wide variety of dating methods have been applied to the destruction of Thera, or Santorini (Hardy and Renfrew, 1989). Downey and Tarling (1984) used archaeomagnetic results to argue that the destruction of Minoan civilization on Crete ca. 1450 B.C. occurred in two phases. Archaeomagnetic directions and paleointensities in central Crete were consistent with each other and paleomagnetic results from ashfall deposits on Thera, 120 km to the north. Archaeomagnetic directions and paleointensities in eastern Crete were consistent with each other and paleomagnetic results from stratigraphically younger volcanic deposits on Thera. The difference in directions between these two groups, along with typical rates of secular variation, suggests a time difference of 20 ± 10 years. Downey and Tarling (1984) argued that if the first eruption did not eradicate civilization throughout Crete simultaneously, then different earthquakes are more likely causes than volcanic eruptions for the two phases of destruction.

However, archaeomagnetic dating has most often been used as an absolute dating method by comparing the direction of the feature to be dated against a pre-established secular variation curve. Because the nondipole field of the earth constitutes regional anomalies of the dipole field, archaeomagnetic dating becomes a "regional pattern-matching" dating method. Secular variation data from different regions are geophysically important in understanding the behavior of the magnetic field (Creer *et al.*, 1983). In the American Southwest, archaeomagnetism has become a routine dating method (Eighmy and Sternberg, 1990); the secular variation curve can be calibrated by tree-ring dating at the higher elevations of the Colorado Plateau, but archaeomagnetic dating can be applied in the nearby desert where tree rings are too complacent for dendrochronology. The accuracy and precision of archaeomagnetic dating in this region are comparable to ^{14}C dating (Sternberg *et al.*, 1991). Paleomagnetic results for recent volcanic rocks can also be compared with and dated against archaeomagnetic results. For example, as shown in Fig. 2, paleomagnetic data for the Sunset Crater volcanic rocks in northern Arizona indicate that the flow from Gyp Crater could indeed have been erupted in A.D. 1066 (Sternberg and McGuire, 1990), as is suggested by stunted tree rings dating to that year.

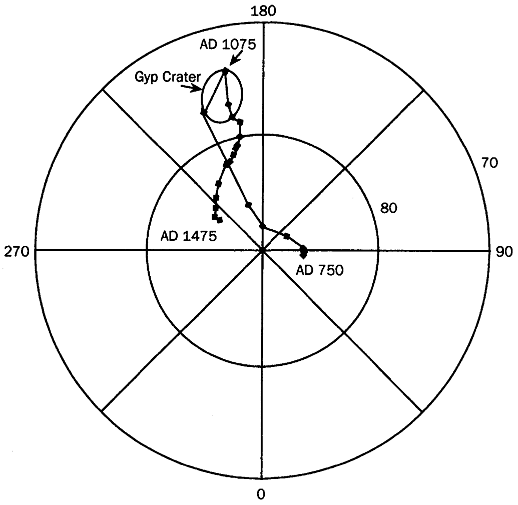

FIG. 2. Archaeomagnetic dating of igneous rocks from the Sunset Crater volcanic field, northeastern Arizona (Sternberg and McGuire, 1990). View is looking down on the north geographic pole. The archaeomagnetic directions are represented as geomagnetic poles. The points on the secular variation curve cover the time period A.D. 750–1475; each point on the curve represents a 50- or 100-year average of archaeomagnetic directions. The paleomagnetic direction and 95% oval of confidence for the lava flow from Gyp Crater yields an archaeomagnetic date of A.D. 1000–1175 by comparison to the secular variation curve.

The paleointensity experiment is tedious and difficult, and so, although it can ideally resolve ambiguities in directional dating for oriented samples (Downey and Tarling, 1984), it has been rarely used for dating alone. One example was the use of paleointensities to examine the ceramics from the Glozel site in France. It has been suggested that these very unusual ceramics may be fakes; one element of this argument is the inconsistency of different dating methods, including ^{14}C, TL, and paleointensity (Jones, 1990). On the basis of additional results from other well-dated ceramics, Shaw (1979) concluded that the paleointensity in Europe varied more rapidly between 100 B.C. and A.D. 300 than was previously thought, yielding a revised Glozel paleointensity date of about 50 B.C.–A.D. 100 that would be consistent with thermoluminescence dates. Although it did not resolve the Glozel controversy, this study emphasized the important archaeomagnetic principle that if the secular variation curve is revised, the original basic paleomagnetic results on the dated object can be reinterpreted to give a new date in accordance with the new pattern.

Another type of field variation that is useful in archaeology is the geomagnetic reversal: Occasionally, the magnetic field reverses polarity as the north and south magnetic poles exchange positions. There have been at least 23 reversals in the past 5 million years, the last major reversal being at 730 000 years ago. The recent reversal chronology pattern was established through paleomagnetic studies and potassium-argon dating of igneous rocks. Magnetic reversal stratigraphy has been used to calibrate the evolution of hominids. Brock and Isaac (1974) used reversals recorded via depositional remanent magnetization in sediments from the Lake Rudolf area of the African Rift Valley to examine the chronology of hominid fossils and associated artifacts and to compare these dates with other potassium-argon and paleontologic ages. Dating by use of globally synchronous magnetic reversals is a "global pattern-matching" dating method.

2. PROSPECTING

Archaeological excavation is a time-consuming and laborious undertaking. Geophysical prospecting (also known as prospection, surveying, exploration, and field geophysics) can help archaeologists optimize their available time and resources for field work. Geophysical prospecting at archaeological sites utilizes the same principles of geophysics used to prospect for geologic features and resources (Wynn, 1986), but with an emphasis on shallow and small-scale targets (Burger, 1992).

All geophysical surveying methods depend on an "operative physical property" (Kearey and Brooks, 1984, Chap. 1). Contrasts in these properties between different rocks and different archaeological materials are necessary to generate detectable anomalies in the quantity being measured. Different methods are sensitive to different properties, and so the technique used for a particular survey depends on the features being sought, their expected properties relative to the surrounding material, the area to be covered, the desired resolution, and the ability to see through cultural noise (fences, power lines, *etc.*) (see GEOPHYSICS).

2.1 Magnetics

The operative physical property in magnetic surveying is magnetization. Archaeological materials may carry a remanent magnetization, such as that used for archaeomagnetic studies, which is considerably stronger than the induced magnetization of surrounding material. The magnetic susceptibility and induced magnetization of archaeological features and soils can also vary, largely depending on the magnetite content. These variations in the magnetic properties of materials at archaeological sites generate anomalies in the earth's magnetic field.

Magnetic surveys differ from archaeomagnetic studies in that the magnetization of samples is not directly measured; rather, the geomagnetic field, including its perturbation by the field due to these magnetized materials, is studied. Two types of field magnetometers are in common use today. In proton precession magnetometers, a field applied by the instrument torques the nuclear magnetic moments of the proton-rich sensor fluid into alignment; when the applied field is turned off, the protons precess into alignment with the ambient field at a frequency equal to the product of the proton's gyromagnetic ratio and the strength of the ambient field. Counting the frequency thus gives a measure of the total field strength. The cycle time for the proton precession magnetometer is typically several seconds, limiting the spatial resolution or speed with which surveys can be carried out. The fluxgate magnetometer uses a sensor of two soft ferromagnetic cores wound such that a signal is generated with an amplitude proportional to the strength of the magnetic field along the axis of the sensor. The fluxgate magnetometer is generally used to measure the vertical component of the magnetic field. The measurement precision of these instruments is better than 1 nT, out of a typical midlatitude geomagnetic field strength of 50 000 nT. The method of data treatment and display affects the ability of the user to identify meaningful anomalies. Various methods are available for the great number of points that are measured during magnetic surveys, 2500–10 000 for a typical European site (Scollar *et al.*, 1986).

The geomagnetic field undergoes a diurnal variation of up to several tens of nanoteslas due to ionospheric currents. This variation may be an order of magnitude greater than anomalies of interest. One way to account for this is to establish a base station at which readings are periodically or continuously monitored. Both types of magnetometer can also be operated in the vertical gradient mode using two sensors. This has the dual advantage of eliminating the effects of diurnal variation, and of emphasizing the effects of near-surface (archaeological) over deeper seated (perhaps geological) features.

Breiner and Coe (1972) discussed an unusual application of magnetic prospecting for individual features: carved basalt monuments, weighing up to 40 tons, of the Olmec civilization that inhabited southern Mexico from 1200 to 400 B.C. These impressive features were individually identifiable through their anomalies of over 100 nT, presumably due to the remanence of these features. Magnetic susceptibility contrast in disturbed soil is responsible for the 10–20-mT anomalies shown in Fig. 3 (Clark, 1986), from a site in Oxfordshire, U.K. The two large circles represent ditches of the Bronze Age burial mounds; other circular and linear features are also visible.

2.2 Resistivity

Magnetic surveying is "passive" in that it reads a potential field that already exists. Gravity is a similar passive geophysical method but has only seen limited application in archaeology because of the limited resolution of conventional gravity surveying. Several other geophysical methods are "active," in that currents or waves are sent out, and the response of the earth is then measured.

Electrical resistivity has been the most commonly used active method for archaeological prospecting. The operative physical property in this technique is electrical resistivity,

$$\rho = RA/l, \tag{4}$$

where ρ is resistivity in ohm-meters, R is electrical resistance in ohms, A is the cross-sectional area of the current flow path, and l is the length of this path. Resistivities of earth materials can vary by over six orders of magnitude. Resistivity depends not only on the material itself but also on porosity, fraction of the pore space filled with water, and the resistivity of the pore water. Thus, resistivity surveying is often used to locate relatively low-porosity building structures in a matrix of higher-porosity soil.

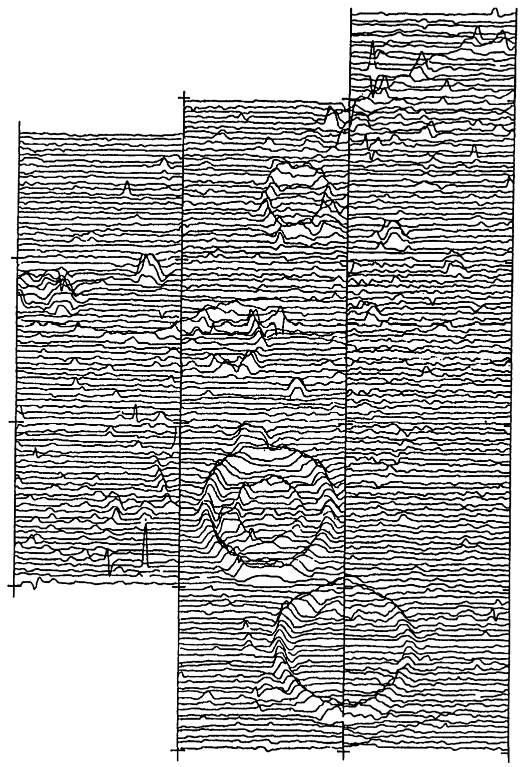

FIG. 3. Magnetic anomalies due to Bronze-age burial mounds at Oxfordshire, England (Clark, 1986; reproduced by permission of the Society of Exploration Geophysicists), shown by individual traces from a fluxgate gradiometer survey. Sensitivity is 7.5 nT/line interval.

Resistivity surveying is commonly done with a four-electrode setup, with two electrodes used to inject dc or low-frequency ac current into the ground, and the other two electrodes being used to measure the resulting voltage. A typical current is 30 mA. For the Wenner electrode array, the electrodes are collinear, equally spaced, with two outer current electrodes and two inner potential electrodes. For a uniform earth with resistivity r, the resistivity will be

$$\rho = 2\pi aV/I, \tag{5}$$

where a is the electrode spacing, I is the current, and V is the measured voltage. However, when the resistivity varies laterally or horizontally, this becomes an apparent resistivity ρ_a, which integrates the varying resistivity of the ground below. The effective depth of penetration for the Wenner array is about $1.5a$.

Resistivity surveys are carried out in two modes: sounding and profiling. In the sounding mode, using the Wenner array as an example, the spacing a is increased, with the center of the array remaining at the same point. As the spacing a increases, more of the current penetrates to greater depth, and a vertical electrical stratigraphy can be inferred. Various methods of interpretation can be used to infer the resistivities and thicknesses of horizontal, planar, electrically homogeneous layers. When profiling, the entire array is moved forward between measurements, maintaining the same spacing a.

The goal is now to find lateral changes in resistivity. These two modes can be combined to generate a pseudosection, where apparent resistivities are plotted horizontally at the midpoint of the array, and at a depth corresponding to the spacing *a*, to give an apparent cross section. Figure 4(a) shows contoured results from an electrical survey at historic Fort Wilkins, Michigan (Young and Droege, 1986). Privies were among the targets of this study; privies become convenient dumping grounds for one-time garbage that has now become archaeological artifacts. Resistivity anomalies A and B mark the site of known privies, whereas C is an anomaly of unknown origin. The pseudosection [Fig. 4(b)] indicates that the anomalies are strongest at depths between 1.0 and 1.5 m.

2.3 Other Electrical Methods

Two other methods that are receiving increased attention also involve electrical response of earth materials (Wynn, 1990). Electromagnetic conductivity (conductivity = 1/resistivity) surveying uses waves rather than electrical currents, transmitted and received via antennae with frequencies of typically 10–100 Hz. Anomalies are due to secondary magnetic fields at the receiver from eddy currents generated in the ground. This method is less useful than resistivity for sounding because antenna separation is fixed in most instruments, but faster for profiling because there are no electrodes to insert into the ground. Ground-probing radar (GPR) is a rapidly developing method, where dual antennae send radar waves between 80 and

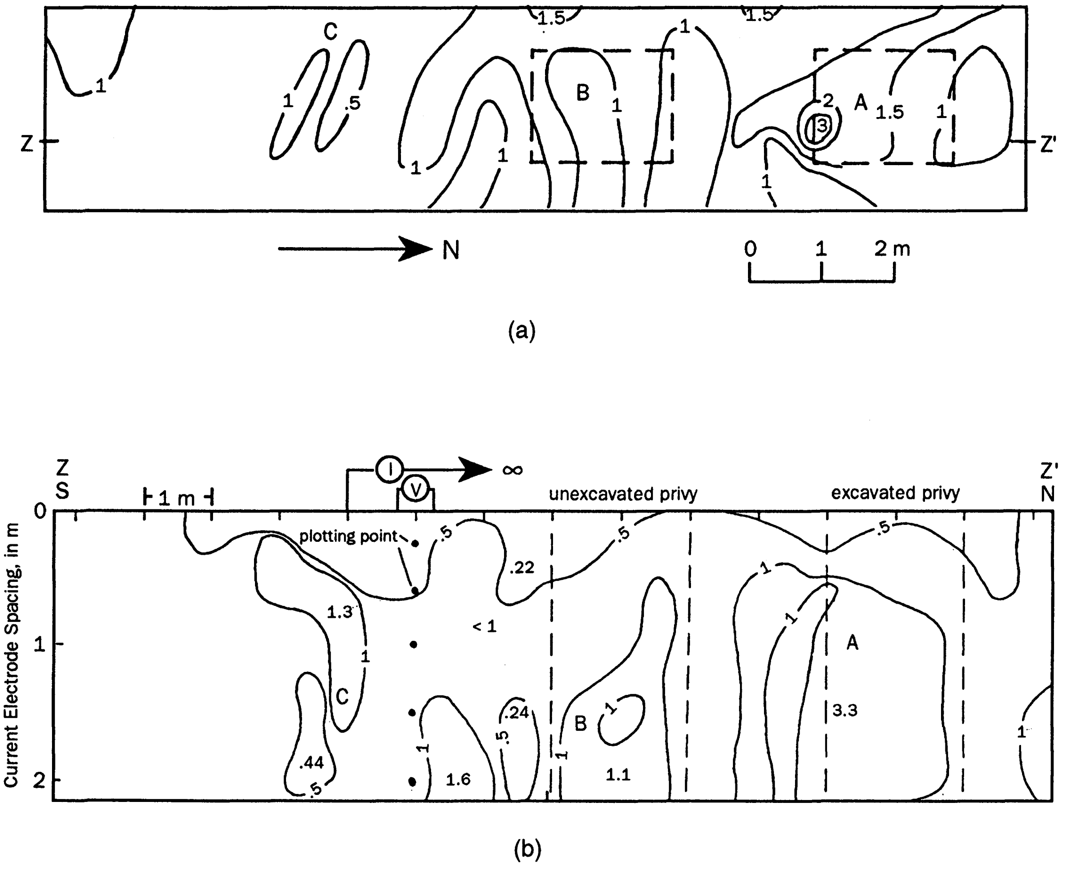

FIG. 4. Resistivity results from historic Fort Wilkins, Michigan (after Young and Droege, 1986; by permission of the Society for Exploration Geophysicists). Resistivities are contoured in units of kΩ-m. (a) Map view showing resistivity high-low anomaly pairs over two known privy locations at A and B. The source of anomaly C is unknown. (b) A resistivity pseudosection along the line of profile Z-Z′; maximum values are shown within contours.

1000 MHz into the ground and continuously map the reflections as the antennae are pulled across the ground. Both discrete parabolic reflectors and layered planar reflectors can be seen by radar when there is sufficient contrast in electrical impedances. Highly conductive soils can greatly limit the depth of penetration of the radar waves.

3. ARTIFACT CHARACTERIZATION

Studies that characterize artifacts involve almost every type of archaeological material, including pottery, stone, glass, and metals. Parkes (1986) provides a useful overview of the goals and methods of these studies. A wide variety of analytical methods has been used to determine the source location (or provenance) of the raw materials, to follow the trade routes of the materials or manufactured artifacts, to infer how the objects were manufactured, and to suggest how these objects were used. The method to be used depends upon the problem to be solved (e.g., which elements are of interest for chemical composition), whether quantitative (e.g., content) or qualitative (e.g., presence vs absence) results are needed, whether the artifact can be destroyed or not, and whether the surface or bulk properties of the artifact are of interest.

3.1 Provenance Studies

Provenance studies involve chemical characterization of the materials of interest to determine their source, or place of origin. Chemical analyses may focus on the major elements (≥2%), minor elements (0.1–2%), or trace elements (≤0.1%). Most chemical analyses are done using some type of spectroscopy. Besides the choice of analytical method, the other major methodological problem in provenance investigations is having analyses available from all possible source deposits and using appropriate statistical methods for comparing the artifact and potential source compositions (Rapp and Gifford, 1985).

Lead isotopes have been particularly useful in provenance studies of metallic artifacts (Gale, 1989), including objects made of lead, copper and copper alloy, iron, and silver. Of the four isotopes of lead, ^{204}Pb is nonradiogenic, and ^{206}Pb, ^{207}Pb, and ^{208}Pb are in part due to the radioactive decay of uranium and thorium. Thus, the lead isotope composition, which varies by 5% between deposits, depends upon the primeval lead content and the radiogenic history of the body. The lead isotope content shows little variation within an ore body and is essentially unaffected by smelting, two prerequisites for provenance analysis. The same cannot be said for chemical composition of ores and artifacts. The most common analytical method is thermal ionization mass spectrometry, which can measure ratios to ±0.1% on 100 ng of lead. Among the applications cited by Gale (1989) is the question of the source of copper for the Mycenaeans and Minoans in Crete ca. 1700–1500 B.C. The conventional assumption is that Cyprus (the root of the word copper) was the major source area, because Cyprus was a known copper producer, and Mycenaean and Minoan pottery was found in Cyprus. However, the lead isotopes indicate instead that the Laurion field in Attica on the Greek mainland was the likely source area.

Among nonmetals, stable isotopes of the lighter elements carbon and oxygen have also been useful for provenance studies of marble (Herz, 1985). The variations of the isotopes ^{13}C and ^{18}O are expressed as δ^{13}C and δ^{18}O, where

$$\delta(‰) = \left(\frac{R_{\text{sample}} - R_{\text{standard}}}{R_{\text{standard}}}\right) \times 1000 \qquad (6)$$

where $R = {}^{13}\text{C}/{}^{12}\text{C}$ or ${}^{18}\text{O}/{}^{16}\text{O}$ and the per mil variations are relative to the PDB (Pee Dee belemnite) fossil standard. Variations in these isotopes in the carbonate fraction of marble are due to the chemistry of the parent sedimentary rock, the composition of waters involved in the history of the rock, the temperature of metamorphism, and the later weathering of the rock. Measurement by mass spectrometry yields a precision of 0.2‰ or better. Within the Carrara district in Italy, the variation is less than 0.5‰ within a block, and less than 2‰ within an outcrop, whereas the variation between quarries is as much as 10‰ (Fig. 5).

3.2 Ancient Technology

Much archaeometric work on that most important of archaeological materials, pottery (Olin and Franklin, 1982), has involved

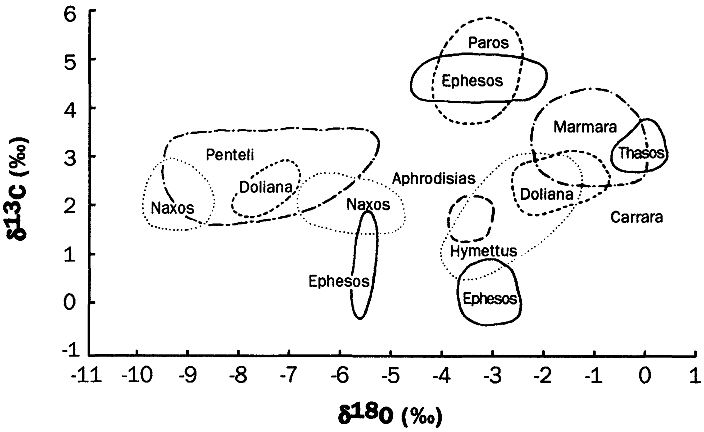

FIG. 5. Carbon and oxygen isotope fields for classical marble quarries (after Herz, 1985; by permission of Yale University Press).

sourcing the clay or temper according to chemical "fingerprints" (Perlman and Asaro, 1970; Hughes, 1991). Other ceramic studies have focused on the technology of production. One of the key aspects of production is firing temperature, which will depend on the method of firing and the fuel used. The final pottery product will depend upon the original raw materials as well as the temperature, time, and the atmosphere of firing. Three of the more traditional methods of assessing firing temperature are color evaluation, mineralogical analysis (because different minerals are stable over different temperature ranges), and measurement of thermal expansion (which changes markedly when the original temperature of firing is exceeded).

Newer, more technical, methods for inferring firing temperature include the use of scanning electron microscopy (SEM) and Mössbauer spectroscopy (Heimann, 1982; Maniatis *et al.*, 1982; Tite *et al.*, 1982). SEM uses a beam of electrons to scan the surface of the object under investigation. Backscattered electrons are detected in a density proportional to the atomic weight and hence to the elemental composition of the surface of the material. On the other hand, secondary electrons are emitted by the surface material and detected at a concentration depending on the angle at which the primary electrons strike the surface, thus giving an image of the surface's microstructure. In Mössbauer spectroscopy, a radioactive source, ^{57}Co, emits a γ ray as it decays to ^{57}Fe. These γ rays can be reabsorbed by ^{57}Fe in the sample. Because the source and target are both embedded in solids, the recoilless emitted and absorbed γ rays have small differences in their energies. Thus, the γ rays will only be absorbed if the source is moving relative to the sample, creating a Doppler effect. A measure of γ-ray absorption vs source speed indicates the transition energies of the sample's ^{57}Fe, which depends on the oxidation state (valence) of iron and its mineralogic form in ceramics. The iron mineralogy depends in turn on the temperature and atmosphere of firing as well as on the raw material. Thus, the Mössbauer results give clues to these aspects of the technology of pottery manufacture. Mössbauer spectra will vary as the sample is reheated in the laboratory (Fig. 6) because the iron oxidation state and mineralogy change. As an example of the joint application of these techniques, Maniatis *et al.* (1982) describe measurements on a small group of potsherds from a large Iraqi ceramic collection. The SEM patterns show the characteristic microstructure of calcareous clays fired between 850 and 1050 °C. Although microstructure does not vary within this temperature range, Mössbauer spectra can provide additional resolution. The sherds were refired to 950 °C, in the middle of the possible temperature range, in an oxidizing atmosphere. The spectra before and after refiring are the same, so the firing temperature for these sherds is narrowed to 950–1050 °C.

Glass, though technically a ceramic, is in many ways different from pottery. Henderson (1989) discusses the scientific analysis of ancient glass. One aspect of these studies is the nature and source of colorant for glasses. In the first detailed technical study of ancient manufactured materials, Sir Humphrey

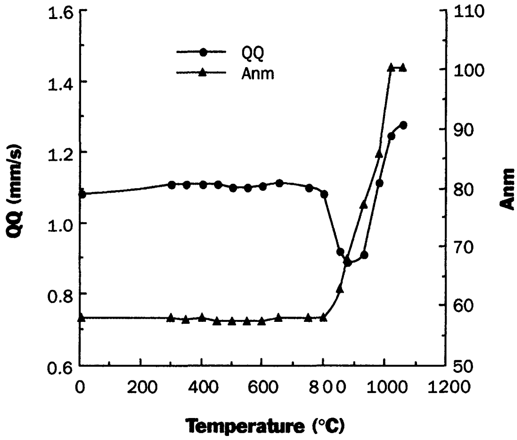

FIG. 6. The effects of laboratory reheating on Mössbauer spectra parameters for a brick from the Spandau Citadel, dating from A.D. 1540 (after Wagner *et al.*, 1986; by permission of Smithsonian Institution Press). The increase in the nonmagnetic Fe^{+3} quadrupole splitting (QQ) and the fractional intensity of the nonmagnetic Fe^{+3} and Fe^{+2} contributions (A_{nm}) indicate an original firing temperature of about 800 °C.

Davy, in 1815, suggested that cobalt was used to color ancient blue glass (Craddock, 1991). During the later Iron Age in Celtic Europe, from 500 B.C. to the Roman conquest, cobalt blue was one of the most common glass colors. Henderson (1989) cites several studies that considered whether cobalt-blue glass was actually made in late Iron Age Europe, or imported from the Mediterranean and then worked and shaped into the final product on site. This has technological implications: the temperature required to fuse silica and produce glass is 300–400°C higher than temperatures needed to work glass that has already been made. Many glass beads and armlets are found at the large European settlements of this era, and a high proportion of them are colored blue in the characteristic Celtic La Tène art style, suggesting local sources for the cobalt. Chemical analyses at several sites have also suggested that local ores could indeed provide the raw material for this colorant.

4. PALEOENVIRONMENT

Many paleoenvironmental questions concerning archaeological sites can be addressed through archaeological geology (Rapp and Gifford, 1985). These include studies of climate, ancient landscape, site formation processes, plant and animal resources, and diet. Paleoenvironmental problems are often studied through analysis of floral and faunal remains and geological studies of sediments and landforms. After brief comments on isotope paleoclimatology, this discussion will focus more narrowly on isotopic studies of paleodiet, rather than on a more general discussion of how the overall physical and biological environment can be reconstructed.

4.1 Paleoclimate

Aside from biological and geological reconstructions of climate, the major physicochemical methods used in paleoclimatology during the time period of interest to archaeology are oxygen and hydrogen isotope studies (Friedman, 1983; Herz, 1990). Isotope fractionation between ^{16}O and ^{18}O and between ^{1}H and ^{2}H is temperature dependent so that these isotope pairs can be used as paleothermometers. Oxygen isotopes in carbonates from harvested shells have been used in this way. Variations of $\delta^{18}O$ within seasonal bands of mollusc shells have been used to infer the seasonal occupation of sites. Isotope paleothermometry has also been applied to nonarchaeological materials that date to archaeological time, in particular sedimentary cores, glacial ice, cave speleothems, and tree rings. Complicating factors in isotope paleothermometry include varying isotopic composition of the original atmosphere and water (especially due to glaciation), isotopic composition of various shell minerals, and postdepositional chemical change (diagenesis).

4.2 Paleodiet

The most important light elements for dietary studies have been carbon and nitrogen, with the useful stable isotopes being ^{12}C, ^{13}C, ^{14}N, and ^{15}N. Nitrogen fractionation is presented as a per mil difference relative to the AIR (ambient inhalable reservoir) standard. Bone is the archaeological material commonly used for isotopic studies of diet because it is most often preserved; most analyses are made on the bone protein collagen because it is relatively stable.

Carbon isotopes were the first light element used for paleodiet studies (van der Merwe, 1982). Terrestrial plants metabolize carbon dioxide into more complex molecules by two different photosynthetic pathways that are significant in archaeology. The C_3 pathway, followed by most North American and European species, fractionates the stable isotope ^{13}C to an average value of $\delta^{13}C = -26.5‰$. Plants using the C_4 pathway, including maize and sugarcane, have less depleted $\delta^{13}C$ values of $-12.5‰$ on the average. Additional fractionation occurs as these foodstuffs move up the food chain, into the human diet, and are incorporated into human tissue. The fractionation between diet and human bone collagen for carbon seems to be about 3–5‰. This does not preclude inferences about major changes in diet but does complicate attempts to determine the proportions of different dietary components. Nonetheless, carbon isotopic ratios in collagen do appear to be directly related to the consumer's diet. Van der Merwe (1982) presents an example of how carbon isotopes can be used: $\delta^{13}C$ values in human bone collagen from peoples of the North American woodlands remained at about $-21.5‰$ from 4000 B.C. to 1 A.D., then increased to $-12‰$ by A.D. 1200. Thus, the proportion of carbon in the collagen from C_4 plants went from 0 to over 70%, indicating the introduction of and dramatic increase in the importance of the cultivation of maize in the diet of these people. This dietary change was accompanied by other major cultural changes, including increases in population and changes in settlement patterns.

Analysis of a single isotope does not necessarily yield a unique diet since different combinations of foodstuffs can yield the same isotope values. Use of carbon and nitrogen isotopes together extends the range of problems that can be addressed (DeNiro, 1987; Herz, 1990; Schoeninger and Moore, 1992). For nitrogen isotopes, the $^{15}N/^{14}N$ ratios vary between legumes and nonlegumes; legumes can directly fix atmospheric nitrogen, while nonlegumes must derive their nitrogen from the soil. Prehistoric legumes probably had $\delta^{15}N$ values of $+1‰$, while nonlegumes were most likely about $+9‰$.

DeNiro (1987) describes how isotopic dietary information can be "scraped" from a potsherd. In one of his studies, carbon and nitrogen isotopes were used together to show that the dietary importance of maize and legumes varied over time for some sites in the central Peruvian Andes. Residues from cooking ware indicated that the pottery was not used to cook legumes. Measurements in that study were made on the plant remains themselves.

The isotopic composition of carbon and nitrogen isotopes in human bones has also been used. In both terrestrial and marine environments, passing up the food chain to higher trophic levels increases fractionation of $\delta^{15}N$ values. Fractionation into human bone collagen typically increases $\delta^{15}N$ values by 3‰ relative to diet. Terrestrial C_3 and C_4 agricultural products have $\delta^{15}N$ values about 5‰ lower than marine foods. Nitrogen isotopic signatures in bone thus appear to be useful as paleodiet indicators in some, but not all, ecosystems. The simpler relationships seem to break down, for example, in arid environments, where water and/or protein stress may be factors. Figure 7 illustrates how carbon and nitrogen isotopes are useful in distinguishing between several diets from North American cultures (Schoeninger and Moore, 1992). The marine diet from the northwest coast is reflected in distinctly higher $\delta^{15}N$ values than the other diets shown. Some of the variation in this cluster of data is due to a temporal change in diet, with increasing reliance on marine foods through the late prehistoric period. The high $\delta^{13}C$ values for Pecos Pueblo are due to the dietary importance of maize. The Ontario population shows slightly elevated $\delta^{15}N$ values due to fish in the diet, and lower premaize $\delta^{13}C$ values. Bones from the people of St. Catherine's Island, Ontario, show intermediate $\delta^{13}C$ values due to the mix of C_4 values from maize and C_3 from deer meat and varying $\delta^{15}N$ values because of some fish in the diet.

Trace elements in bone and teeth have also been used to study paleodiet (Roberts, 1991). Strontium, like calcium, is an alkaline-earth element, and so it can substitute for calcium in trace amounts. Strontium can be a useful dietary discriminant because its concentration is high in plants, nuts, and marine invertebrates, but low in meat. It can thus be used to indicate the main food source for protein. Strontium concentrations, typically about 1000 ppm, can be measured by chemical methods such as inductively

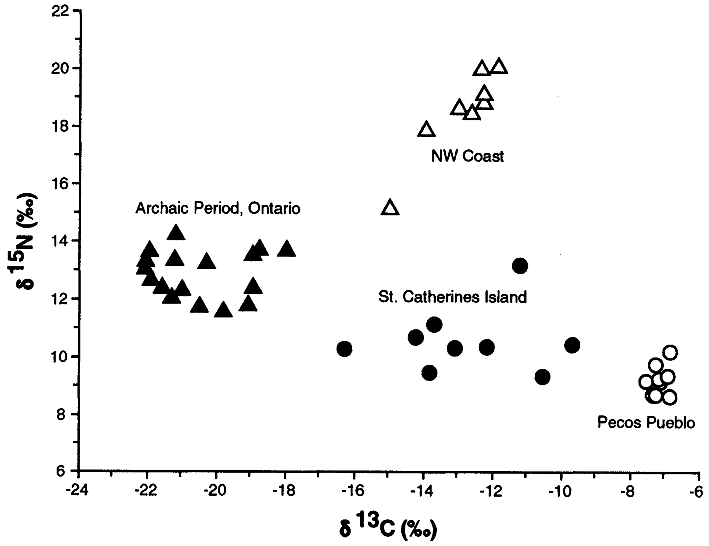

FIG. 7. Nitrogen and carbon isotope fields for several North American diets (after Schoeninger and Moore, 1992; by permission of Plenum Press). The major components of the various diets are as follows: NW coast, nonmaize plants and salmon; Archaic period, Ontario, nonmaize plants and freshwater fish; St. Catherine's Island, maize and coastal marine; Pecos Pueblo, maize and mule deer.

coupled plasma spectroscopy (ICPS). As with most chemical methods, contamination is a potential problem, in this case due to diagenesis from leaching or deposition by groundwater. Various cleaning methods are being investigated to minimize this overprint, a process quite similar in principle to demagnetization in archaeomagnetic studies.

4.3 Organic Residues

Analysis of other organic residues from pottery and tools is becoming a very promising area of research (DeNiro, 1987; Loy, 1991; Roberts, 1991). Materials recovered include blood, paint, tissue, plant remains, and hair. Identification of these residues and consideration of their preservation has accounted for much of this research so far. Some of these trace residues can also be dated by AMS ^{14}C dating. In the future, DNA extracted from skeletons of varying ages will be compared for genetic similarity or distance due to evolution or for the presence or absence of genetic diseases.

GLOSSARY

Accelerator Mass Spectrometry (AMS): Mass spectrometry after accelerating the ions to be measured, used for direct counting of ^{14}C in radiocarbon dating.

Anomaly: Unusually high or low measurement in geophysical prospecting due to a change in the subsurface material, indicating for example the presence of an archaeological feature.

Archaeomagnetism: The paleomagnetic study of archaeological materials, or rocks dating to archaeological time, providing the basis of archaeomagnetic dating.

Archaeometry: The application of the natural sciences to archaeology.

Chronometric Dating: A dating method using archaeometric techniques.

Electron-Spin Resonance: The measurement of electrons trapped in crystalline defects by their absorption of microwaves in the presence of a magnetic field, used as the basis for ESR dating.

Geophysical Prospecting: The use of the methods of physics to make measurements on the earth's surface in order to infer subsurface materials or properties, including the presence of archaeological features.

Mass Spectrometry: The measurement of isotopic masses after separating moving ions in a magnetic field.

Mössbauer Spectroscopy: A resonance technique utilizing the spectrum of γ rays absorbed from a moving source by a recoilless target; used to infer the iron mineralogy and temperature of firing in archaeological materials.

Paleoenvironment: The environment (e.g., climate, landscape, resource availability) at some time past.

Paleomagnetism: The study of the history of the earth's magnetic field, including the subfield of archaeomagnetism.

Provenance: The place of origin of a raw material.

Radiocarbon Dating: Dating of geological or archaeological materials using the radioactive isotope ^{14}C.

Scanning Electron Microscopy: The study of a surface's composition or microstructure by measuring backscattered or emitted secondary electrons resulting from a beam of incident electrons.

Spectroscopy: The study of matter by the wavelengths of radiation emitted or absorbed by atoms or nuclei, forming the basis for most chemical analysis techniques in archaeology.

Thermoluminescence (TL): The emission of light when electrons are ejected from traps in crystalline defects by heating an artifact, used as the basis for TL dating.

Thermoremanent Magnetization (TRM): Permanent magnetization acquired when a rock or archaeological object is heated above its Curie temperature.

INTRODUCTION

Books on physics are quite old as a means of communication; they date as least as far back as Aristotle. Journals, on the other hand, are a relatively recent development. The first scientific and technical journals are only a little more than 300 years old. The *Journal des Sçavans* (later called the *Journal des Savants*) was founded in 1665 by Denys de Sallo in France; it provided summaries of important books and reports on philosophical, scientific, and literary research. The *Philosophical Transactions of the Royal Society* in England also first appeared in 1665; in 1887 it was split into two series, with Series A containing the physics and mathematics articles, and is still being published. In Germany, the *Acta Eruditorum*, founded in 1682, published contributions from Leibniz. The first Russian periodical was *Yezhemyesyatchnüya Sochineniya*, published by the Academy of Sciences from 1755 to 1764. Ever since, the formal communication of research information has been carried on through the medium of the printed journal.

The journal literature of physics serves several important functions. It is a public archive and it establishes priority for the authors. It is also a means of controlling quality through the referee system (as the late Simon Pasternack, an editor of *The Physical Review*, remarked, the information store is like a gigantic grocer's warehouse, filled with everything from gourmet goodies to rotten materials that will make one ill if ingested). The referee system for journals, which relies on volunteers, is a means of ensuring the quality of the archive. (Book publishers usually pay an honorarium for a review.)

It was not until after the middle of the nineteenth century, when the first physical societies were established, that specialized journals devoted exclusively to physics appeared. *The Physical Review* was published at Cornell University in 1893 by E. L. Nichols and Ernest Merritt. It was published with "the cooperation of the American Physical Society" in 1903, and published by The American Physical Society (founded in 1899) only starting in 1913.

As the number of physicists grew, and publication expanded, societies formed special interest groups and journals began to specialize by property, techniques, phenomena, etc. Journals and journal articles proliferated, and the need for abstract journals became apparent. One of the first abstract journals, the *Journal du Journal*, was published in 1670. The number of abstracting and indexing services grew as journal publi-

cation increased. By 1975, there were 330 abstracting and indexing services in the United States alone, covering all fields and processing nearly 3 000 000 items per year.

1. TYPES OF LITERATURE

The literature of physics can be divided into many formats: journals and reprints, abstracts, reviews, monographs, reference books, conference proceedings, report literature, and preprints (information exchange groups).

1.1 Journals

It has been estimated (King and Roderer, 1982) that there were as of that date about 450 journals devoted exclusively to physics, of which 150 are published in the United States; about 23% of the U.S. physics journals are published by scientific societies, 57% are published by commercial publishers, and 20% are published by other organizations, such as educational institutions, government agencies, and companies. In a study of the 2000 journals scanned for *Physics Abstracts* (Singleton, 1976), it was found that almost half of the journals were published by learned societies and somewhat more than half by commercial publishers. Publishers in the United Kingdom and the Netherlands dominate the European scene, particularly Elsevier/North Holland and the Institute of Physics, while the not-for-profits in the United States and Japan account for most of their journals. Commercial organizations publish a slightly larger number of journals, but the not-for-profit organizations publish a far larger number of articles, partly as a result of the publishing programs of the American Institute of Physics and its member societies, the Institute of Physics in the United Kingdom, and the Japanese physical societies. The American Institute of Physics and its member societies, with their 80 journals, now publish more than one-quarter of the world's research literature in all fields of physics.

Most journals are now available both in printed form and on microfilm or microfiche. Although these are not popular formats with readers, libraries find them useful as a means of saving scarce library storage space, and also saving on the cost of binding back copies. CD-ROM is a more expensive process, since it requires that the manuscript be in computer-readable form; the advantage is the capability of browsing through large collections of articles.

A major difference between commercial and society publishers is in the area of growth and capital investment. The not-for-profit societies usually have no risk capital for new ventures, and are frequently hard put to find money for research, development, and investment in new equipment to replace that outmoded by advancing technology, without government support in the form of grants and contracts. Another difference between society and commercial publishers is that learned societies tend to create new journals by dividing journals of broad scope into more specialized ones. Commercial publishers are more active in seeking wholly new journals, either by starting them or by publishing journals for the smaller societies.

Table 1 shows the number of all U.S. scientific and technical periodicals by type of publisher in 1977 as estimated (King *et al.*, 1981).

Among the largest journals in terms of the number of articles published per year are the *Physical Review* (American Physical Society), the *Journal of Chemical Physics* and the *Journal of Applied Physics* (American Institute of Physics), the *Journal of Physics* (Institute of Physics), and *Nuclear Physics* and *Nuclear Instruments and Methods* (North Holland), all of which have become so large that they have been split into sections. As journal size increased, the concomitant delay in publication gave rise to letters journals such as *Physical Review Letters*, *Applied Physics Letters*, *Physics Letters*, etc.; these offered rapid publication of short reports of important results.

Table 1.

	Journals	Other periodicals (bulletins, etc.)	Total
Societies	1734	1653	3387
Commercial publishers	1557	1072	2629
Educational institutions	1247	800	447
Other	356	1296	1652

An analysis of the journal literature of physics (Keenan and Atherton, 1964) based on 1961 *Physics Abstracts* found that 20 287 abstracts appeared in 405 journals published in 39 countries. Of these, 13 874 were in English, 3087 in Russian, 1472 in French, and 1304 in German. Articles in the major Japanese journals were published in English. The remainder of the articles were scattered among other languages, including Spanish, Polish, Ukrainian, and Greek. By 1992, the number of abstracts published had escalated to 151 677, reflecting the increase in the number of physicists doing research as well as the proliferation of primary journals.

1.1.1 Journal Costs Table 2 shows the revenue and expense of publishing two journals of 6000–8000 pages and 3000–4000 subscribers; Journal A has page charges and Journal B has advertising income but no page charges.

The first four expense items are fixed costs, which are incurred no matter how many copies of a journal are printed. The miscellaneous category includes microfilm and microfiche, storage, insurance, back numbers, and so forth. The main source of income is from subscriptions, although some journals have additional income from advertising. Voluntary page charges were introduced by The American Physical Society for *The Physical Review* in February 1930 (Barton, 1963), as a means of keeping subscription costs low for members. At first, they were only $2 per page, but rising costs have brought them to $70 or more per page. Page charges were requested from the institutions supporting the reported research, and were intended to cover the fixed costs of preparing a manuscript for publication; member subscribers pay only for the runoff cost of printing and distributing their copies of the journal, and do not contribute to the editorial and composition costs. Page charges are more common in the United States, where they are used by professional societies and nonprofit organizations, than elsewhere in the world.

Table 2.

	Journal A	Journal B
Revenues		
Page charges	15%	—
Advertising income	—	3%
Reprint sales	6	6
Subscriptions	77	89
Miscellaneous income	2	2
Expense		
Composition	18%	22%
Editorial mechanics	14	17
Editorial management	17	11
Administration	15	12
Printing and binding	9	14
Reprint print and bind	6	4
Paper	7	6
Mailing, postage	11	10
Fulfillment	1	1
Marketing	2	3

Since the late 1960s, most publishers have experienced a steady decline in the number of subscriptions to their printed journals. As subscriptions decrease, the unit cost of the remaining subscriptions increases, since the fixed expenses are averaged over a smaller number of subscriptions. Several factors are responsible for the decline. Libraries are canceling multiple subscriptions and are relying on interlibrary loan for the less frequently read journals. Physicists are relying less on personal subscriptions and more on library subscriptions, preprints, reprints, and photocopies. The number of pages published has increased for many journals; *Applied Physics Letters* published 1600 pages in 1977 and 4300 pages in 1987, and the *Physical Review* grew by 75% in 10 years. Some journals have reduced or eliminated page charges. To compensate, publishers have been forced to raise prices, and by 1987 nonmember subscriptions to physics journals, per 1000 characters published, varied from 0.39 to 31 cents for 1987 journals (Barschall, 1988).

Publishers have attempted to control production costs by accepting "compuscripts" or machine-readable manuscripts, and by optical character recognition systems, which scan manuscripts. The American Physical Society has developed a guide for submission of compuscripts (Sutherland, 1989), and 20% of *Physical Review* manuscripts are now submitted in REVTEX.

1.1.2 Bibliometrics The Institute for Scientific Information publishes an annual listing of the impact factors for all of the major scientific journals (except for translation journals), taken from the *Science Citation Index*. The "impact" of a journal is defined as the average number of citations in a given year to articles published in that journal in the previous 2 years.

In 1972 and 1973, the National Science Foundation supported a series of studies (Narin *et al.*, 1972; Narin and Carpenter, 1973) to develop a model of the interrelationship of scientific journals, based on citations to and from journals in the *Journal Citation Index*, a file derived from the *Science Citation Index*. Seventy-nine physics journals were in the database. The first study found that the journal cited most frequently was *The Physical Review*. Journals listed as "preferentially cited" were the *Astrophysical Journal*, the *Journal of Applied Physics*, the *Journal of Chemical Physics*, and the *Journal of Geophysical Research*. "Highly cited" journals were *Applied Physics Letters, Nuclear Physics, Proceedings of the Royal Society A, Physics of Fluids, Physics Letters, Physical Review Letters*, and *Soviet Physics—JETP*. The largest journals were found to be cited out of proportion to their size, perhaps reflecting a perception of quality. The second study found that a group of 81 physics journals formed distinct clusters based on citations to and from.

1.2 Abstracts

There are two comprehensive abstracting services in English. *Physics Abstracts*, a section of INSPEC, is published by the Institution of Electrical Engineers in Great Britain. *Physics Briefs* (formerly published in German as *Physikalische Berichte*) is compiled by the Fachinformationszentrum Energie, Physik, Mathematik and printed and distributed by VCH Publishers in Germany. Each of these services published approximately 150 000 items in 1992 in printed and electronic formats. *Bulletin Signaletique* and *Referativni Zhurnal*, which have physics sections, are the corresponding French and Russian services. *General Physics Advance Abstracts* covers research to be published in 46 primary journals of the American Institute of Physics and its member societies; it is available on PINET. The SPIN (Searchable Physics Information Notices) database includes abstracts from the AIP and member society journals as well as other American physics journals; it is available on the PINET and DIALOG information systems. *Current Physics Index* is a quarterly abstracts journal containing approximately 8000 articles from 53 journals of the American Institute of Physics and its member societies.

There are, of course, other services that overlap physics, such as *Chemical Abstracts Service* from the American Chemical Society and *Compendex* from Engineering Information, Inc., as well as specialized services such as *Solid State Abstracts*. Another form of secondary literature are titles journals, such as *Current Contents* from the Institute of Scientific Information, which lists the table of contents of journals. Many research laboratories circulate their own collections of tables of contents and abstracts.

1.3 Review Literature

Reviews are essential for the evaluation, synthesis, and consolidation of the literature. Prominent review journals include *Reviews of Modern Physics, Reports on Progress in Physics*, and *Uspekhi Fizicheski Nank*. There are a number of serials for different fields of physics such as "Advances in . . ." and "Progress in . . .". Reviews can vary from critical, to exhaustive, to bibliographies.

1.4 Books

> "The book, however it is formed, has been entertaining human beings for 3,000 years, is doing so now, and will do so 5,000 years from now, if we're still here."—Isaac Asimov (1920–1992)

Asimov added that the book is a portable device, and the ultimate technology for thought transfer. It is easily transported, private for the end user, kinetically activated but requiring no energy source, easily filed, and browsable so that the end user can go back and forth.

Research is disseminated through the journals, summarized in abstracts, and distilled into reviews, eventually appears in a monograph, and finally is captured in handbooks and encyclopedias. At one time, monographs were almost exclusively published by commercial publishers, such as John Wiley & Sons and Plenum Publishers in the United States, Elsevier in the Netherlands, and Springer-Verlag and VCH Publishers in Germany. Other major publishers of physics books include Cambridge University

Press and Oxford University Press in England, and Mir and Nauka in the former Soviet Union. Recently, the American Institute of Physics and the Institute of Physics in England have expanded their book publishing programs in order to provide books for members at a lower cost.

Dover Publications has had a long-standing program of reprinting some of the classic books of physics that were out of print. These include, among many others, works by Sir Lawrence Bragg, Paul Ehrenfest, Werner Heisenberg, Sir James Jeans, James Clerk Maxwell, Sir Isaac Newton, Max Planck, Erwin Schrödinger, and Sir Edmund Whittaker.

Two recent one-volume encyclopedias of physics are those edited by Besançon (Van Nostrand Reinhold) and by Lerner and Trigg (VCH Publishers). Multivolume works include the McGraw-Hill *Encyclopedia of Science and Technology* and the *Encyclopedia of Physical Science and Technology* from Academic Press. Handbooks of physics include the *AIP Handbook of Physics*, edited by Gray, and the *Handbook of Physics* edited by Condon and Shortley, although there have been no new editions of these two. The *Physicist's Desk Reference*, edited by Anderson, has been recompiled and is a concise collection of useful formulas, numerical data, definitions, and references. Springer-Verlag is the publisher of two well-known series of multivolume reference works: the *Handbuch der Physik/Encyclopedia of Physics* edited by Flügge and the *Landolt-Börnstein Numerical Data and Functional Relationships in Science and Technology*.

Dictionaries of physics have been compiled by Thewlis and by Isaacs; there is also an IEEE *Dictionary of Electronics* which is useful for physicists, and a *Dictionary of Space Technology* by Williamson.

Other useful general reference sources include the 1990 *AIP Style Manual* by Scott, the *Energy Source Book* edited by Howes, directories of members of various physics organizations, a *Dictionary of Scientific Quotations* edited by MacKay, and *Database Systems in Science and Engineering* by Rumble and Smith.

1.5 Conference Proceedings

In recent years, the number of scientific meetings has escalated so that there are many meetings every week in all parts of the world. Many of these meetings result in conference proceedings, which include congresses, workshops, symposia, seminars, and summer schools. In general, these papers are not refereed; they are reports of work in progress and may subsequently appear, in revised form, in a refereed journal or as a journal supplement. Most proceedings are produced from camera-ready copy supplied by the authors. Some proceedings are published as books, while others appear in journals.

Conferences that are held on a regular basis frequently change publishers, making it difficult to locate and obtain a copy of the proceedings. Conferences in physics are listed every two months in *Physics Today* with the name of a contact person; *Chemical and Engineering News* publishes a listing of conferences in chemistry and related fields every 6 months. Some journals, such as the *Review of Scientific Instruments*, publish announcements of conferences in their field. Published proceedings are listed in the Science, Engineering, Medicine, Technology section of the *Directory of Published Proceedings* (Interdok). One study (Barschall and Haeberli, 1992) found that one publisher produced one-quarter of the physics proceedings listed by Interdok; 10% of the total listed were proceedings of NATO workshops. They also found that the cost of individual proceedings ranged from free volumes to participants to 50 cents per page, with an average of about 15 cents per page.

1.6 Report Literature

Reports are sometimes referred to as the "grey literature" because of the difficulty of obtaining copies. They are unrefereed publications. In the United States, reports resulting from research supported by the U.S. government are distributed in print form or microfiche by the Clearinghouse for Scientific and Technical Information. The National Aeronautics and Space Administration supports STAR, Scientific and Technical Aerospace Reports.

1.7 Information Exchange Groups

Information exchange groups are usually informal arrangements among research groups to exchange preprints and reports. A well-known group is the SLAC Preprint Exchange, which issues lists of preprints received and an "anti-preprint" list of articles that have been published indicating which preprints can be removed from the collection. An "e-print" (electronic preprint) archive is hosted by the Los Alamos National Laboratory, the Scuola Internazionale Superiore di Studi Avanzati in Trieste, the Supercomputer Computations Research Institute at Florida State University, and Duke University. Scientists can acquire abstracts and preprints by e-mail or ftp, have title and author abstracts of any new papers automatically sent to their e-mail mailbox, and contribute their own papers to the mailing list of their choice. The first of this series of electronic bulletin boards was Hep-th (High Energy Particle Theory) set up by Ginsparg at the Stanford Linear Accelerator Center.

At one time, the U.S. government (particularly the National Institutes of Health) supported some information exchange groups, but the groups dissolved when support was withdrawn.

2. DATA COMPILATIONS

Numerical/factual data have been defined by Kaufman (1993) as "quantitative data with the supporting textual facts; it is not . . . limited to numeric data, but . . . it includes additional factual information in whatever format needed to describe the usefulness or limitations of the numeric part of the data." The additional information may include the significance level of the data, and the conditions and methods of measurement. Quantitative scientific and technical data usually appear in tables and graphs, and come in ranges as well as discrete values and a variety of units, making it difficult to capture the information in a form suitable for computer-searchable databases.

Earlier in this century, data compilations had broad coverage. Publications included the *International Critical Tables of Numerical Data*, the *Landolt-Börnstein Tabellen*, and the *Tables Annuelles de Constantes et Données Numériques*. The amount of effort that went into these compilations is not likely to be repeated; as the amount of data grew, it became necessary to develop specialized tables and databases.

2.1 Information Analysis Centers

There are now a number of information centers, dedicated to critically evaluating data and compiling specialized numerical databases. Several of them are located within the Office of Standard Reference Data (OSRD) of the National Institute for Science and Technology, or are sponsored by the OSRD. OSRD, jointly with the American Chemical Society and the American Institute of Physics, publishes the *Journal of Physical and Chemical Reference Data*, which collects the results of critically evaluated data in various fields and also makes articles available as separates; the journal also occasionally publishes supplements that are too long for a journal article, such as the JANAF Thermochemical Tables. Some of these data collections are also available as computer databases. Other data collections include the *Nuclear Data Sheets* and occasional publications such as the *Particle Properties Data Booklet* and the *Review of Particle Properties* compiled at the Lawrence Berkeley Laboratory.

Other information analysis centers include those at Oak Ridge National Laboratory, the Center for Information and Numerical Data Analysis and Synthesis (CINDAS) at Purdue University, the Crystallographic Data Centre in Cambridge, England, and the Canadian Scientific Numeric Database Service (CAN/SND). STN International, an online database service, offers two data compilations: the Materials Property Data Network and the Chemical Property Data Network.

2.2 CODATA

The work of information centers in all fields is promoted and encouraged by the Committee on Data for Science and Technology (CODATA), established in 1966 by the International Council of Scientific Unions. CODATA's mission is to improve the quality, reliability, and accessibility of data of importance to science and technology. In 1986, CODATA released its new recommended values for the fundamental physical constants (Cohen and Taylor, 1986). The reevaluation was made necessary by the extraordinary amount of experimental and theoretical work published since the previous evaluation in 1973, such as the redefinition of the speed of light, the discovery of the quantum Hall effect, and the measurement of the electron anomalous magnetic moment.

2.3 Symbols, Units, and Nomenclature

The General Conference of Weights and Measures, established by international treaty, in 1960 founded the Système International d'Unités (International System of Units), known as SI. The system is based on seven units: length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity; all other units are defined from these. The cgs system, based on the centimeter, gram, and second, is still used in some fields of physics. A revised set of symbols, units, and nomenclature was published by the International Union of Pure and Applied Physics in 1987 (IUPAP, 1987).

3. ELECTRONIC PUBLISHING

The term "electronic publishing" is used both for production of publications by computer composition and for electronic versions of publications.

3.1 Computer Composition

Many publishers are using computer composition to produce journals and books, and some are encouraging authors to submit computer-readable manuscripts. As equipment prices have come down, computers are also being used to scan and digitize figures and graphs, and to make up pages. These developments will improve the linkage between primary and secondary publishers, and between primary journals and numerical data centers.

The Standard Generalized Markup Language (SGML) has made it easier to exchange data. SGML is an international standard, implemented by a number of system vendors. It is platform independent, and provides the ability to link graphics and other nontext data to the text.

3.2 Electronic Journals

The electronic journal and the electronic library are logical consequences of the ability to create machine-readable full text. An electronic journal can be established by a group of authors with local or network access to a computer. An author would keyboard his article into a computer file, and authorize the editor to look at the file and copy it. The editor would select the referees, who are given access to the file. The referees would evaluate the article, entering their comments and suggestions into the file. The author may revise his article, and the editor enters it into the journal archive, which is a public file available to subscribers. The electronic journal would have no publication deadlines, and could publish new articles as they are accepted by the editor.

There have been several attempts to establish electronic journals. The best-known of these in the *Online Journal of Current Clinical Trials*, started in July 1992 by the American Association for the Advancement of Science and the Online Computer Library Center, Inc. It was the first peer-reviewed electronic journal to support graphs, tables, illustrations, and mathematical equations. Articles are published within 48 hours of acceptance. Authors have the option of having a short version of their article considered for publication in *Lancet*, the British medical journal. Beginning in 1994, abstracts from this journal will appear in the Index Medicus database.

After a pilot study in 1993, Springer-Verlag, AT&T Bell Laboratories, and the University of California at San Francisco (UCSF) have announced a 2-year joint experiment called Red Sage, which will deliver journals to departments at UCSF through the campus computer system, using AT&T's RightPages technology (Hoffman *et al.*, 1993). Copyright fees for printed copies will be recorded and processed by RightPages; each publisher will set its own prices for copying and collect fees through the system.

Other experimental scientific journal collections include the American Chemical Society's Chemical Journals Online (text only, no figures) and the Chemical Online Retrieval Experiment (CORE) at Cornell University. The University Licensing Program (TULIP), an Elsevier Science Publishers project, is another major electronic library.

There is even an online journal about online journals: the *Public-Access Computer Systems Review*, published by the University of Houston Libraries, and distributed free on the Internet.

4. DOCUMENT DELIVERY

Document delivery services have become the focus of much attention and concern among publishers and librarians because of the possible impact on the economics of journal publishing. Providing copies of documents has become a service provided not only by libraries but by online vendors and service organizations.

The Commission of European Communities explored the feasibility of a document delivery system, named ARTEMIS for Automatic Retrieval of Text from Europe's Multinational Information Service. ARTEMIS would accept a document in digital form (either text or facsimile), store it in a computerized database, and transmit it by telecommunications to the requester's terminal.

The European Space Agency conducted a pilot project, named APOLLO for Article Procurement with Online Ordering, based on the ARTEMIS recommendations. A consortium of American and European publishers is experimenting with a system similar to ARTEMIS, called ADONIS for Article Delivery Over Network Information Services. A commercial version of ADONIS began in 1991 with approximately 350 titles on CD-ROM. The American Institute of Physics and the American Chemical Society are also conducting experiments in online delivery of full text of journals, both facsimile and fully digitized.

5. COPYRIGHT

In 1976, the United States Congress passed the first major revision of the Copyright Act since 1909; the new law went into effect in 1978. The changes were necessary because of new communication technologies, including computers, photocopiers, television, and videotape recorders. Statutory copyright now rests automatically with the author as soon as the manuscript is "fixed in any tangible medium of expression, now known or later developed, from which [it] can be perceived, reproduced, or otherwise communicated, either directly or with the aid of a machine or device" (Title 17, U.S. Code). There are two exceptions: "work made for hire," in which the employer holds the copyright, and works by federal government employees as part of their official duties (although in the latter case, copyright may exist outside the United States). Since 1989, when the United States joined the Berne Copyright Convention, copyright owners are no longer required to put a copyright notice on the work or register the work to claim copyright, although registration is necessary at a later time in case of infringement. Since the United States became a signatory to the Berne Copyright Convention and the Universal Copyright Convention, the same rights are extended to foreign authors as to domestic authors; this applies to all the countries adhering to these conventions.

The new law provides several basic rights to the copyright holder:

1. the right to authorize reproduction of the copyrighted material;
2. the right to prepare or authorize derivative works, such as abstracts;
3. the right to distribute copies of the work; and
4. the right to display the work publicly, e.g., in print or on a cathode-ray tube.

Transfer of copyright to a publisher is no longer automatic, but requires a written transfer. This transfer permits the publisher to distribute reprints and microform versions of the article, allow abstracting and indexing services to use material from the journals and books, authorize photocopying, and produce computer tapes of the material.

The development of microfilm as a substitute for interlibrary loan of printed publications raised copyright issues which led, in 1935, to the "Gentlemen's Agreement" between librarians and publishers on fair use. The subsequent proliferation of photocopies has exacerbated the continuing controversy on the limits of fair use, balancing the rights of the copyright holder against the right of access to information.

Most publishers belong to the Copyright Clearance Center in the United States, or similar organizations in other countries. A line is printed at the bottom of the first page of a journal article identifying the journal and giving a price for copying the article; the money is then sent to the Center, which distributes it to the publishers. Some of the larger commercial organizations have annual contracts that permit them to make lump-sum payments rather than keeping track of individual articles copied. National copyright offices may still have to determine whether delivery of documents on demand over computer networks constitutes a publication or a public performance.

6. SUMMARY

"They that weave networks shall be confounded." Isaiah, chapter 19, verse 9.

The worldwide growth of computer networks will make information readily available to those who have access to computer terminals. All of the necessary technology exists today to create an electronic library, but there are still legal, regulatory, and management issues to be resolved. These include problems of copyright, transborder data flow, telecommunications regulations, and standards. It remains to be seen whether an electronic library is economically viable—whether publishers can afford the startup and input costs, and whether users will be willing to pay the delivery costs.

Although some have predicted the demise of printed publications, they are not likely to be completely replaced by the electronic library. Printed journals and books have their own advantages, including browsability, portability, the ability to underline and write in margins, and accessibility to those without computers. There is certainly room for both modes of communication. The automobile may have replaced the horse, but the airplane has not replaced the automobile!

INTRODUCTION

Many physics experiments today are required to be done on state-of-the-art, complex facilities that are very expensive and centrally located. The researcher, wherever located, travels to the facility, which is operated by a resident permanent staff. It is these facilities that will be discussed here. The host laboratory where the facility is located also has a staff that may conduct research at the facility, but the arrangements for research include the availability of the facility to qualified researchers regardless of their affiliation. In this category of physics research facilities are perhaps less than a hundred worldwide, depending on the definitions. This article will focus on the most important ones, representative of four different categories of physics research: condensed matter physics, nuclear physics, particle physics, and plasma physics.

A facility includes the machine or device that produces the neutrons, protons, photons, electrons, or other particles, together with the associated detectors and instruments. The basic device is originally constructed with only a few instruments and detectors. With time, the experimental program matures and new instruments are added by the research community. Many of the experiments are conducted by teams of researchers from many different institutions. Typically, frontier facilities under construction cost many hundreds of millions of dollars to construct and will require tens of millions of dollars to operate annually. The annual operating budget includes the electrical power, materials and supplies, and the staff to run the facility. The research to be done at the facility usually is funded separately. A researcher generally has to submit a proposal to obtain approval and an allocation of time

in these facilities. Every facility has its own set of rules and the prospective experimenter should contact the individual facility management to obtain specific guidelines on how to seek approval for research in any of the facilities discussed here.

1. CONDENSED MATTER PHYSICS

In the field of condensed matter physics, neutrons and photons are extremely useful as probes to study the structure and dynamics of condensed matter. Facilities built to produce neutrons and photons for condensed matter physics are at the same time useful for other fields of science such as materials research, biology, chemistry, and others. Neutron sources are reactors or spallation sources, and photon sources are called light sources. Each facility usually provides many beam lines individually instrumented for a particular class of experiments.

1.1 Neutron Sources

Modern high-flux neutron sources for beam research are of two types: (1) fission reactors, which produce neutrons through the use of fissionable fuel, and (2) accelerator-driven devices which produce neutrons through a spallation process when high-energy particles hit a heavy-element target such as tungsten.

When a new material is discovered, often its basic atomic and magnetic structures as well as the dynamics of the atoms and magnetic moments need to be established. Neutrons, with their unique capability to penetrate materials and scatter from magnetic moments and their ability to discern light elements, are extremely useful as probes to investigate these materials. An example of the use of neutrons in such investigations is the crucial experiments done with neutrons on high-temperature superconducting oxides. Neutrons were used to determine the oxygen positions and content, the role of phase stability and impurity phases, as well as the nature of the magnetic structure and lattice dynamics. Neutrons have also been important in studies of heavy-fermion systems, in obtaining information on their magnetic properties; of fullerenes, in determining the structure, the lattice and rotational dynamics, and phase transitions; and of quasicrystals, in determining the atomic and magnetic structure as well as the vibrational frequencies.

More common materials are also investigated with neutrons using their unique characteristics for probing special effects. For example, the characterization of the structural consequences of bone mineralization has provided insight on the role of calcification on the structure and strength of bone. Neutrons continue to provide unique information on hydrogen effects in metals. Important neutron experiments have been performed on a variety of glasses to understand the domain sizes and the dynamics of spin glasses and disordered ferromagnets, as well as dipolar glasses.

Neutrons are used in some of the most fundamental studies vital to understanding matter in the condensed state. One of the most fundamental systems that has been illuminated with neutron scattering is the liquid and solid phases of helium. Experiments have provided important information on the structures and parameters of the various phases of this simple system. Neutrons have also been essential to understanding low-dimensional (one- and two-dimensional) systems. Neutron scattering has shown that one-dimensional spin systems are excellent realizations of spin liquids, with qualitatively different properties depending on whether the spin is an integer or a half-odd-integer. In the area of layered and multilayered structures, neutron scattering has provided detailed information about the magnetic structures on the nanometer scale, showing, for example, that magnetic order can propagate through nonmagnetic layers and that giant magnetoresistance is not necessarily associated with antiferromagnetic couplings.

Other areas of research using neutrons include chemistry- and biology-related investigations. In chemistry, neutron diffraction is used to determine the structure of molecules and of molecular assemblies. The uniqueness of neutron diffraction lies in the particular distribution of neutron cross sections across the periodic table and with different isotopes. This aspect differs from x-ray diffraction and allows investigations of particular atoms. Inelastic neutron scattering in chemistry permits the study of the dynamics of molecules and molecular assemblies. Biological investigations using neutron probes are

Table 1. Reactor neutron sources.

Reactor	Location	Number of spectrometers	Neutron flux (10^{14} neutrons/cm^2 s)
High Flux Beam Reactor (HFBR)	Brookhaven National Laboratory (U.S.A.)	13	5
High Flux Isotope Reactor (HFIR)	Oak Ridge National Laboratory (U.S.A.)	9	11
National Institute of Standards and Technology (NIST) Reactor	NIST (U.S.A.)	12	4
High Flux Reactor Institute Laue Langevin (ILL)	Grenoble, France	32	12

increasing for many reasons. Neutrons are complementary probes and sometimes essential in the study of complex biological molecules. Isotope effects can be exploited, especially between hydrogen and deuterium with labeling experiments since hydrogen is the most abundant element in biological systems.

The importance of neutron diffraction and neutron scattering was recognized with the awarding of the 1994 Nobel Prize in physics to two of the developers of these techniques, Clifford Shull and Bertram Brockhouse. More than 40 years previously, the two researchers pioneered methods to investigate the properties of materials using neutrons, independently. Shull worked at Oak Ridge National Laboratory on techniques of neutron diffraction to determine the atomic structure in solids and then joined the staff at the Massachusetts Institute of Technology where he continued his research with neutron beams. Brockhouse did his early work at Chalk River, Canada, where he developed the technique of inelastic neutron scattering to study the vibrational structure of atoms in solids, and later moved to McMaster University.

There are advantages for each type of neutron source: reactor type or spallation type. Small-angle scattering is best done at a reactor cold source. The higher-energy neutrons readily available at a spallation source provide advantages for experiments at high pressure and with glass and liquid materials. Diffuse scattering to display planes in reciprocal space is well suited for pulsed spallation sources. However, small-crystal diffuse-scattering studies, especially near Bragg peaks, are more suited for a reactor source. Residual stress measurements and time-resolved studies can be done equally well at either source. Table 1 provides a sample listing of some of the most powerful reactor neutron sources. Table 2 provides a similar listing of the spallation neutron sources.

1.2 Synchrotron Radiation Sources

Photons emitted from synchrotron radiation sources have become extremely attractive probes for experiments, not only in physics, but also in biology, materials science, chemistry, and other technological fields. Synchrotron radiation results from charged particles traveling in curved paths. The electromagnetic radiation given off can be controlled by controlling the particle energy and other characteristics of the particle beam. By constraining a particle beam with a magnetic field in a storage ring, the radiation produced can be made extremely in-

Table 2. Spallation neutron sources.

Source	Location	Number of spectrometers	Proton beam power (kW)
Los Alamos Neutron Scattering Center (LANSCE)	Los Alamos National Laboratory (U.S.A.)	8	38
Intense Pulsed Neutron Source (IPNS)	Argonne National Laboratory (U.S.A.)	12	6
Pulsed Spallation Source (ISIS)	England	13	77

tense over a broad range of wavelengths. Radiation emitted from such storage rings ranges from the infrared through the visible and ultraviolet into the soft and hard x-ray regions. The advantage of synchrotron radiation over other sources of photons lies in the combination of high intensity, broad spectral range, collimation, pulsed time structure, and partial coherence for the wavelengths produced.

Some photon sources were designed for purposes other than synchrotron-radiation research devices and are called first generation sources. The sources specifically designed and optimized for dedicated synchrotron radiation research are referred to as second generation sources. Those designed later and optimized for dedicated synchrotron radiation research using insertion devices are termed third generation sources.

Many experimental stations are possible at a storage ring. Electrons or positrons are circulated in a closed orbit within a storage ring. Radiation is emitted from all curved parts of the orbit. Radiation from bending magnets and from specially designed magnetic insertion devices leave the ring through tangential ports called beam lines on which experimental stations are located. Usually the storage rings are optimized to produce radiation in either the ultraviolet or the x-ray region of the spectrum. Storage-ring sizes range from a few meters in circumference operating at a few hundred million electron volts to large rings, 1500 meters in circumference, operating at 8 GeV.

In addition to the usual diffraction, microscopy, and chemical analysis experiments, which can be done with greater precision, quicker, and on smaller samples, new experiments are possible on synchrotron radiation sources. Additionally, new technological applications such as x-ray lithography, micromachining, and x-ray angiography are possible.

For certain experiments, photon flux [photons/s·mrad·(unit bandwidth)] hitting the sample is all that is important. For others, brightness [photons/s·(unit solid angle)(unit source area)(unit bandwidth)] is increasingly becoming important. Time-lapse experiments require a certain time structure to the radiation. Electrons in a storage ring are bunched, causing light to be emitted in pulses. Each bunch may be typically 0.5 to 5 cm long, resulting in a pulse duration of 100 ps for a 3-cm-long bunch, as an example. The spacing, typically, between bunches can be adjusted to result in light pulses from a few picoseconds to a microsecond apart.

There are more than 30 rings operating worldwide. Table 3 provides a sample listing of some of the most powerful x-ray rings. Table 4 contains a similar list for ultraviolet/soft x-ray rings.

2. PARTICLE PHYSICS

Experimental facilities to accelerate, collide, and detect nature's smallest particles have enabled the scientific community to study and understand the basic constituents of matter. Particle accelerators, colliders, and detectors have increased in size, energy, and sophistication in order to peel back successive layers of the building blocks of matter from the atom to the electron, proton, and neutron to the subnuclear particles to the quarks. Observing these fundamental constituents has enabled physicists to put together a picture or model of the known basic constituents of matter, the forces that control their behavior, and the carrier particles

Table 3. Synchrotron radiation sources (x-rays).

Ring	Location	Energy (GEv)	Ring generation
SPEAR	Stanford, CA (U.S.A.)	3.5	First
CESR	Ithaca, NY (U.S.A.)	5.5	First
SRS	Daresbury, England	2	Second
Photon Factory	Tsukuba, Japan	3	Second
NSLS II	Brookhaven, NY (U.S.A.)	2.8	Second
APS	Argonne, IL (U.S.A.)	7	Third (under construction)
ESRF	Grenoble, France	6	Third
SPring-8	Nishi Harima, Japan	8	Third (under construction)

Table 4. Synchrotron radiation sources (UV).

Ring	Location	Energy (GeV)	Ring generation
BESSY I	Berlin, Germany	0.8	Second
CAMD	Baton Rouge, LA (U.S.A.)	1.2	Second
ALADDIN	Stoughton, WI (U.S.A.)	1	Second
NSLS I	Brookhaven, NY (U.S.A.)	0.75	Second
Super ACO	Orsay, France	0.8	Third
ALS	Berkeley, CA (U.S.A.)	1.5	Third
ELETTRA	Trieste, Italy	1.5	Third
SRRC	Hsinchu, Taiwan	1.3	Third

which communicate the forces. This so-called Standard Model, however, has many arbitrary parameters, leaving still-unanswered questions about the origin and basic composition of mass. Some of the important contemporary experiments focus on efforts to understand fully and detect the postulated quark structures, to detect the postulated carrier particles such as the Higgs particle, and to understand the matter–antimatter asymmetry. To continue these experiments and to move to additional frontiers, the following facilities are among the most important.

2.1 CERN, European Laboratory for Particle Physics

CERN is a large scientific laboratory built through a collaborative effort of 15 member states from Western Europe. It straddles the French-Swiss border just west of the city of Geneva. CERN has a 27-km electron–positron collider ring (LEP) fed by a 20-GeV Super Proton Synchrotron (SPS). The electrons and positrons are first taken to 600 MeV in a 100-m-long preinjector, then accelerated to 3.5 GeV before passing into the SPS. In addition to electron–positron collisions, CERN can supply researchers with proton beams of both high and low energy, nuclear beams, proton–antiproton collisions, and low-energy antiproton beams. When LEP is operating, the injectors can continue to handle proton beams, interleaved with electrons and positrons destined for LEP. At various LEP intersections, detectors are located to pick up the particles resulting from the collisions and measure their energy and momentum. LEP has four large detectors built of modules, each to carry out a specific detector task.

Since the Higgs particle is likely to be present only at higher energies than is presently available, CERN is planning an upgrade. A new facility, the Large Hadron Collider (LHC), will utilize the existing LEP tunnel, replacing the existing magnets with high-field superconducting magnets. The plan is to collide proton beams with 7 TeV energy each.

2.2 Fermi National Accelerator Laboratory

Known as Fermilab, this laboratory is located about 35 miles west of Chicago, Illinois (U.S.A.). The main facility is the Tevatron which is the final of five separate accelerators working in tandem to accelerate protons to an energy of nearly 1 TeV. A tunnel that contains the main ring, which accelerates protons to 150 GeV, also contains the superconducting magnets of the Tevatron proton synchrotron. With the energies available at Fermilab, experiments are under way to confirm the detection of the top quark. An upgrade of the injector system is under way and will permit the production of antiprotons to be increased fivefold and will enable the delivery of three times as many protons to the Tevatron. Both colliding and fixed-target experiments with protons and antiprotons are conducted at Fermilab. Two large colliding-beam detectors are presently available.

In April of 1994, after a year of experimentation at Fermilab, a research paper was presented giving the first direct evidence for the top quark. The bottom quark was discovered at Fermilab in 1977, leaving the top quark the last undiscovered quark of the six predicted by the Standard Model. Although more experimental data are needed to confirm the preliminary results, the researchers believe they have detected the top quark and measured its mass using the collider detector, CDF. Because of the background and the statistics for confirmation, plus some discrepancies concerning another detector, the D-zero, which could not detect any particles, the researchers are gathering more data in order to definitely confirm these results.

2.3 Stanford Linear Accelerator Center

The Stanford Linear Accelerator Center (SLAC) is located near the campus of Stanford University at Menlo Park, California (U.S.A.). This 30-GeV linear accelerator facility includes experimental areas for fixed-target and colliding-beam experiments with electrons and positrons. Two storage rings are located at the facility, the larger positron–electron storage ring (PEP), and the smaller ring SPEAR which is now used exclusively for synchrotron radiation research. The present focus at the laboratory is to complete a recently initiated construction project to build a facility called a B-Factory that will produce copious quantities of b-mesons. The objective of the facility will be to understand why the universe is made up of mostly matter and not equal quantities of matter and antimatter. Several other laboratories around the world are also pursuing this objective; the KEK facility in Japan, for example, is undertaking to use the same approach of building a B-Factory.

2.4 Alternating-Gradient Synchrotron

The Alternating-Gradient Synchrotron (AGS) is located at Brookhaven National Laboratory, New York (U.S.A.). It is a high-intensity proton accelerator with a maximum energy of 30 GeV. Although not the highest-energy proton accelerator in the world, it has been continually upgraded since it first began operation in 1960. Kaon decay, neutrino experiments, and polarized-proton physics are among the areas of current interest. Shortly, it will take on a new role as the injector for Brookhaven's newest accelerator, the Relativistic Heavy Ion Collider (RHIC), to be completed about 1998.

2.5 KEK, National Laboratory for High-Energy Physics

The KEK-PS proton synchrotron is a 12-GeV machine built for high-energy physics that is now being used for both particle and nuclear-physics experiments. Begun in 1976, the accelerator is located at Tsukuba, Japan. Ten secondary beam lines in two experimental halls deliver antiprotons and pion and kaon beams in various momentum ranges and intensities. A polarized-proton beam of 40% polarization is also available up to 3.5 GeV.

3. NUCLEAR PHYSICS

The goal of nuclear physics research is to understand the structure and forces within that part of the elemental universe called the nucleus. In the nucleus, matter is densely packed and accelerator facilities are needed to study this strongly interacting matter together with the forces that govern its structure and dynamics. The topics in nuclear physics include the electroweak force, which plays an important role in nuclear stability, precision tests of fundamental interactions, large-scale collective nuclear behavior, motions of individual nucleons and mesons in atomic nuclei, and the underlying distribution of quarks and gluons. Because the science of the nucleus involves extremes of temperature, pressure, and density, the research has a strong relationship to astrophysics and cosmology. In the pursuit of nuclear physics research, it is necessary to have accelerators that produce high-quality beams of electrons, hadrons, and heavy ions over a very large energy range together with detectors and targets of novel design. In view of the variety of experiments needed, there are many facilities, worldwide, that are used to conduct nuclear-physics research. The following list contains a sampling of these facilities.

3.1 Argonne Tandem/Linear Accelerator System (ATLAS)

Located at Argonne National Laboratory, Illinois (U.S.A.), this facility is the world's first superconducting accelerator for heavy ions. The accelerator consists of a 40-MV superconducting linac and a 9-MV Tandem Van de Graaff injector. ATLAS is used for high-precision nuclear research using beams of heavy ions such as uranium.

3.2 Tandem/Alternating Gradient Synchrotron

This facility is located at Brookhaven National Laboratory, New York (U.S.A.), and provides beams for relativistic heavy-ion research. Ions up to gold have been accelerated. The facility consists of two linked machines, the Alternating-Gradient Synchrotron (AGS) and the Tandem accelerator. A Booster, a smaller accelerator that began operation in 1991, accelerates particles before they enter the AGS, where they are accelerated to 15 GeV per nucleon. The complex of Tandem/Booster/AGS will provide a full range of heavy-ion beams for fixed-target experiments and also constitute the complete injector system for the Relativistic Heavy-Ion Collider (RHIC), under construction as of 1995.

3.3 Relativistic Heavy-Ion Collider (RHIC)

To be completed in 1998, RHIC will be a dedicated research facility capable of accelerating two beams of nuclei to energies of 100 GeV per nucleon and colliding them. The collider consists of two 3.8-km rings of superconducting magnets for accelerating and storing beams of ions. The collisions at high energies are expected to create a quark–gluon plasma for study. This hot, dense matter is postulated to resemble matter shortly after the Big Bang.

3.4 Continuous Electron-Beam Accelerator Facility (CEBAF)

Experiments at this new facility are expected to begin in 1995. The facility is located in Newport News, Virginia (U.S.A.). The accelerator is designed to deliver high-quality electron beams in the energy range 0.4 to 4.0 GeV with an intensity of 200 A. The racetrack-shaped accelerator consists of two parallel superconducting linear accelerators joined at the ends by recirculation arcs, with three experimental areas. Its main goal is to understand the structure of the nucleon and of nuclei at the quark-gluon level, especially the nature of the low-energy, quark-confining strong interactions.

3.5 Clinton P. Anderson Meson Physics Facility (LAMPF)

LAMPF is located at Los Alamos National Laboratory, New Mexico (U.S.A.). The facility consists of a high-intensity proton linac and associated experimental areas. The 800-MeV linac produces three beams:

1. used to create secondary beams of pions, muons, neutrinos and spallation products,
2. for nucleon-nucleon and nucleon-nucleus studies and production of polarized neutron beams, and
3. to fill a storage ring used to produce spallation neutrons.

The main emphasis in the nuclear physics research program has been to study the interaction of pions with target nuclei; proton and neutron reactions with nuclei; basic proton-proton, neutron-neutron, and pion-nucleon interactions; and fundamental aspects of the weak interaction.

3.6 Bates Linear Accelerator Center

The Bates facility is located in Middleton, Massachusetts (U.S.A.), and is capable of providing very high-quality electron beams with energies up to 1 GeV. The facility contains an energy-loss spectrometer system for high-resolution electron scattering, a 180° scattering facility, an out-of-plane magnetic spectrometer, and other experimental spectrometers used to study a variety of nuclear elementary excitations.

3.7 Indiana University Cyclotron Facility

Located in Bloomington, Indiana (U.S.A.), this facility utilizes two coupled cyclotrons to accelerate polarized and unpolarized light ions. The beams are used directly in experiments and also injected into a synchrotron accelerator (Cooler Ring) that allows electron cooling of the stored beam. After proton energies of 200 MeV are achieved, the protons are extracted and steered into one or more of the various experimental areas. The Cooler Ring is used if higher energies or a finer beam quality is needed. The synchrotron ring is capable of accelerating the beam to 500 MeV and the beam can circulate for long periods of time while being used for in-ring nuclear experiments. In order to produce a higher-quality narrower beam at these higher energies, the ring has a short segment over which the proton beam is accompanied by a precisely tuned, concentric, renewable electron beam. This electron beam damps out the normal oscillatory behavior of the proton beam. The electron beam in this short ring segment runs parallel to the proton beam, is cylindrical with a diameter of about 25 mm, and causes the proton beam to be reduced in diameter from 6 mm to about 1.5 mm.

3.8 National Superconducting Cyclotron Laboratory (NSCL)

The NSCL is located at Michigan State University in East Lansing, Michigan (U.S.A.), and is dedicated to research with heavy nuclear beams with intermediate energy. Two superconducting cyclotrons are available for research.

3.9 Tri-University Meson Facility (TRIUMF)

Located at Vancouver, British Columbia (Canada), TRIUMF operates a six-sector isochronous cyclotron accelerating protons to 520 MeV. Two proton beams are extracted simultaneously to feed two experimental areas, the proton hall and the meson hall. Fields of research include decay modes and other fundamental properties of pions and muons, strong interactions of pions with nucleons and nuclei, elastic and inelastic scattering of nucleons by nuclei, and symmetries of the nucleon-nucleon system.

3.10 UNILAC/SIS/ESR Accelerator Facility

This heavy-ion accelerator facility is located in Darmstadt, Germany and consists of a linac (UNILAC), a heavy-ion synchrotron (SIS), and a storage cooler ring (ESR). Research under way includes nuclear reactions up to relativistic energies, and exotic nuclei far off stability.

3.11 Nuclear Structure Facility

The Nuclear Structure Facility is a 20-MV, vertical Tandem Van de Graaff accelerator, located in Daresbury, England. The research program includes nuclear spectroscopy at high angular momentum, nuclear moment measurements, and low-energy heavy-ion reactions and scattering.

4. PLASMA PHYSICS/FUSION RESEARCH

The energy produced in the sun and the stars is the result of the fusion of light atoms. This type of energy production is believed by many to be the ultimate energy source for Earth if it can be controlled and economically developed. For fusion to occur, an extremely high temperature must be attained with the fuel, this resulting in the fuel material being in the plasma state. Experimentation on heating and confining these hot plasmas is ongoing and necessary in order to develop fusion energy.

There are many different nuclear fusion reactions possible. However, the most readily attainable fusion process on Earth, that is, the one occurring at the lowest temperature, is the combination of a deuterium nucleus with one of tritium. Most fusion technology developmental programs aim to use deuterium–tritium fuel, but a considerable amount of plasma physics research is done on nonradioactive systems. In order to release energy at a level needed for practical use in the production of electricity, the gaseous deuterium–tritium fuel must be heated to about 10^8 K. Attaining these temperatures is not as difficult as the problem of confining the fuel under these extreme conditions. Since at these temperatures the fuel is in a plasma state, magnetic fields can be used to confine the electrons and ions, keeping them from striking the walls of a containment vessel. In order to achieve fusion, a minimum temperature, energy confinement time, and plasma density is necessary. Plasma instabilities of many types are a major obstacle to achieving the proper conditions for net fusion energy release to be greater than the energy needed for heating. In addition to plasma physics research, research is under way on technology development for economical energy production.

Of all the many concepts for containment that have been studied, the one receiving the most attention today is the tokamak concept. The tokamak is a toroidal device which has a hollow, doughnut-shaped vessel through which magnetic fields twist to confine the enclosed plasma. Magnetic fields are produced by current passing through wires or the plasma. Plasma heating can be achieved by a combination of resistive heating, high-energy neutral beam injection, magnetic compression, and radio-frequency heating.

Two examples of major fusion research facilities follow. The experiments to achieve an economical fusion reactor are so large currently that cooperation among countries is necessary. The International Thermonuclear Experimental Reactor (ITER) is an international project to demonstrate the scientific and technological feasibility of fusion energy for peaceful purposes and is being designed by the United States, Russia, Japan, and the European Community.

4.1 Princeton Plasma Physics Laboratory (PPPL)

Located in Princeton, New Jersey (U.S.A.), the major experimental facility at the PPPL is the Tokamak Fusion Test Reactor (TFTR). TFTR is the latest in a series of experimental devices located at PPPL and designed to study high-temperature fusion plasmas. The facility has a major radius of 2.5 m and a minor radius of 0.9 m. The toroidal magnetic field strength is 5.2 T. In December 1993, the TFTR achieved a world record of 6.2×10^6 W of controlled fusion power using a mixture of deuterium and tritium fuel. A new facility, the Tokamak Physics Experiment (TPX), is currently in the design/construction phase and will be built at PPPL in the test cell now occupied by the TFTR. It will be operated as a national user research facility. The purpose of the TPX is to develop the scientific basis for a compact and continuously operating tokamak fusion reactor. TPX is designed for continuous operation, with both high plasma pressure and enhanced plasma confinement. The TPX will be the first tokamak with fully superconducting magnetic field coils. In addition to superconducting technology, TPX will pioneer internal shielding and robotics for maintenance.

4.2 Joint European Torus (JET)

The Joint European Torus (JET), located at Abingdon, England, is jointly funded and staffed by 14 European countries. The overall objective of the JET facility is to study plasmas in conditions and with dimensions close to those that would be needed in a fusion reactor. The experimental facility is a D-shaped tokamak toroid with a major radius of 3.0 m, a minor radius of 1.3 m, and a toroidal field of 3.5 T. In preliminary tritium experiments, JET has produced 1.7×10^6 W of fusion power. The four main areas of research at JET are studies of scaling of plasma behavior as parameters approach the reactor range, studies of plasma heating, studies of plasma–wall interactions, and studies of alpha-particle production, confinement, and consequent plasma heating. Additionally, key technologies such as tritium handling and remote maintenance and repair are being actively investigated. JET will soon implement a new Pumped Divertor Phase of its operation, which will establish the effective control of plasma impurities prior to full deuterium–tritium operations.

INTRODUCTION

The development of twentieth-century physics has been closely tied both to the rise of modern industry and to the building of technologically advanced weapons systems. Traditionally, many governments have funded physics research as a means to a better national defense. During the last decade, this perception has changed as the industrialized nations have adopted the position long held by developing nations that a strong basic science infrastructure forms an essential building block for an economically competitive industrialized society. The importance of a scientifically literate work force is reflected by a global call for investment in human capital. While these trends are worldwide, they can be examined by looking at the evolution of the interaction between physics and society in the United States and comparing it to the development of physics in other societies.

1. BASIC PHYSICS RESEARCH AND THE DEVELOPMENT OF TECHNOLOGY

The distinction between basic physics and applied physics is generally easier to draw in principle than in practice. Ideally, basic research asks questions about the nature of the universe that arise only from the curiosity of the investigator. For example, physicists are searching for the top quark to see whether it exists and whether their current theoretical models of the structure of matter and the evolution of the universe are correct. No current plans exist to develop any specific technology on the basis of the "standard model."

Applied physics seeks to solve a specific practical problem using the results of basic physics research. For example, an applied physicist might develop a new photoelectric cell with a higher efficiency for use in portable solar-powered electric devices or study the interaction of sound waves with defects in metals in order to build a detector for locating metal fatigue before the metal structure fails. In these cases, the physics experiment is driven by the need for a technology.

In practice, distinguishing an applied physics laboratory from one engaged in basic research can be impossible. Workers in both discuss the same theories and experiments. In many cases, they use identical equipment. Applied physicists may make observations or develop theories that advance fundamental understanding, while physicists doing basic research may develop technologies. The search for new materials that exhibit high-temperature superconductivity can belong to basic or applied research, depending only on the goal of the research group. Physics research lies on a continuum stretching from basic research through applied research and on into the development of specific technologies. The lines are not clearly drawn.

Physics and technology feed one another. New discoveries in physics frequently lead to new technologies. Without physicists' attempt to confirm Einstein's prediction of stimulated emission of radiation, lasers would not exist, along with applications ranging from compact disc players to lecture pointers. Conversely, new technologies make possible advances in basic physics. The use of inexpensive, powerful computers in data collection allows modern nuclear- and particle-physics experiments to be done in a finite time. Available high-vacuum, high-voltage systems for construction of cathode-ray tubes led directly to the discovery of the electron and the beginning of modern physics.

2. PHYSICS, TECHNOLOGY, AND PUBLIC POLICY

Just as new physics promotes new technologies and new technologies give rise to new physics, so the availability of new technologies can shape public policy and public policy can influence the development of new technologies and encourage or discourage new fundamental physics. The influence of new technologies on societies has long been recognized. The steam engine triggered the industrial revolution. For further examples, life in the United States has been shaped by inexpensive private automobiles, and new computer technologies are rapidly changing the culture of today's work place. Policy makers must understand the capabilities and limitations of new technologies in order to respond to their social impacts. Because few policy makers have studied science, they rely on science advisers.

Recent concerns over the "competitiveness" of U.S. industries stress the role of public policy in shaping the development of both basic physics and technologies. Funding policies have allowed the growth of "big science" (Weinberg, 1967), that is, experimental facilities involving groups of tens to hundreds of physicists. By directing funds, the government can emphasize particular subdisciplines in physics. Industry supports research areas where managers see promise of commercially successful technologies.

2.1 Shaping of Policy by Physics and Related Technologies

Because of its role in the development of radar and the atomic bomb during World War II, physics has been particularly closely associated with the making of public policy in the United States. In contrast, agricultural research has dominated public policy discussions in much of the developing world. To understand the interplay between physics, technology, and public policy in the United

States, which mirrors the interplay between science and public policy in other nations, several case studies are presented.

2.1.1 The Arms Race and the Cold War During World War II, physicists applied basic results from modern physics to developing military technologies. Although enormous advances were made in fields such as the use of vacuum electronics for radar and understanding of sound propagation for sonar, the use of nuclear physics to develop the first atomic bomb was probably the most spectacular and certainly the best publicized use of physics in weapons development (Rhodes, 1986). Politicians and physicists alike recognized that nuclear weapons changed the way wars of the future would be fought. Because the physics on which the nuclear weapon is based was commonly known in the international community, nations that wished to be considered major contenders on the world stage rushed to develop their own nuclear arsenals. Nations such as India, Pakistan, and Iraq pulled technical talent and money away from industrial and agricultural development to support the development of nuclear technology.

Nuclear weapons offered a cheap substitute for large deployments of military manpower. The United States and the Soviet Union grappled for the control of Europe and developed powerful nuclear arsenals. The awesome destructive power of nuclear weapons meant that each side realized that a nuclear war would destroy not only the enemy but itself also. Physicists and other scientists and engineers were hired by the military to develop more capable nuclear warheads. The two great nuclear powers were effectively at war, but neither side dared actually to attack the other for fear of the terrible destructive power of the nuclear arsenals (Schroeer, 1984; Barash, 1987).

In the meantime, new technologies increased the accuracy of long-range nuclear delivery systems (Mackenzie, 1990). This opened the possibility of attacking the other side's arsenal rather than its population centers. New guidance technologies effectively drove strategic policies (Scowcroft, 1983). Physicists played prominent roles in analyzing strategic options (U.S. Congress Office of Technology Assessment, 1981).

On 23 March 1983, in a nationally televised address, President Reagan announced a new technological initiative designed to make nuclear weapons "impotent and obsolete." The Strategic Defense Initiative (SDI), popularly called "Star Wars," called for research into new defensive military technologies based on recent developments in the physics of directed-energy weapons and the possibility of directing an attack on missiles in the early phases of their trajectories from weapons based in space. Controversy erupted on whether or not such a defensive shield would be technically possible and politically desirable (U.S. Congress Office of Technology Assessment, 1985; Broad, 1985). Physicists featured prominently on both sides of the controversy. Even the nonpolitical American Physical Society produced a technical report on the state of the art in particle and radiation beam weapons (Study Group on Science and Technology of Directed Energy Weapons, 1987).

The resulting debate illustrated that physicists' results can be influenced by their politics. Those who felt that SDI would offer an effective defense against modern nuclear delivery systems generally agreed that the arms race could find a technological solution. Recent evidence suggests that the political beliefs of some actors were sufficiently strong to influence their perceptions of the results of their experiments and calculations (Broad, 1992). Physicists who believed that there could be no effective defense in a nuclear war generally held that the arms race should be solved through the traditional political means of arms control. A consensus gradually emerged that, although SDI could not provide a large-scale defense for a population against nuclear weapons, some of its technologies could provide defenses for hardened military targets or against very limited nuclear attacks (U.S. Congress Office of Technology Assessment, 1988). Physicists defined the cost of these limited and practical systems, leaving a political decision concerning whether the military advantages of the defenses justified the cost of deploying them.

In the case of nuclear deterrence, the cold war, and SDI, technologies based on developments in physics shaped possible military and foreign policies. Options available to political leaders were defined and limited by the technology available. Physicists acquired a role in government as judges of what was and was not technically possible.

At the same time, the utility of physics in the development of military technologies and the resulting support of physics by the federal government, defense contractors, and the military shaped the way in which physics research was conducted. The massive national laboratories established to support the Manhattan Project developed into models for today's large accelerators. Today's research groups in physics mimic the group of physicists and supporting engineers and other scientists who designed the atomic bomb. Physicists specialized, with some individuals doing only theoretical work and others, experimental work. Some became specialists in the design and construction of apparatus. The individual who did theoretical work and then designed, constructed, and carried out his own experiment nearly disappeared.

Finally, physicists have learned the limitation of their ability to control the use of devices they create. Following their success in creating an atomic bomb, many physicists were shocked by the destruction at Hiroshima and Nagasaki. They quickly learned that their technical expertise bought them no ability to control the use of the bomb. Science advisers may influence policy, but power in our democratic society belongs to those elected through the political process (see articles in Mendelsohn *et al.*, 1988). As more and more nations acquire the technical capability to construct nuclear weapons, the role of physicists in shaping policies for their use seems likely to decline further. For example, sales of nuclear warheads from the former Soviet Union on the world market have become a real possibility.

2.1.2 The Communications Revolution and the End of the Cold War Although the military uses communications technologies, industry has been the primary supporter of basic research in the field, and technological developments have been driven by consumer demands. Even the first computers were developed for civilian applications (Cohen, 1988, pp. 119–120). Development of the transistor and other breakthroughs in fundamental physics came from Bell Telephone Laboratories and other industrial research centers. The first high-temperature superconductors were found in an IBM laboratory. These major corporations have supported basic research in condensed-matter physics because they see the results of this research leading directly to devices that can be applied to communications technologies.

The industrial support of basic physics has proved profitable for industry and productive for physics. The social impact of the new communications technologies based on developments in condensed-matter physics has reached almost all aspects of daily life, from the ready availability of dedicated computers in microwave ovens and automobiles to the business use of personal computers. An extensive literature documents the impact of computer technologies on everything from the changing nature of the workplace to the question of protecting personal data stored in databanks from unauthorized users (see Brunn and Leinbach, 1991; Ganley and Ganley, 1989; Lundstedt, 1990; Pool, 1990).

Perhaps the most dramatic evidence of the impact of the communications revolution is its role in the breakup of the Soviet Union. During the August 1991 takeover of the Kremlin by a hard-line communist faction, the rebels controlled traditional means of communication within the Soviet Union. In the absence of radio, television, or newspapers, the people of Moscow were still able to communicate with the West and with other parts of the Soviet Union via FAX and e-mail. Citizens of Moscow itself received information from Yeltsin and his advisors thanks to desktop publishing and the availability of copy machines. Instant communications kept the coup public and mobilized local, national, and international support that helped lead to its overthrow. Among other effects, sophisticated communications links tend to open closed societies.

Sophisticated communication links form an essential element of a competitive industrialized society. Not only the republics of the former Soviet Union but also developing nations are attempting to develop computer-based communication links. For example, India currently seeks both to increase the number of computers throughout the subcontinent and to network them (Rahman, 1990). The presence of the basis for a nationwide communications network is one of the signs that distinguish the newly industrialized nations of Asia from the undeveloped nations of sub-Saharan Africa (Forje, 1989).

Physicists never controlled the applications of their research in the industrial laboratories. Unlike the social impacts of military technologies brought about by physics research, the social impacts of the communications technologies were a side effect of industrial policies motivated by profit. Physics research was seen as valuable in its ability to produce profit-making devices. Unlike physicists in military development, physicists in communications development neither expected nor attempted to control the social effects of their research.

Because industry has funded basic physics work as an investment in future profits, physicists in industrial laboratories are liable to lose their jobs if management does not perceive their products as being useful. Thus, many industries demand shorter-term profits in hard economic times and many have reduced their staffs in recessions. The type of basic research supported by industry tends to show a clear connection to a possible product and is generally not long term or highly speculative. Like research supporting the military, physics done in industrial laboratories often uses large groups, expensive equipment, and many support personnel.

2.1.3 Energy Policy Basic physics research has long played a role in the development of energy technologies from the fossil-fuel electric generator to the nuclear-reactor electric power plant to photoelectric cells. Most physicists agree that finite supplies of fossil fuels will force reliance on new technologies for energy production within the next few decades and that energy conservation measures are inexpensive means for stretching valuable natural resources. Few expect any technology to be without some adverse side effects. Beyond these limited areas of consensus, physicists disagree strongly as to the best energy sources to replace fossil fuels, the relative importance of seeking new energy sources and implementing conservation measures, and the probable long-range environmental consequences of using various energy technologies (Howes and Fainberg, 1991).

Despite the fact that physicists fail to agree in advocating any single energy policy, individuals have been visible and active as advocates of a number of different policies. The profession has been strongly associated in the public eye with making energy policy.

Funding for basic research to be applied to the development of energy technology has undergone wide swings as concern over U.S. energy supplies has varied with the price of oil. When funding levels were high, as during the mid seventies, energy research showed the same tendencies to large-group work noted in basic physics research related to military technologies. Reduced funding levels have caused researchers to return to the small-group model of research.

Although physicists had long warned that nuclear reactors were dangerous if not handled carefully and that nuclear wastes required development of storage technologies, physicists were seen as supporting the nuclear power industry for their own profit. Since World War II, physicists had been popularly perceived as nearly infallible workers of technical miracles. The accidents at Three Mile Island and Chernobyl badly injured their public credibility. Although physicists were granted a special voice in setting military policy, their public differences over energy reduced their privileged role in policy making. As in the case of communications, physics produced research that could lead to commercial results. Unlike their role in communications, physicists exhibited a strong interest in influencing energy policy, but they found that they would need to work inside the political process as citizens rather than be granted a special role in the policy process.

2.2 Assessing Technologies

Critical issues in energy policy, communications, and military policy center on whether or not technologies work and what their side effects will be on society and the environment. Although these issues are primarily technical, science may not provide unambiguous answers. Policy makers demand guidance on what science does and does not know. In sending technical aid to developing nations, industrialized governments face the complex task of examining the effect of the technology on the recipient society and the ability of that society to make the imported system work (Carnegie Commission, 1992a, 1992b, 1993). In technology assessment, physicists are asked to clarify those issues where science can provide answers and outline the decisions that are essentially political.

2.2.1 The Cold-Fusion Issue In 1989, the University of Utah called a press conference to announce that Dr. Stanley Pons and Dr. Martin Fleischmann had discovered a revolutionary form of nuclear fusion at room temperature that promised an almost unlimited source of inexpensive energy. Unfortunately, room-temperature or "cold" fusion violated the established laws of nuclear physics. The physics community reacted to the news with skepticism and excitement. All over the country, physics laboratories attempted to duplicate the Utah results. The Utah group had not published its results and refused to release details of its experiments pending patent application procedures. The physics community gathered information from the pages of *The Wall Street Journal* and buzzing e-mail networks. For three turbulent weeks, reports confirming and denying cold fusion jostled one another in the press. Dr. Steven Jones of Brigham Young University, who had long studied muon-catalyzed fusion, reported observing cold fusion, although his effect was many orders of magnitude weaker than that in the Utah report.

The press played up the dispute raging within the scientific community, billing it as a feud between all chemists and all physicists. Sober debates on the statistics and technology of neutron counting got lost in colorful name calling and interviews with graduate students who listed pizzas as part of their expenses in seeking cold fusion. Politicians, particularly in Utah, began campaigning for large research grants to support cold fusion. Serious technical issues played a small role in popular discussion.

The early stages of the cold-fusion debate indicate how technology assessment can be done in a way that damages society. Hope of technological breakthroughs and personalities jockeying for professional advancement and public recognition distort the public debate and polarize the scientific community. Fortunately physicists (and chemists) recognized their public responsibility to clarify the technical possibilities for political decision makers. A series of papers gradually began to appear reporting detailed experimental results and offering theoretical explanations for results and lack thereof. The early Pons and Fleischmann results were shown to be overoptimistic. On the other hand, the debate on a possible relationship between nuclear physics and condensed-matter physics was probably healthy for both communities once the physics began to dominate the political debate. Funding returned to a level consistent with the physics issues involved, and a textbook example of how not to conduct technology assessment came to a quiet end (Huizenga, 1993; Pool, 1990; Mallove, 1991).

The cold-fusion question provides an excellent illustration of major elements in technology assessment: scientific knowledge and uncertainty, political and economic ramifications, and public pressure.

2.2.2 Nuclear Reactors and Electric Power Generation Like cold fusion, the use of nuclear fission reactors to generate electric power provides a case study in technology assessment featuring technical uncertainty, economic pressures, and strong public feelings. The technical issues involved in nuclear fission for electric power generation center on the risk of a major nuclear accident and its consequences for the public. Reactors are complex systems, and analysis of their possible failure modes has established the state of the art for risk assessment in large systems (Vogelsang and Barschall, 1991). Despite the excellent work that has been done in the field, risk assessment yields at best a probability that a major accident could occur. The magnitude of the probability and the consequences of a particular accident are a function of individual reactor design and the geography of its location. Consequences also depend on the biological effects of low-level radiation, which, again, are just beginning to be understood and are necessarily presented as a statistical measure, such as the probability of the occurrence of a particular type of cancer at a particular exposure level.

The economic stakes in constructing nuclear reactors are much larger than those involved in cold fusion. The expense of a nuclear power plant can bankrupt an electric utility if the reactor does not generate useful electric power. Public concern over safety has increased the cost and complexity of both the licensing and the construction process to the point where many utility companies cannot afford to borrow capital to construct a new nuclear plant. There are currently no nuclear reactors on order in the United States. Insurance companies cannot bear the risk of giant claims following a nuclear accident, and so the federal government assumes a major portion of the risk under the Price–Anderson Act. The public questions whether or not the government should absorb the risks of a technology that earns profits for private corporations.

Finally, nuclear power plants have been sold to the public in a manner that had little to do with the technical issues of their safety. In the 1950s, the power industry oversold reactors as a safe, cheap way to generate electric power. Throughout the sixties and seventies, few outside the physics community questioned the safety of nuclear reactors. With the accidents at Three Mile Island and Chernobyl, the public became aware of the dangers of the technology and reacted strongly against nuclear power generation.

The physics community generally prefers to compare the risks and benefits of nuclear reactors to the coal-fired plants that are the other major choice for electric power generation. Public opposition to nuclear reactors has become so great that nuclear power generation has been assessed negatively, not by physicists and the rest of the technical community, but by public opinion. Unlike the case of cold fusion, the nuclear power issue in the United States has been settled politically rather than on technical merit.

Other nations conduct risk assessment on a considerably different basis. Japan and France are currently developing and using plutonium-fueled reactors, and Britain has announced the intention of constructing a major facility to process plutonium reactor fuel. The republics of the former Soviet Union continue to operate nuclear power plants that are known to be less safe than western systems, despite their experience with the accident at Chernobyl. In each of these cases, the national government has determined that the economic benefits of nuclear power outweigh the risk to the population.

2.2.3 How Much Verification? In arms control, verification of treaties refers to the use of technical means to ascertain that all parties to the treaty are complying with the provisions of the treaty. Physicists, the military, and politicians have long accepted the fact that no treaty verification can produce certainty that all parties are in total compliance with the provisions of the treaty. Thus, verification regimes are designed to insure that compliance is good enough so that no party to the treaty can gain a militarily significant advantage by violating the provisions of the treaty (Krass, 1985).

Physicists can analyze the capabilities of various monitoring technologies, such as satellite imagery or overflight. On the basis of known properties of detectors and electronics, scientists can tell politicians how likely it is that a particular property of a missile system or a radar can be measured and to what accuracy this can be done. In many cases, treaty provisions are written to limit precisely those properties of weapons systems that can be measured. For example, the Anti-Ballistic Missile Treaty limits the apertures of radar transmitters and their orientation, both of which can be readily measured from satellite imagery.

As in the case of nuclear-power risk assessment, analysis of the capabilities of monitoring systems yields at best a probability of detecting a violation. The acceptance of a verification regime becomes a political decision based on how certain the decision maker feels the U.S. should be of treaty compliance. Physics provides a baseline but cannot make the final judgment call.

Public opinion plays a role in verification, but it has usually been a minor one since the arcana of treaty verification are too complex to be of enormous public interest. In this arena, the political arguments are generally among different constituencies within the executive branch and Congress, who are driven by their perceptions of the threat posed to the U.S. by other treaty parties and their own agendas (for example, the military may wish to build a particular weapon and not wish it to be limited). Unlike the cold-fusion issue, which was primarily resolved by the physics community, and the nuclear-fission power-generation issue, which was primarily resolved by public opinion, the question of how much verification is enough is resolved by a group of specialists, including physicists, and presents still another model of technology assessment.

2.3 How Policy Makers Get Technical Information

Governments have long recognized the need of high-quality scientific advice. To provide it, the National Academy of Science was established during the Civil War. European academies of science, which today support ministries of science, were established much earlier to promote and reward scientific research. Developing nations have generally established government agencies to promote science and advise government officials. In many cases, these agencies have been so involved in the political process that they have been ineffective in providing sound technical advice.

The stakes for science advice to policy makers can be very high. Mistakes are costly both in economic terms, as for example in funding of projects that are not technically feasible, and politically, as in holding up negotiations for a treaty based on a technical misperception or in negotiating a treaty whose provisions cannot be enforced. Because jobs depend on technical issues, such as which weapon system to build, and because issues like nuclear power touch public emotion, pressure can be brought to bear on science advisors. Thus, good science advisors not only must possess technical expertise and sound scientific judgement, but they must have the character to withstand a considerable amount of personal and professional pressure and be adept in politics as well as science.

2.3.1 Scientists in the Executive Branch Almost all the executive branch agencies have staffs with technical expertise. Physicists are located prominently on the staffs of the U.S. Departments of Energy, Defense, and State. The Department of Energy is responsible for the operation of the National Laboratories, which are a repository of scientific expertise and experience. In addition, agencies such as NASA, the U.S. Arms Control and Disarmament Agency, the CIA, the Agency for International Development, the National Institute for Standards and Technology, and the National Oceanographic and Atmospheric Agency have large technical staffs and may be headed by people with technical training.

At the highest level, the Science Advisor to the President must be confirmed by the Senate and heads the White House Office of Science and Technology Policy. The Science Advisor does not hold cabinet rank and his influence depends upon his personal relationship with the President. Models have ranged from the strong influence of Kistiakowsky on President Eisenhower to the relatively weak influence of Keyworth and Graham on President Reagan. Physicists have frequently served as Science Advisor (Golden, 1980, 1988).

On 23 November 1993, President Clinton issued an executive order forming the National Science and Technology Council (NSTC), which he will chair personally. The Cabinet-level body will function in parallel to the National Security Council and the National Economic Council. Beneath the NSTC, there will be a system of nine or ten committees with interagency representation at the assistant secretary level. The areas addressed by the committees have not yet been completely determined, but a preliminary list includes such topics as health, safety, and food research, civilian industrial technology, national security research and development, and fundamental science and engineering research. The intent of the new administrative structure is to coordinate the $76 billion research and development budget and to increase cooperation among the various agencies that conduct research. Each of the major committees will be supported by a system of subcommittees. The administration expects to produce a new statement on science policy during 1994 that is analogous to the statement on Technology issued in February 1993 (Clinton and Gore, 1993).

Most other nations have long had formal science advice at the cabinet level or immediately below. It is also common for nations to issue formal statements of science or industrial policy. The United States has been relatively late in promoting science to a formal position in the executive branch and developing science policy, probably because of a national reluctance to control any aspect of industrial operations.

2.3.2 Classification and Physics Research Physics advice to the military and foreign policy makers frequently involves classified information. From the days of the Manhattan Project, a fundamental tension has existed between the freedom to tap broad-based knowledge for new ideas and the military need for secrecy. In physics literature, not to cite one's sources constitutes plagiarism. In the world of classified policy making, physicists are warned that to cite their sources is to lose them. From Rabi's legendary World War II refusal to design a radar tube unless he was told its purpose, an uneasy compromise has existed between the two communities.

Classified research contracts flow to a number of major corporations and "think tanks." Not infrequently, the contract monitors are very honest, capable young scientists and military officers who hold advanced degrees in technical fields. They are asked to judge the work of senior scientists in fields outside of their own, an impossible task. No form of peer review exists within the classified system, and even library research is limited. The flow of information depends on private contacts and individual physicists' knowledge of what experiments have been conducted by whom.

Most physicists agree that some circumstances demand secrecy. Certainly no one wishes to publicize the technical details of the construction of nuclear weapons. Physicists who work within the classified community must accept security clearance. By their acceptance, they agree not to discuss their work with colleagues who are outside of the loop of cleared personnel and to publish in the field only with permission of security personnel. The system is closed, which is probably good for keeping technical secrets necessary to the national security, but is bad for the quality of scientific advice received by policy makers. This problem probably extends to other nations, but, for obvious reasons, cannot be documented.

2.3.3 Advice to Congress Congress receives technical advice from four sources (Golden, 1988; Kuehn and Porter, 1981). First, the staffs of the Congressional committees and individual members increasingly contain people with scientific training. Programs such as the Congressional Fellowship Program of the American Association for the Advancement of Science, the American Institute of Physics, and The American Physical Society have successfully encouraged physicists to become involved in the legislative process. A handful of members have scientific training themselves.

Second, the Congressional Budget Office and the General Accounting Office, which report to Congress on matters touching the budget, contain staff members with training in several sciences, including physics. Although the agency reports are primarily oriented towards financial issues, technical issues become critical to budget estimates and are discussed in the reports. Third, the Office of Technology Assessment was established chiefly to provide members of Congress with impartial analysis of technical issues that separates uncertainties in scientific information from aspects that are primarily political. The Congressional Budget Office, the General Accounting Office, and the Office of Technology Assessment explore issues only at the request of members of Congress. These agencies have developed a reputation for separating political issues from technical ones and making concise, clear presentations of what is and is not scientifically understood. Finally, the Library of Congress has a growing research division that prepares reports at the request of members. Division specialists include physicists.

Like physicists who advise the executive branch, those working for Congress are limited by their personal relationships with members and the bounds of classification. However, the number of members of Congress allows for a much wider variety of interactions than does the vertical structure of the executive branch agencies. The number of physicists advising Congress has grown steadily as staff sizes have increased and more members have recognized the importance of physics to issues, such as energy policy, that directly touch their districts.

2.3.4 The Nongovernmental Organizations—NGOs Since the turbulent years of the Vietnam War, many physicists have chosen to present their advice to government through organizations outside of government. The federal government had long used groups of civilian experts for advice. Experts were paid by some federal agency for part-time service as advisors. The most famous group is the Jasons, who are a group of physicists advising the Department of Defense on weapons of the future. Perhaps their best-known project is the electronic defensive MacNamara Line constructed during the Vietnam War. The Air Force funded the

Rand Corporation to examine technical issues of interest, and the Department of Defense supported professors at a variety of universities in the Institute for Defense Analysis. Each of these groups and others like them worked closely with the agency that funded it.

The campus uprisings of the late 1960s and early 1970s convinced universities that agencies like the Institute for Defense Analysis should not be a part of their academic mission. Thus, these agencies became not-for-profit corporations that have full-time employees and stables of consultants. These think tanks continue to perform a major portion of the analysis of physics issues that is conducted by the government.

In addition to the independent corporations, which developed from groups of advisors established by the federal government, a second group of organizations grew from the interest of physicists and other scientists in particular policy issues. They are supported by public contributions and grants from foundations. In contrast to the think tanks, they receive no federal money. Some of these organizations, such as the Sierra Club and the Federation of American Scientists, grew from the changing interests of established lobbying groups. Others, such as the Union of Concerned Scientists and the Natural Resources Defense Council, were formed by groups of scientists, with physicists playing prominent roles. The founders of these lobbies felt that the U.S. government had misled the pubic on issues such as the possibility of a nuclear test ban treaty and nuclear fission energy. They collected small, dedicated staffs of highly trained scientists, which were supplemented by volunteers.

During the 1980s, the lobby groups played an increasingly significant role in presenting technical issues to the public and, hence, Congress. Professional scientific organizations, such as The American Physical Society and the American Association for the Advancement of Science, have occasionally submitted reports to their memberships clarifying technical discussions with policy impacts. These reports also served to inform the public, the press, and policy makers.

Although neither the NGOs nor the think tanks appear on any organizational chart, they provide much of the physics input to the making of policy in the United States. Their variety and lack of formal structure allow creative thinkers to present their ideas to policy makers, and they are important to the role that physics plays in shaping public policy.

In the developing world, technical advice provided by the NGOs may play a critical role in providing science advice. The various agencies of the United Nations have provided most of the technical advice available to many African governments (Forje, 1989). Among the less-developed nations, regional cooperation for science has become increasingly important since no single nation can afford to develop all aspects of science. In Latin America, nations recently increased their emphasis on international collaboration (Stann, 1993).

3. THE IMPACTS OF PHYSICS ON SOCIETY

Although physics has played a significant role in shaping U.S. policy, particularly on defense, energy, and the environment, it also affects American society in other less formal ways. While the precise effects of developments in basic physics on such areas as the economy and the structure of the workplace are difficult to quantify, there seems little doubt that advances in basic physics do change these important aspects of society.

3.1 Economics

Developments in basic physics frequently lead to new technologies that can be marketed. The justification for industrial funding of physics research has been its long-range economic benefit. On the other hand, commercial exploitation of breakthroughs in physics requires years of applied research and development. Thus, the connection between economic development and basic physics research can seem very tenuous (Smith, 1990).

3.1.1 Benefits of Research American technological heros have generally been portrayed as practical men of genius who lacked formal education. Contrary to this image, many American inventors were students of basic physics. Benjamin Franklin not only published *Poor Richard's Almanac* but also a number of serious scientific papers advancing his theory of two types of electric charge. Samuel Morse had studied physics at Yale, and even Thomas Edison had a solid understanding of the basic research in electricity and magnetism of his day (Smith, 1990, pp. 17, 25–26).

The Manhattan Project represented an unusually rapid advance from the basic physics of nuclear fission announced in early 1939 to the first nuclear reactor (1942) and the atomic bomb (1945). Less-publicized applications of basic physics made radar and other vital weapons systems possible. American leaders perceived scientific research, particularly physics, as a key to the industrial and military might of the country. Their philosophy was codified in Vannevar Bush's report, *Science, the Endless Frontier* (1945).

The launch of Sputnik in 1957 convinced remaining doubters that basic science research must be a key to national prestige. The glamour of the Apollo Program of the 1960s persuaded talented students to study physics. Thus, for 25 years following World War II, U.S. policy makers and citizens accepted the vital role of physics research in promoting the economic growth of the country without serious question. Funding for physics research was plentiful, and the community thrived. Physics held the key not only to defense technology but to space and to the development of high-technology industry. American technology dominated the world's market and was transferred to other countries through a profitable trickle-down mechanism of licensed manufacture.

By 1970, policy makers and the public had begun to doubt the efficacy of basic physics research in promoting economic success. The Defense Department had produced a study that seemed to indicate that basic research had little relationship to new ideas that came in the development phase of projects (Chalmers and Isenson, 1966). The Apollo Program came to an abrupt end, and American industries began to lose their total domination of the global economy. The environmental side effects of uncontrolled technological development had an impact on public consciousness, and public belief in technological miracles and science as a cure for all ills disappeared.

Although the physics research community pointed out that the DOD study simply had not looked back far enough at the research basis for new ideas and that the Apollo shutdown was for good technical reasons, funding agencies began to demand clearly defined links between economic products and basic research. Conventional wisdom indicates that the payback time that the American public is willing to accept is no more than three years. On that time scale, concrete links between basic physics and economic development are difficult to demonstrate. Public funding of huge demonstration projects that were supposed to set models for private development during the oil crises of the 1970s failed to meet national energy needs. Distrust of these projects was transferred to basic physics research. The research infrastructure, particularly in the universities, lost funding. Meanwhile, aging American industries continued to lose market share in the global economy.

In the mid 1980s, policy makers realized that neglect of basic physics research damaged the development of high-technology industries, which produced the most lucrative employment opportunities. The time scale for the process might be too long to expect individual companies to support this research, but the support was necessary for future developments. The end of the cold war and the decline of the need for new weapons meant that the power of the national laboratories should be focused on supporting civilian industry. The U.S. recognized a need for a science policy that both fostered basic research and helped companies utilize research results in industrial development. The policy took two forms: encouragement of technology transfer from universities and the national laboratories to industry and changes in policies toward the formation of research consortia.

Technology transfer encouraged the formation of industry–university partnerships. Universities developed policies to allow the conduct of proprietary research on campus. Similarly, policies were changed so that the national laboratories could enter into cooperative research and development agreements (CRADAs) with industrial partners. Industry would be able to use the supercomputers and other advanced capabilities of the national laboratories to support research with immediate applications in industry. The system of CRADAs has proven difficult to implement because the laboratories and industry, not to mention the universities, are used to very different research objectives. University researchers worry about freedom to publish, industries about proprietary information, and the laboratories about leaks of classified information. The CRADAs themselves involve complex negotiations over intellectual property rights, the time scales for anticipated results, and even favoritism in selection of firms with which to develop them. Despite a slow start, the system appears to be gathering momentum. The Clinton administration and Congress appear to share a commitment to streamline the creation of industry, university, and national laboratory partnerships. Legislation to accomplish this is under consideration.

U.S. antitrust laws have discouraged cooperation between competing companies for technology development. The government has stayed carefully away from supporting any research that might benefit a private concern. To support industrial development, new interpretations of the antitrust laws hold that they do not apply to basic research. Furthermore, the government now should support basic research to aid industry as long as its results are shared by all U.S. firms in the arena. In 1987, the government and the semiconductor industry formed a partnership to create Sematech, a research effort to improve the manufacturing technology for semiconductor devices. The semiconductor industry had been losing its majority market share to the Japanese. Encouragingly, recent trade figures show that the U.S. firms have begun to regain a lead in the field. It seems likely that Sematech will set a pattern for other government aid to basic research. Certainly, cooperation among government agencies including the national laboratories, the universities, and industry will increase in the future support of basic physics research.

3.1.2 Funding for Research and Development Traditionally, federal funding and university employment have dominated physics research. This pattern seems to be shifting. In 1990, 46.1% of R & D funding in the United States came from the federal government about 20% from industry, and the remaining funding from states, private sources, and universities (Hirano, 1992, p. 582). During 1990–1991, of graduates with Ph.D.s in physics who found employment that might be permanent, 27% entered higher education, 42% entered industry, and 25% joined the government or federally funded research centers. Of bachelor's degree recipients, 42% entered industry, 12% entered education at the college or secondary level, and 23% either joined the military or entered government service. Twenty-one percent of bachelors found only part-time work or no work at all, and 70% of new Ph.D.s either accepted postdoctoral temporary positions or were unemployed (Ellis and Mulvey, 1992). Clearly, the traditional academic career pattern of a research physicist is no longer a dominant model in the U.S. and is rapidly declining in other countries.

Federal grants for research have always existed in the United States. However, following World War II, the magnitude of support for research increased dramatically because policy makers saw research as an engine for economic growth. Despite efforts by Vannevar Bush and others to establish an umbrella organization to oversee funding in all areas of research, the major funding channel became large federal agencies, such as the Departments of Defense and Energy and NASA, which supported development and basic research that had promise of specific application to their missions. The National Science Foundation assumed responsibility for science in general, science education, and those areas of basic research not supported by the agencies (Smith, 1990).

Research funding emphasized support of individual projects rather than umbrella grants to laboratories. In part, funding patterns respected the individual genius, and in part, they made a political compromise to avoid supporting universities on the coasts where postwar research was well established. Research grants were awarded following a review by a committee of scientific peers to establish the merit of proposals. Congress entered the process occasionally to establish programs to target researchers in specific geographical areas or with specific demographic characteristics, such as gender, race, or age, but the majority of grants were awarded on the peer review system.

The review system has been widely criticized for supporting an "old boys" network in the prestigious research universities at the expense of talented researchers elsewhere.

Peer review may also foster conservatism among authors of proposals, since radical ideas are unlikely to attract funding. On occasion, university researchers have bypassed the review system by appealing directly to Congress for research support. These "pork barrel" projects have been criticized for lacking scientific merit. The ultimate political battle for research funding involved the siting of the multibillion dollar Superconducting Super Collider. States submitted proposals offering various financial incentives to the Department of Energy, and the selection process certainly considered these bids and the clout of state representatives in Congress as well as the technical merits of proposed sites. In 1993, Congress discontinued funding for the SSC because of the perception that it offered little potential for economic benefit in comparison with its cost. Legislators were also distressed by management problems that surfaced on inspection of the project.

The space station represents the largest of the "big science" projects that have dominated funding debates in recent years. The mission-oriented agencies have long supported projects involving entire laboratories so that funding might come from an umbrella grant rather than on a project-by-project basis. Even the NSF has begun to support science and technology centers, such as the controversial Supercomputing Centers. Physicists apply to use the centers on a competitive basis since equipment is too expensive for duplication at individual universities. Thus, research physicists increasingly travel to research sites and work with large groups. In high-energy physics, group sizes range up to several hundred physicists. Critics fear that funding for big science will cut off funding for individuals and small groups, particularly those working in universities. Lack of funding can destroy individual creativity and discourage physics research that does not fall in the mainstream of current thinking, as well as damaging the education of graduate students.

Individual states have recently begun to fund some physics research in efforts to promote economic development. State funding has become important in attracting federally funded science and technology centers. Because many states mandate a balanced budget, recessions force immediate cuts in the support of physics research. Similarly, physics research in high-technology industries has been cut during economic hard times. The link between physics research and economic development that produced comfortable funding levels during periods of economic growth and led to the expansion of the physics community has led to job crises during economic recessions.

3.2 Social Impacts of Physics and Related Technologies

Physics discoveries and related technologies have influenced almost every aspect of American life. Information flows around the country by electronic networks, and desktop publishing allows literally any private citizen to develop a newsletter. The flood of information available swamps individual abilities to absorb and process it. The way in which business is done and policy made depends increasingly on information exchange. In many ways, the value of information as a commodity in its own right has vastly increased.

Electronic communications link people in different countries instantly. National borders pose no barrier to information flow. Pictures of atrocities in Bosnia and starvation in Somalia reach American television screens and change national policy. Citizens actually watch wars live and in color on television signals relayed by satellites. All aspects of life have become encoded in various databases. Marketing can be done by targeting a very narrow group with special interests. Access to databases provides information on such private matters as driving record, credit rating, or even medical history. Even white-collar criminals take advantage of today's communications technologies.

The computer technologies that grew from developments in condensed-matter physics have allowed industry to automate its production processes. Automated production requires fewer workers with higher technical skills. Automated manufacturing has displaced unskilled workers from manufacturing into the service sector. Even a new crop of injuries arises from computer use.

Finally, global communications links and satellite imagery of the Earth from space present the Earth as a small planet whose problems are indeed global in scope. Emphasis in foreign policy has shifted from the interaction among nation states to a discussion of international organizations designed to implement world peace and solve worldwide environmental problems, which themselves are partially defined by physics research. Developments in basic physics thus have an impact on both the mechanics of day-to-day life and the philosophical assumptions that underlie national policy.

3.3 Making Science Policy

As yet, the United States has no entity called science policy although one seems to be under development. For many years, the federal government has carefully avoided even the appearance of interfering in private competition. On the other hand, policies have been implemented to fund research through specialized agencies. The best example of this is the large-scale reorganization of energy research during which the Department of Energy was created. Legislation fostered the development of large-scale technology demonstrations and research directed at new sources of energy, such as the Synfuels project. Similarly, Congress controls the direction of basic research by funding or not funding initiatives, such as the space station or the SSC.

Like other legislation, proposals for science legislation come from members of Congress and the committees they form, as well as from a variety of agencies within the executive branch. No single agency or congressional committee has been charged with making a unified science policy. Outside of a general consensus that national well-being requires support of basic and applied research, there has been little coherent attempt to develop a long-range science policy. It should be noted that while a typical physics experiment requires times on the order of 5 years from conception to publication, the term of a Representative is only 2 years. The time scale for industrial development is at least 10 years, and a weapons system requires 15 years from conception to deployment. Funding cycles run on an annual basis, and elected officials prefer tangible results before the next election.

The problem of long-range planning is particularly acute in physics education, since a graduate physicist typically requires at least 20 years of education. Policies changing elementary science education will bear fruit only after 15 years or so. The NSF and the Department of Education have attempted long-range planning, but political changes happen too quickly to allow a follow through on these policies.

4. PUBLIC KNOWLEDGE OF PHYSICS

One problem in making science policy is public ignorance of science. The work force in a technologically sophisticated society needs a basic knowledge of physics that most American workers lack. Education of physicists and of the general public about physics has become a major concern of a large segment of the physics community.

In the next decade, women, African- and Hispanic-Americans, and other minorities will constitute the majority of new members of the U.S. labor force. These groups, who are presently conspicuously missing from the physics community and college physics courses, will have to be attracted into physics if the profession is to remain healthy.

4.1 Formal Education

Most citizens encounter physics as a part of their formal education in either high school or college. While physical science is part of the middle-school and elementary curriculum, it is hidden in general science courses, which often center on the biological sciences.

4.1.1 The General Public About 20% of high-school graduates have completed a course in physics. These students tend to be those who plan to attend college. High-school courses depend on the quality of the teacher instructing them. Although there are many excellent, creative, and dedicated high-school physics teachers, there are also many teachers who have been recruited from other fields to offer a single course in physics and lack preparation. Thus, a high-school physics course provides widely varying background.

Students who do not enroll in high-school physics must depend on physics taught as part of general science courses for the background they need in their jobs. In the elementary classroom, all science tends to be neglected in favor of teaching basic reading and mathematics. Mathematics may also be neglected in favor of reading. In part, this is due to time pressure in the classroom. In part, it is due to fear on the part of teachers and lack of experience with hands-on physical science. Many teachers complete college training and remain afraid of, and confused by, basic mathematics. They see physical science as an extension of the dreaded math. Elementary science texts tend to be lists of vocabulary words with little stress on experiment. Students are forced to memorize words that they do not comprehend. Understandably, they find science boring.

In middle school, much physics is taught as a vocabulary list. Teachers have limited laboratory space and preparation time, if indeed they have any. Although there are outstanding exceptions, middle-school science remains isolated from the rest of the curriculum, and a book and worksheet course.

One exciting trend in middle-school and high-school education comes through technology education, the old shop teachers. Technology curriculum today can be hands-on and oriented toward solving real world problems and working in groups. The students are prepared to enter the labor force and work in the milieu of high-technology industries. Such students will need to acquire an understanding of the rudiments of physics, which can be presented to these students in such a way as to tie directly to their career goals.

4.1.2 College Graduates Almost all colleges and universities require a laboratory science course as part of their general education curriculum. Few who do not plan to major in the sciences or engineering elect to take physics because physics is popularly perceived as both difficult and dull. Majors in other disciplines, such as premedicine, all too frequently take specially designed courses. They perceive these courses as obstacles in their chosen career paths in which they badly need a grade of A. Courses in physics designed for liberal arts majors struggle to teach physics without mathematics. At best, they provide a strong overview of the most important concepts of physics but may be so superficial as to be misleading. Many introductory physics classes are taught in large lecture sections with laboratories and problem sessions led by graduate assistants. This instructional style may repel bright students who otherwise could succeed in basic physics (Tobias, 1990).

If basic courses in physics do little to increase the physics literacy of non-major college graduates, few college lecture series correct the problem. Distinguished physicists rarely appear on the lecture circuit. Thus, college graduates frequently have little more knowledge of physics than is provided by their high-school educations.

4.1.3 Professional Physicists Issues in training professional physicists center on maintaining a supply of physicists for the research laboratories of the next century. In addition to the problems of attracting women and minority students to physics in the first place, the first college course in physics discourages many potential physics majors who leave the field.

A second major attenuation of the supply of physicists in the educational pipeline occurs at the entrance to graduate school. Nearly half the students in physics Ph.D. programs are not U.S. citizens. Should the supply of foreign students decrease, physics departments could not maintain the current supply of physicists. Universities, critics claim, are using graduate students to support their research efforts without realistic expectations that these students can eventually find jobs. Others argue that the current poor job market is largely due to the recession, which has been particularly damaging to high-technology industry that employs the majority of physicists who work in industry.

Industries expect physics graduates to be experienced in use of state-of-the-art technology, which is not available in many university laboratories. The DOE, NSF, and even DOD have initiated programs to upgrade university instrumentation, but the problem remains serious and is exacerbated by the rising cost of modern sophisticated systems.

Although funding for research has increased, funding per physicist in academia has declined. Thus, junior faculty are caught in a cycle of grant applications and hasty experimentation that certainly damages their teaching performance. The extreme pressure to publish in order to get tenure at a major university may inhibit creativity, as young physicists pursue established lines of inquiry that are more likely both to attract outside funding and to be published in established journals.

4.2 Informal Sources of Information

Since most Americans gain a very limited knowledge of physics during their formal education, they rely on a variety of media and experiences to increase their knowledge of current events in physics. Many are fascinated by breaking events in high-energy physics and cosmology, which basic courses rarely cover.

4.2.1 Magazines, Journals, and Newspapers Most people interested in physics rely on popular magazines such as *Scientific American* or *Science News*. These provide solid coverage of major science issues and are available on newsstands or by subscription. Leading physicists prepare articles for these journals aimed at an audience of nonspecialists.

Few interested citizens read technical journals, which are geared for specialists. These journals provide an avenue for communication within the field and are generally subject to a peer review process. They are criticized for belonging to the same old boys' network doing grant proposal reviews. Also, many journals have increased their cost so that libraries find it difficult to maintain their collections. In addition, much information travels through preprints, which are sent only to people whose names appear on selected lists, thus tightening an elite network. Various suggestions to these problems are being discussed, including a variety of ways to use electronic mail for publishing.

Major newspapers employ reporters who specialize in science writing. Coverage by these papers is accurate and interesting but limited in scope, as physics must compete with medicine or political analysis for space. Local papers rarely have science reporters on their staffs and inform their readers on technical issues only when those issues make headlines, as during the Chernobyl reactor accident or the cold-fusion incident. Local coverage of physics issues varies widely in quality and does not provide a major source of public information.

4.2.2 Science Museums Following the lead of the Chicago Museum of Science and Industry and San Francisco's Exploratorium, many cities have established museums dedicated to hands-on science exhibits. These museums use considerable ingenuity in designing exhibits that entice their visitors, both children and adults, to perform simple experiments. They successfully introduce participants to the basics of physics and convince them that physics can be fun. Such museums have experienced a growing popularity, and their numbers are increasing, but they are still limited to major metropolitan areas.

National laboratories and universities also participate in community outreach programs that provide opportunities for hands-on experiences with science. Such programs frequently target such special groups as students from the inner cities or especially talented high-school students. In areas without museums, college or high-school physics teachers frequently provide a sort of traveling road show to carry physics demonstrations to younger students.

4.2.3 The Electronic Media and Films Radio and television provide some coverage of physics. National Public Radio carries news stories related to physics on such programs as "All Things Considered." Public television has taken a lead in presenting programs like "Nova" and "Newton's Apple," which are designed to educate the interested public. Other cable networks such as the Arts and Entertainment Network also produce excellent physics programs. Such media presentations do an excellent job of making physics accessible to the viewing public.

The major networks provide less regular coverage of developments in physics. Network news shows present developments related to physics, but the coverage is limited by time and depth. Occasionally a science-related issue will surface on one of the news magazine programs, but the networks provide little if any programming at the level of "Nova." In general, physicists who appear in television programs are either mad scientists or absent-minded professors (Weart, 1988). The public image of physics and physicists presented on television and in films generally lacks the glamour afforded either lawyers or doctors. Thus, the public not only fails to gain information from the commercial electronic media but also is given little reason to want to learn about physics.

5. THREE POST–WORLD WAR II CASE STUDIES CONTRASTED WITH THE U.S.

Physics has traditionally been an international enterprise. Although the criteria and goals of basic research cross national borders, even a cursory examination shows that funding patterns and research philosophies differ widely from country to country. In particular, different countries have defined widely different roles for national governments and industry in directing and funding basic physics research, which in turn has played differing roles in fostering industrial development.

The three case studies presented below study nations or groups of nations with well-developed science establishments. European science experienced a long, slow growth without the sudden impetus that World War II provided for the U.S. The Confederation of Independent States (CIS) provides a model for sudden growth of science under government central planning. The Japanese model describes the role played by an initial partnership between government and industry that continues to dominate research.

None of these models applies to most of the developing nations. Even such relatively industrialized countries as Australia carry a legacy of colonial domination that still hampers their scientific development (Rowayne and Boag, 1989). In much of Africa and Latin America, colonial powers oriented any scientific development toward the agricultural and mineral resources they wanted the colony to produce. They trained the native population only sufficiently to ensure production. Newly independent colonies found themselves with little scientific infrastructure and almost no technically trained personnel. Attempts to develop human capital and scientific infrastructure have been inhibited by political instability and the tendency of scientifically trained personnel to try to return to the colonial institutions. Universities and laboratories are poorly staffed and equipped, and industries fund little research despite elaborate declarations of science policy (Forje, 1989; Stann, 1993). Many of these nations have attempted to follow the model of centralized development used by the Soviet Union.

India has managed to develop an indigenous scientific establishment and several sophisticated industries, including space-launch capability and a nuclear explosive. In this case, the colonial pattern was overcome by the leadership of Nehru, who stressed the importance of developing an educated population (Rahman, 1990). The Indian model followed that of Britain. The newly industrialized nations of Southeast Asia have followed a still different pattern in copying the ideas used by Japan. Thus, the three examples below, in addition to the U.S., show the basic patterns of scientific development that have been copied by other nations.

5.1 Western Europe

World War II devastated European economies and physics laboratories. Before the war, major developments in physics had been driven by European scientists working in a small-science model rather than in the big-science model that developed during World War II. Following the war, nations faced the problems of rebuilding their scientific enterprises (Anderson, 1992; Franklin, 1988; Merton and Gaston, 1977).

Many countries established a system of national research institutes, which provided direct funding to laboratories rather than to individuals. Universities funded basic research equipment. Thus, physicists working on small-science projects were supported over the long term without the constant need to seek funding by writing grants. This steady, relatively noncompetitive funding has encouraged innovative lines of research reflected in the Nobel prizes awarded for the discoveries of high-temperature superconductivity, the quantum Hall effect, and scanning tunneling microscopy. On the other hand, the model does not encourage competitive exploitation of the new discoveries and may induce a more leisurely research pace than is found in U.S. laboratories. Current financial hard times have led to funding cutbacks and debates over the proper role of research and teaching, such as the discussion of the abolition of tenure in the U.K. Funding for small science is still done on a national basis, and one of the problems facing the European Community is encouraging collaborations that cross national borders.

In arenas such as high-energy physics requiring large, expensive equipment, European nations could not afford individual efforts. The tradition of establishing a European center of excellence that would collect the best scientific minds in Europe and provide equipment for their experimental work began with the European Laboratory for Particle Physics, CERN. CERN is located in Geneva, Switzerland, and funded by annual contributions from 17 member nations. The laboratory works closely with the national research institutes and universities in member states. The political issues of national "ownership" have been handled by rotating high-level administrative positions and taking decisions by consensus. Experimental resources are allocated strictly on the basis of merit, and all members have equal access to facilities for training their students.

Despite its success in leading research in high-energy physics, CERN has remaining problems. The recession in Europe has caused member states to question the value they obtain for their contributions. Germany, which is paying the expenses of reunification, and the United Kingdom, which has severe economic problems, have debated reducing their commitments to CERN. Spain, which is a major contributor, has very few physicists actually working at CERN and questions whether it is getting its money's worth. Nevertheless, CERN continues to produce exciting results, and plans to build the Large Hadron Collider (LHC) in the existing tunnel housing the Large Electron Positron storage ring. The LHC was designed as a rival for the larger SSC, but CERN believes it can be built faster and cheaper in the existing tunnel, although critics point out that it is more technically challenging. Like SSC, LHC has been the subject of a major funding debate. Other areas of physics have begun international cooperation including the European synchrotron x-ray source at Grenoble, the Joint European Torus fusion laboratory in Culham, England, the Institut Laue-Langevin at Grenoble, and the European Southern Observatory.

Industrial research in European nations has been closely linked to government support. The strength of the ties varies from country to country. In some cases, such as the development of the Concorde or Airbus, government support from several countries has assisted industrial development. European industries are so strongly supported by governments that the U.S. blocks mergers with European firms in industries that are considered critical to national defense. Unlike funding in the U.S., national funding for specific industrial projects has been the rule rather than the exception in Western Europe.

5.2 The Former Soviet Union

Marxist doctrine held that science should dominate the growth of the communist state. Thus, the communist government of the Soviet Union stressed the growth of science and its direct role in advancing the planned economy. All science funding was channeled through the All-Union Academy of Sciences, which also served as the employer of most of the scientists in the Soviet Union. The Academy was composed of 365 institutes, including such prestigious physics research centers as the Lebedev Institute. Except for a few university departments in large cities, the Academy performed all basic physics research. Ranking physicists in the Soviet nuclear weapons program were members of the Academy. Almost all the institutes were concentrated in Moscow and Leningrad (St. Petersburg), except for a few science centers like Novosibirsk. National science academies formed in individual republics were dominated by the All-Union Academy (Dickman, 1991; Fortescue, 1986; Hutchings, 1976; Medvedev, 1978).

Basic science research was more or less tightly controlled by the Kremlin. Although physics escaped the political disaster associated with Lysenko, many physicists were isolated from their field and denied foreign travel for political "errors." Equipment tended to be poor in basic research laboratories, although Soviet physicists are famous for work in areas such as mathematical models. Certainly, basic physics principles were readily applied to the Soviet military research and development programs, although they seem to have found less application in civilian industries. The 1957 launch of Sputnik demonstrated Soviet determination to become a technological superpower.

The Soviet approach to military development concentrated on incremental improvements using stable design bureaus rather than on the radical new designs favored by the U.S. Universities, with a handful of notable exceptions such as Moscow State University, concentrated primarily on teaching.

Public education in the Soviet Union stressed physics literacy, and high-school graduates had far greater exposure to physics and mathematics than in the U.S. Popular physics magazines such as *Quantum*, now available in the U.S., enjoyed wide circulation among both students and citizens. The state-controlled media educated nonspecialists about physics. Scientists were held in great social esteem and enjoyed high salaries and perquisites such as good apartments, cars, and *dachas*.

With the collapse of the Soviet Union following the 1990 coup attempt, Soviet physicists found themselves faced with severe problems. Inflation reduced salaries, which had been generous, and scientists were forced to struggle for survival in very basic terms. In addition, research money dried up. Institute directors bartered for food supplies. Many physicists accepted appointments abroad, and many areas of science suffered a brain drain, particularly of younger people, in areas where Soviet science had made outstanding progress. Western governments worried about Soviet weapons designers accepting employment with third-world nations and funded programs for them, but western help has been slower to arrive for other physicists. Finally, the All-Union Academy has become the Russian Academy of Science and is embroiled in political strife. The other national academies are asserting their newfound independence (Dickman, 1991).

The centrally controlled model of funding and directing basic physics research and policies creating an elite social position for scientists produced an outstanding scientific enterprise in the former Soviet Union. It is anybody's guess whether physics can maintain its leading position in the turbulent political and economic times that have followed the fall of communism.

5.3 Japan

Western scientific tradition conflicts sharply with such Japanese values as respect for seniors, refusing to criticize others in public, or even lifelong employment. Physics developed more slowly in Japan than other sciences such as seismology and biology because it was seen as uniquely western in its values (Bartholomew, 1989). By the time of World War II, Japanese physics had matured to world-class status and produced its first Nobel prizes (Yukawa in 1949, Tomonaga in 1965, and Esaki in 1973), but the structure of research funding and policy still reflected traditional values. Modern Japanese physics continues to be a mix of traditional and western approaches (Anderson *et al.*, 1992; Maddox and Swinbanks, 1992; Shigeru *et al.*, 1974).

Faculty in the 98 national universities in Japan elect their presidents; however, Monbusho, the powerful Ministry of Education, appoints the rest of the administrative staff, who actually run the campus. Monbusho finances the national universities, including all research, and oversees and subsidizes the private universities. Unlike American professors, Japanese professors depend mostly on the university for their research funds. Although the government has made several recent efforts to provide sources of outside grant funding, these are still limited.

Universities are structured around chairs or *koza*, which are allocated to disciplines. The allocations are political decisions and may not be driven by student demand or need of the university. Each *koza* has one professor, one assistant professor, and two assistants and is allocated about $65,000 per year for expenses. After the university and department have collected overhead, the *koza* unit has about $8000 per year for research. As each member of the unit has a guaranteed lifetime job, pressure to do cutting-edge research is not great. University facilities tend to be run down and equipment poor.

Japanese industries perceive basic research as a key to retaining a lead in high-value–added, technology-based industries. They support private laboratories, where researchers are encouraged to design their own research programs within very broad guidelines established by the management. The Canon Research Institute, for example, automatically grants $8000 to employees to explore their new ideas, and grants further funds if the idea looks interesting. At present, Japanese industry supports 39% of the basic research done in the country, although industrial managers designate their work as applied to the development of products, while only universities do basic research.

The research efforts are coordinated, at least to some extent, by the Ministry for International Trade and Industry (MITI), which also jointly funds some industrially oriented research. The Science and Technology Agency (STA) also supports laboratory work in such fields as materials science and condensed-matter physics, which are of interest to industry. This research partnership between the government and the industrial laboratories has worked very effectively in using research results quickly to develop new commercial products. Other nations, notably the U.S., are studying the system to facilitate technology transfer from research labs into industry.

The government, usually through MITI, also funds a system of national laboratories devoted to various sorts of research. These laboratories pursue projects of interest to industry and also support "blue sky" ideas through grants targeted at frontier fields and young researchers. Many experimental programs are funded for a definite limited time, typically five years, and reviewed at the end with a possibility that they will be canceled if they do not show promising developments. Like the industrial laboratories, government laboratories are well equipped and well funded. Major physics projects, including the SuperKamiokande neutrino detector, the JT-60 tokomak, and KEK, the National Institute for High Energy Physics, are government institutes. In some cases, the government laboratories encourage participation by university faculty.

In the past, Japanese science has discouraged foreign participation, although Japanese students have always traveled abroad. Today, industry and the government have programs to encourage foreign participation in Japanese research. These programs are new and starting slowly. Similarly, Japanese research papers have gradually become of greater interest to the outside world. Japanese companies support this new stress on basic research and foreign integration in Japanese labs. They speak of doubling their research budgets even though the country is in an economic recession. It remains to be seen whether their efforts will move Japanese research into the mainstream of world science.

6. SUMMARY: MUTUAL INFLUENCES

In all cultures, physics research leads to the development of new technologies. These technologies, in turn, change the society that uses them.

The same cycle operates equally effectively in reverse. Societies determine the technologies they desire to have and encourage their development by funding and regulating basic research. Technologies make possible new types of physics research. Technology developers demand particular basic research results.

The lines of communication among physics, technology, and society are difficult to trace. Even the boundaries between these areas become blurry. Physics is not done in a vacuum, and so the interaction among physics and technology and society forms a support for the creation of and a background for the analysis of basic results in physics.

GLOSSARY

Applied Research: Research designed to produce a specific product or technology.

Basic Research: Research designed to answer fundamental questions about the nature of the universe.

Science Policy: Legislation and executive orders designed to control what research is done and how it is conducted through mechanisms such as funding or regulation.

Technology Assessment: Evaluation of the scientific merit of a new technology and its possible effects on society and the environment.

Technology Transfer: Incorporation of basic research results into commercially useful products.

INTRODUCTION

Piezoelectricity was discovered by the brothers Curie in 1880. The Curies found that in certain materials such as zincblende, tourmaline, cane sugar, topaz, and quartz, mechanical stresses were accompanied by the production of electric surface charges. The following year, Lippmann, from thermodynamic considerations, predicted the converse effect: an imposed voltage produces mechanical deformations. The name "piezo" derives from the Greek, meaning "to squeeze"; in more modern terminology, we say that the effect couples the electric and elastic field variables (Cady, 1964).

The piezoeffect remained a curiosity until the early 1920s when its presence in quartz was utilized to realize crystal resonators for the stabilization of oscillators, thereby launching the field of frequency control. With the introduction of quartz control, timekeeping moved from the sun and stars to small, man-made sources that exceeded astronomy-based references in stability. Since then, the applications of devices based on piezoelectricity have expanded dramatically. The quartz resonator has continued to evolve to become a device capable of precision one million times greater than the original. It also serves as the "flywheel" in atomic frequency standards, which make frequency the most accurate entity known.

Piezoelectric devices are additionally used as transducers in applications from telephone speakers to sonar arrays; newer and

rapidly burgeoning areas of utilization are those of sensors, actuators, and microelectromechanical structures (MEMS). In many traditional applications, applied voltages conform to the norms for electronic circuits; accompanying mechanical displacements are then usually nanometers or less. Newer configurations available today for actuators often have much larger amplitudes at comparable voltages.

One of the most appealing aspects of piezoelectricity for modern applications is the compelling immediacy and simplicity of the transduction mechanism. Micro- and nanoelectronics are built upon the behavior of charged species subjected to electric fields; the extreme miniaturization of these structures is owed in large measure to their ability to take on a capacitorlike form. Bulky inductors are banished and done without, and thin, planar electrodes introduce the electric fields to operate the circuits. These fields provide exactly the forces required to drive mechanical motions in a piezoelectric device. Elastic field/mechanical considerations are therefore incorporated into the operations of modern electronic components in a clean, efficient, and very direct manner, by making use of the voltages resident on the chips.

1. FUNDAMENTAL PROPERTIES OF PIEZOELECTRIC MATERIALS

1.1 Piezoelectricity—Definition and Mathematical Description

Formally stated, piezoelectricity couples the mechanical stress (T) and strain (S) fields with the electric intensity (E) and displacement (D) fields (Nye, 1957, 1985; Mason, 1966; IEEE, 1978). Depending on variable choice, four sets of material constitutive relations are defined for the linear case of insulating dielectric materials; these are, in compressed matrix form,

$$[T] = [c^E][S] - [e]'[E];$$
$$[D] = [e][S] + [\epsilon^S][E];$$

$$[T] = [c^D][S] - [h]'[D];$$
$$[E] = -[h][S] + [\beta^S][D];$$

or

$$[S] = [s^E][T] + [d]'[E];$$
$$[D] = [d][T] + [\epsilon^T][E];$$

$$[S] = [s^D][T] + [g]'[D];$$
$$[E] = -[g][T] + [\beta^T][D].$$

Because the electric variables $[E]$ and $[D]$ are tensors of rank 1 (i.e., three-dimensional vectors), and the mechanical variables $[T]$ and $[S]$ are tensors of rank 2 that have been converted to six-dimensional vectors, $[c^E]$, $[c^D]$, $[s^E]$, and $[s^D]$ are (6×6) symmetric matrices representing the elastic stiffnesses and compliances at constant E and D; $[\epsilon^S]$, $[\epsilon^T]$, $[\beta^S]$, and $[\beta^T]$ are symmetric (3×3) dielectric permittivity and impermeability matrices at constant S and T, while $[e]$, $[h]$, $[d]$, and $[g]$ are (3×6) piezoelectric matrices. A prime denotes transpose.

The material constitutive relations given may be further broadened to include couplings to thermal, magnetic, and other fields. Figure 1 depicts the phenomenology arising from the mutual couplings among the electric, elastic, and thermal fields. The outer quantities are the thermodynamic intensive variables (generalized forces); the inner quantities are the extensive variables (generalized displacements).

Piezoelectricity is a linear effect; reversal of the electric field reverses the mechanical deformation. Conditions for its existence in crystals are given below. Electrostriction, on the other hand, exists in all dielectric solids. It is a deformation quadratic in the applied electric field. Biased electrostriction, where small electric field variations are superimposed on a constant component, is phenomenologically equivalent to linear piezoelectricity; this artifice may be used with nonpiezoelectric crystals such as silicon, but the coupling depends upon the bias, and is often not large.

Resonance measurements on thickness-mode plate vibrators and pulse-echo (transit-time) measurements determine values for the matrix elements $[c^E]$, $[e]$, and $[\epsilon^S]$, from which the other material parameter sets may be computed if desired. Resonance measurements on low-frequency bar and rod specimens lead alternatively to determination of the set $[s^E]$, $[d]$, $[\epsilon^T]$. These dynamic techniques are both more accurate and more precise than static measurements.

FIG. 1. The phenomenology arising from the mutual couplings among the electric, elastic, and thermal fields.

1.2 Electromechanical Coupling Factors

Electromechanical coupling factors k ($0 \leq k < 1$) are dimensionless scalar measures of efficacy of piezoelectric transduction, and are far more important than the piezoelectric constants taken by themselves. They appear in considerations of bandwidth and insertion loss in transducers and signal-processing devices, in location and spacing of critical frequencies of resonators, etc. For high-frequency plate resonators, they have the generic form $k = e/\sqrt{\epsilon c}$; for low-frequency bar and rod vibrators, the form becomes $k = d/\sqrt{\epsilon s}$; alternative forms using the h and g piezo parameters are used as well. Here, e, d, ϵ, c, and s are scalars, contracted from the material tensors according to the geometry at hand. These quantities are also called piezocoupling factors; representative values are listed below.

1.3 The Piezoelectric Effect and Crystal Symmetry

Crystallographers have, over the centuries, catalogued the various geometrical arrangements of atoms that can exist in crystal structures. The starting point is the unit cell, which normally contains the smallest grouping of atoms representing the chemical formula of the substance. In a crystal, this cell, with its particular size, shape, and internal arrangement of atoms, is repeated over and over in three dimensions. The result is an orderly stacking of cells that has translational invariance, meaning that moving one's observation point by an integral number of cells in any direction yields a completely equivalent view. The shapes of the unit cells suitable for such stacking fall into seven general types, or systems. These are triclinic, monoclinic, orthorhombic (also called rhombic), tetragonal, trigonal, hexagonal, and cubic (also called isometric). When the actual arrangements of atomic species possible within the unit cell are compounded with the possible shapes of unit cells, the total number of independent geometrical arrangements available in three dimensions is 230. These are the space groups.

In most practical situations, one deals with a continuum approximation, where considerations of the exact placement of atoms in the cells are not important, and the situation simplifies considerably. For example, elasticity is described by the few phenomenological stiffness and compliance constants used in the equations above. These numbers arise from a "smearing-out" of the effects of the individual interatomic potentials; only important are the directional aspects stemming from the atomic arrangements, not the arrangements themselves. Variation with direction of continuum properties such as acoustic wave speed is known as anisotropy. All the requisite geometric information specifying the varieties of anisotropy resides in the classification that the crystallographers call the point groups. These are only 32 in number, and arise simply from the symmetry elements such as two-, three-, four-, or six-fold rotational symmetry, mirror planes, inversion axes, etc. The point groups are described by their Hermann-Mauguin symbols; these are shorthand listings of the symmetries. Alternative notation, due to Schoenflies, is also current.

The crystallographic point-group symmetry elements completely determine the form and symmetries of the elastic, piezoelectric, and dielectric matrices that appear in the constitutive relations given earlier. The specific values of the individual components result, of course, from the particular substance considered.

Of the 32 point groups, 11 have a center of symmetry, and therefore cannot be piezoelectric, because piezoelectricity is a polar effect. Class 432 lacks a center of symmetry, but has other symmetries that, taken together, preclude the existence of piezoelectricity. The 20 piezo classes are triclinic class 1; monoclinic classes 2 and *m*; orthorhombic classes 222 and *mm*2; tetragonal classes 4, $\bar{4}$, 422, 4*mm*, and $\bar{4}2m$; trigonal classes 3, 32, and 3*m*; hexagonal classes 6, $\bar{6}$, 622, 6*mm*, and $\bar{6}m2$; and cubic classes 23 and $\bar{4}3m$.

As examples, we give the [*e*] forms of the piezo matrices pertinent to classes 3*m* (the strong piezoelectrics lithium niobate and lithium tantalate), 32 (quartz), $\bar{4}3m$, and 6*mm* (poled polycrystalline ceramics). The last two classes, $\bar{4}3m$ and 6*mm*, categorize nearly all of the piezoelectric semiconductors, such as silicon carbide and gallium arsenide. For class 3*m*,

$$[e] = \begin{pmatrix} 0 & 0 & 0 & 0 & e_{15} & -e_{22} \\ -e_{22} & e_{22} & 0 & e_{15} & 0 & 0 \\ e_{31} & e_{31} & e_{33} & 0 & 0 & 0 \end{pmatrix};$$

for class 32,

$$[e] = \begin{pmatrix} e_{11} & -e_{11} & 0 & e_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & -e_{14} & -e_{11} \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix};$$

for class $\bar{4}3m$,

$$[e] = \begin{pmatrix} 0 & 0 & 0 & e_{14} & 0 & 0 \\ 0 & 0 & 0 & 0 & e_{14} & 0 \\ 0 & 0 & 0 & 0 & 0 & e_{14} \end{pmatrix};$$

for class 6*mm*,

$$[e] = \begin{pmatrix} 0 & 0 & 0 & 0 & e_{15} & 0 \\ 0 & 0 & 0 & e_{15} & 0 & 0 \\ e_{31} & e_{31} & e_{33} & 0 & 0 & 0 \end{pmatrix}.$$

Two effects that are associated with piezoelectric materials are pyroelectricity and ferroelectricity.

1.4 Pyroelectricity

Of the 20 piezoelectric point groups, ten contain a unique polar axis; crystals in these classes possess electric dipole moments along their polar axes. When the crystals are subjected to a uniform change of temperature, electric charges accumulate on the ends of the polar axes. This phenomenon is known as pyroelectricity; because a temperature change (a scalar number) produces a charge separation, and consequently an electric field (a vector), the pyroelectric coefficients form a tensor of rank 1, i.e., a vector, and would be represented as a (3 × 1) matrix if we were to extend the constitutive equations given earlier to include this effect.

The crystal symmetry classes exhibiting pyroelectricity are 1, 2, *m*, *mm*2, 4, 4*mm*, 3, 3*m*, 6, and 6*mm*. Thus, α-SiC and lithium niobate are pyroelectric, while β-SiC, quartz, and gallium arsenide are not. The presence of piezoelectricity is necessary but not sufficient for a crystal to be pyroelectric.

1.5. Ferroelectricity

The name ferroelectricity is given to those polar crystals capable of having the spontaneous polarization along the polar axis reversed or reoriented, usually in response to an applied electric field. The name is derived by analogy with ferromagnetism, but in the magnetic case the very atoms themselves possess permanent magnetic moments; in the electric case, the permanent electric moment is a property of the placement of the atoms within the unit cells of the structure.

The presence of the ferroelectric state requires that the crystal be of a pyroelectric class; the converse is, however, not true. One cannot conclude *a priori* that a pyroelectric crystal is ferroelectric; one must settle this issue experimentally. The ferroelectric state usually exists only below a certain critical temperature, called the Curie temperature or Curie point. Above this point, the material may belong to a class that is not pyroelectric, or even piezoelectric. Upon cooling through the Curie point, the crystal undergoes a phase transition (which may be either first- or second-order), where the atoms of the structure shift their positions slightly and the crystal changes its symmetry, usually from a nonpolar form, to the symmetry of a pyroelectric class. Since the ferro state has reversible dipoles, upon cooling it is a matter of chance which polarity will be assumed; near the Curie point the structure is very susceptible to disturbance. Because the lattice is relatively unstable around this point, small forces can produce large effects; this is the case with the dielectric constant. This number is the measure of electric displacement produced in response to an applied electric field. Near the Curie point, the dielectric constant assumes very large values; this behavior ("dielectric anomaly") led to the initial discovery of this class of materials. Very often ferroelectrics have quite large piezoelectric coupling values.

Piezoelectric ceramics, such as lead zirconate titanate ($Pb(Ti,Zr)O_3$), are solid solutions comprised of microscopic crystallites, each of which is ferroelectric; the material originally is macroscopically isotropic at all temperatures because of the random orientations of the crystallites. When cooled through the Curie point in the presence of a static electric field (a process called "poling"), the domains are preferentially oriented and frozen into a configuration where the body is macroscopically piezoelectric. It remains isotropic perpendicular to the field axis, but the isotropy is destroyed in the parallel direction. The result is cylindrical polar symmetry, represented by the symbol ∞mm; as far as the elastic, piezoelectric, and dielectric matrices are concerned, the scheme of coefficients is identical to that for the class $6mm$.

Above the Curie point, most (but not all) ferroelectrics belong to one of three classes: 222 (e.g., Rochelle salt), $\bar{4}2m$ (e.g., potassium dihydrogen phosphate, KDP), and $m3m$ (e.g., $BaTiO_3$). In the ferroelectric state, most of the practically important compounds likewise fall into three classes: $4mm$, $3m$, and $mm2$.

1.6 Piezoelectric Polymers

Certain polymers, such as polyvinyl chloride (PVC), polyvinyl fluoride (PVF), and polyvinylidene fluoride (PVF_2 or PVDF), can be made piezoelectric by a combination of mechanical stretching and electric field poling at elevated temperatures. The induced anisotropy varies with the polymer and the subsequent treatment; polymethyl glutamate, for example, has symmetry $\infty 22$, which is equivalent to class 622 for the properties discussed here. PVDF sheet, poled along the thickness, belongs to class ∞mm (equivalent to $6mm$); uniaxial stretching or rolling converts it to orthorhombic class $mm2$, while a biaxial stretching again results in class ∞mm.

1.7 Piezoelectric Semiconductors

In the case of semiconductors, the piezoelectric equations are broadened to incorporate the further coupling to charge transport mechanisms. It is apparently not well appreciated how widespread is the phenomenon of piezoelectricity in semiconductors. The single-element semiconductors silicon and germanium have, of course, no piezo effect because of the inherent symmetry by which the atoms are arrayed in their crystals; they share with diamond the perovskite structure of point group $m3m$. Binary semiconductors, however, because of the dissymmetry of the two atomic species, are generally piezoelectric as well. Table 1 provides a partial listing of these materials, grouped according to the columns of the periodic table. The compounds fall into two categories: those marked "c" belong to the cubic point group $\bar{4}3m$, the sphalerite or zincblende structure, while those indicated with "h" belong to the hexagonal point group $6mm$, the wurtzite structure.

Piezosemiconductors have an encouraging future because of the appealing promise of monolithic, integrated, mixed-effect devices; for example, electronic drivers modulating photonic processors via submicroscopic mechanical actuators containing optical components such as lenses, mirrors, etc.

Zinc oxide, ZnO, is one of the most useful piezosemiconductors as a consequence of its interesting set of properties. It is photoconducting, and is transparent in the visible region; it has a broad band gap, fairly high refractive indices, large piezoelectric constants, and strong acousto-optical, electro-optical, and nonlinear optical coefficients. Chemisorption at its surface results in an electron transfer from the ZnO to the chemisorbed molecule. ZnO thin films, usually deposited by sputtering, have a wide range of applications. Examples are as transducers in surface-acoustic-wave (SAW) filters and delay lines, in integrated optical waveguides and acousto-optic Bragg deflectors, as transparent electrode materials in optoelectronic devices such as light-emitting diodes, and as sensors of oxidizing and reducing gases.

1.8 Numerical Values of Coupling Factors

Table 2 shows the piezocoupling factors of a few representative materials from various crystal classes (Hellwege and Hellwege, 1979, 1981, 1982a, 1982b; Madelung, 1982; Gualtieri *et al.*, 1993).

2. APPLICATIONS OF PIEZOELECTRICITY

2.1 Oscillators, Clocks, and Filters

2.1.1 Introduction The piezoelectric material on which most frequency-control, timing, and frequency-selection devices depend is quartz. A quartz crystal can act as a stable mechanical resonator, which, by its

piezoelectric behavior and high *Q*, determines the frequency generated in an oscillator circuit. Bulk-acoustic-wave (BAW) resonators are available in the frequency range from about 1 kHz to 300 MHz. Surface-acoustic-wave (SAW) and surface-transverse-wave (STW) devices can be made to operate at well above 1 GHz.

About 2×10^9 BAW quartz resonators are manufactured annually for oscillator, clock, and filter applications (Hellwig, 1993; Vig, 1993). Hundreds of millions of SAW devices, mostly filters of various types, are manufactured annually (Ruppel *et al.*, 1993). A major SAW device application is TV IF filters. Every TV set produced currently (i.e., in 1994) contains at least one SAW filter. SAW filters play important roles in communication systems, test and measurement instruments (e.g., synthesizers and spectrum analyzers), and remote-control systems. High-frequency oscillators are another important application of SAW devices.

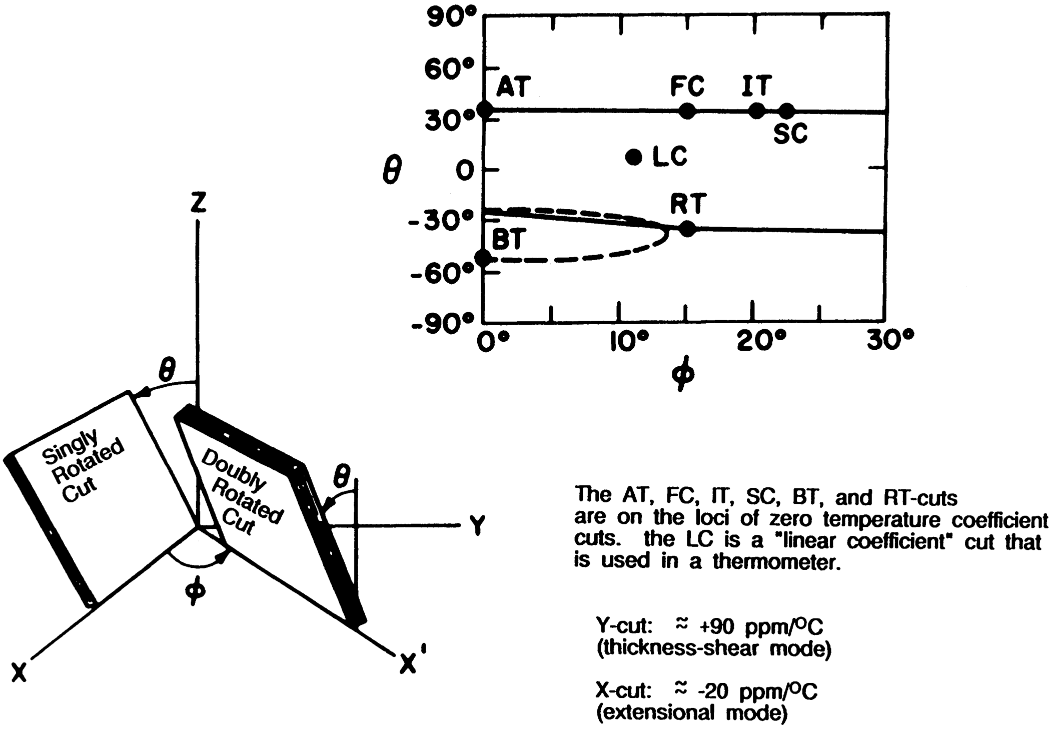
In the manufacturing of quartz resonators (Gerber and Ballato, 1985; Stein and Vig, 1992), wafers are cut from the mother crystal along precisely controlled directions with respect to the crystallographic axes. The properties of the device depend strongly on the angles of cut. After shaping to required dimensions, metal electrodes are applied to the quartz wafer, which is mounted in a holder structure. The assembly is usually sealed hermetically. A BAW resonator is called a crystal unit (or crystal or resonator). SAW devices are excited by interdigital transducers, which consist of two sets of interleaved metal electrodes, called fingers. The resonance frequency of a BAW device depends on the dimensions of the plate. A SAW device's frequency depends on the spacing of the fingers. Much of the remaining discussion will refer to BAW devices, as these are used in the highest production volumes.

To cover the wide range of frequencies, different cuts, vibrating in a variety of modes, are used. The various cuts usually have two-letter names. A *T* in the cut's name indicates a temperature-compensated cut; e.g., the *AT* cut was the first temperature-compensated cut named. The *BT* cut, *CT* cut, *DT* cut, *IT* cut, and *SC* cut are other temperature-compensated cuts. The locus of zero-temperature-coefficient cuts in quartz is shown in Fig. 2. The *X*, *Y*, and *Z* directions are the crystallographic axes, chosen to make the description of properties as simple as possible. The *Z* axis is an axis of threefold symmetry in quartz; i.e., the physical properties repeat every 120° as the crystal is rotated about the *Z* axis. The *AT* cut and the *SC* cut are the most popular cuts for high-stability applications. The *SC* cut has several important advantages over the *AT* cut, as is discussed below.

AT-, *BT*-, and *SC*-cut crystals can be manufactured for fundamental-mode operation at frequencies up to about 200 MHz. *AT*-, *BT*-, and *SC*-cut crystals vibrate in the thickness shear mode. Above 60 MHz, overtone crystals are generally used. Such crystals usually operate at the third or fifth overtone (e.g., a 20-MHz fundamental mode crystal excited on its fifth overtone is a 100-MHz crystal). Below 1 MHz, tuning forks, *X*-*Y* and *NT* bars (flexure mode), +5° *X* cuts (extensional mode), or *CT* and *DT* cuts (face-shear mode) can be used. Several hundred million 32.8-kHz tuning-fork crystals are produced annually for the world watch market.

2.1.2 Equivalent Circuit of Crystal Unit

The circuit designer can treat the behavior of a quartz-crystal unit by considering its (ap-



The AT, FC, IT, SC, BT, and RT-cuts are on the loci of zero temperature coefficient cuts. the LC is a "linear coefficient" cut that is used in a thermometer.

Y-cut: ≈ +90 ppm/°C (thickness-shear mode)

X-cut: ≈ -20 ppm/°C (extensional mode)

FIG. 2. The locus of zero-temperature-coefficient cuts in quartz.

proximate) equivalent circuit (Gerber and Ballato, 1985) (Fig. 3). The mechanical resonance in the crystal is represented by L_1, C_1, and R_1. Because it is a dielectric with electrodes, the device also displays an electrical capacitance C_0. The parallel combination of C_0 and the "motional arm," C_1-L_1-R_1, represents the equivalent circuit to a good approximation. As shown in Fig. 4, the reactance of this circuit varies with frequency.

The Q values ($Q^{-1} = 2\pi f_s R_1 C_1$) of quartz-crystal units are much higher than those attainable with other circuit elements. In general-purpose units, the Q is usually in the range of 10^4 to 10^6. The intrinsic Q of quartz is limited by internal losses. For *AT*-cut crystals, the intrinsic Q has been experimentally determined to be 1.6×10^7 at 1 MHz; it is inversely proportional to frequency. At 5 MHz, for example, the intrinsic Q is 3.2×10^6.

2.1.3 Oscillators The commonly used crystal oscillator circuits fall into two broad categories (Gerber and Ballato, 1985). In series-resonance oscillators, the crystal operates at series resonance, i.e., at f_s. In parallel-resonance or antiresonance oscillators, the crystal is used as a positive reactance; i.e., the frequency is between f_s and f_A, where f_A is the antiresonance frequency. In this latter mode of operation, the oscillator circuit provides a load capacity to the crystal unit. The oscillator then operates at the frequency where the crystal unit's reactance cancels the reactance of the load capacitor. When the load capacitance is changed, the oscillator frequency changes. An important parameter in this connection is the capacitance ratio $r = C_0/C_1$. Typically, the value of r is a few hundred for fundamental-mode crystals. It is larger by a factor of n^2 for nth-overtone crystals.

When a load capacitor C_L is connected in series with a crystal, the series-resonance frequency of the combination is shifted from f_s by a Δf which is related to the other parameters by

$$\frac{\Delta f}{f_s} \approx \frac{C_1}{2(C_0 + C_1)}.$$

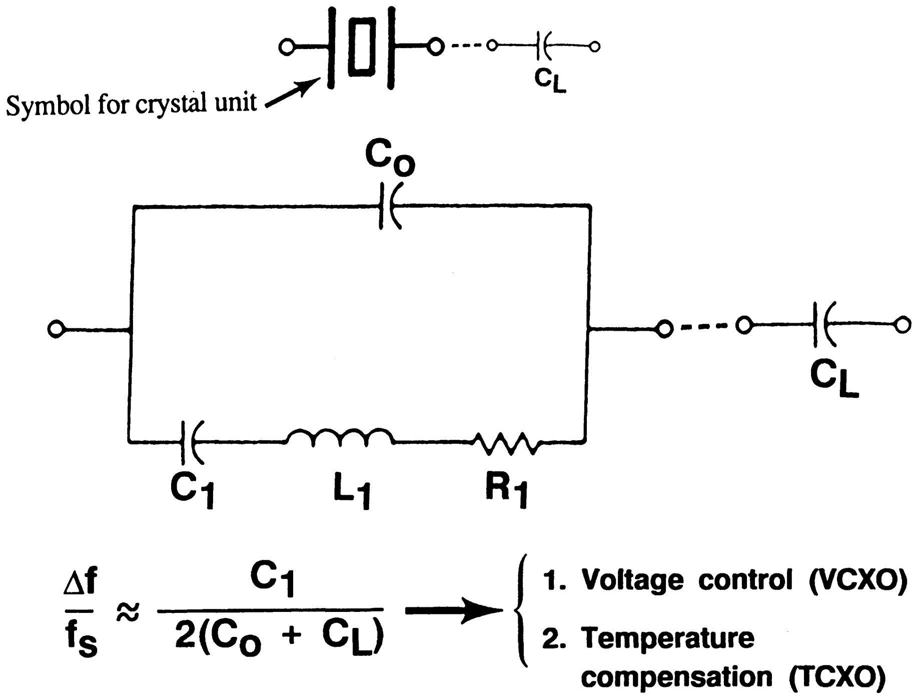


FIG. 3. The equivalent circuit of quartz-crystal unit.

For a typical fundamental-mode *AT*-cut crystal unit with $r = 250$, $C_0 = 5$ pF, and $C_L = 30$ pF, the shift is 286 ppm. If such a crystal unit is to remain stable to, for example, 1×10^{-9}, the load reactance due to C_L and the other circuit components must remain stable to within 1.2×10^{-4} pF. The frequency can also be "tuned" by intentionally changing C_L.

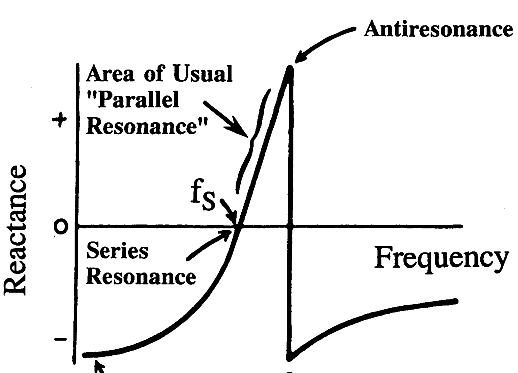

FIG. 4. The reactance of a quartz-crystal unit as a function of frequency.

For the above example, a change of 1 pF in C_L shifts the frequency by nearly 10 ppm.

2.1.4 Factors Affecting Frequency Stability Except for the atomic frequency standards, quartz devices exhibit the highest available frequency stability. However, all frequency sources exhibit frequency instabilities. The main instabilities are as follows (Gerber and Ballato, 1985; Stein and Vig, 1992; Vig and Walls, 1994).

2.1.4.1 Temperature. The frequency-vs-temperature characteristics are determined primarily by the angles of cut of the crystal plates with respect to the crystallographic axes of quartz (Gerber and Ballato, 1985; Stein and Vig, 1992). Typical characteristics are shown in Fig. 5. The points of zero temperature coefficient, the turnover points, can be varied over a wide range by varying the angles of cut.

The frequency–temperature characteristics of *AT*- and *SC*-cut crystals follow an approximately third-order law, as shown in Fig. 5 for the *AT* cut. A slight change in the orientation angle (7 minutes in the example shown in Fig. 5) greatly changes the frequency–temperature characteristic. Curve 1

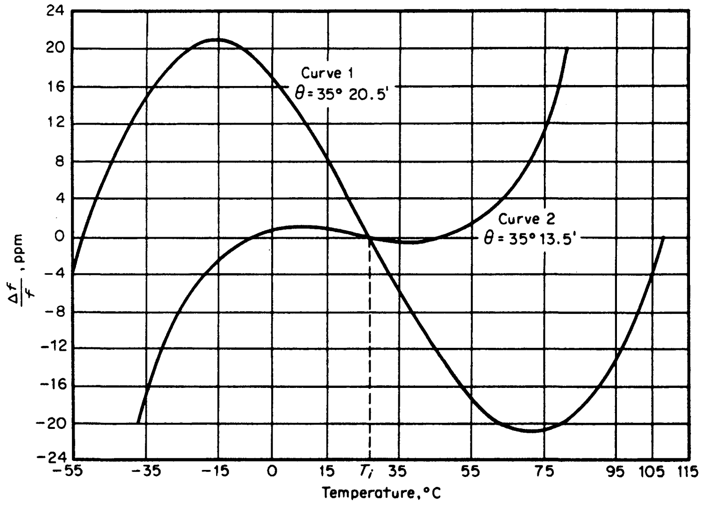

FIG. 5. Typical frequency-vs-temperature characteristics of quartz-crystal units, illustrating how a small change in the angle of cut can significantly affect the characteristic.

is optimal for a wide temperature range (−55 to 105 °C). Curve 2 gives minimum frequency deviation over a narrower range near the inflection temperature T_i. The frequency-vs-temperature characteristic of *SC*-cut crystals is similar to the curves shown in Fig. 5 except that T_i is shifted to about 96 °C. The *SC* cut is a doubly rotated cut; i.e., two angles must be specified and controlled during the manufacturing process. Several of the crystal cuts have a parabolic frequency-vs-temperature characteristic in the range −60 to +100 °C, e.g., the *BT, CT,* and *DT* cuts. The turnover temperatures of these cuts can also be shifted up or down by changing the angles of cut.

To achieve the highest stability, oven-controlled crystal oscillators (OCXO) are used. In OCXOs, the crystal unit and the temperature-sensitive components of the oscillator are placed in a stable oven, the temperature of which is set to the crystal's turnover temperature. OCXOs are bulkier and consume more power than other types. In addition, when an oven-controlled oscillator is turned on, one must wait several minutes for the oscillator to stabilize. During warmup, the thermal stresses in the crystal can produce significant frequency shifts. This thermal-transient effect causes the typical warmup time of an oscillator to be several minutes longer than the time it takes for the oven to stabilize. The thermal-transient effect is absent in *SC*-cut crystals. In oscillators that use *SC*-cut crystals, the warmup time can therefore be much shorter.

In temperature-compensated crystal oscillators (TCXOs) the crystal's frequency-vs-temperature behavior is compensated by varying a load reactance. For example, the output signal from a temperature-sensing network can be used to generate the correction voltage applied to a varactor. Digital techniques are capable of providing better than 1×10^{-7} frequency stability from −55 to +85 °C. TCXOs are smaller and consume less power than OCXOs and require no lengthy warmup times. A major limitation on the stabilities achievable with TCXOs is the thermal hysteresis exhibited by crystal units (see below).

2.1.4.2 Aging and Drift. Aging is the systematic variation of frequency with time due to internal changes in the oscillator, i.e., while all environmental parameters are held constant. Drift is the systematic change in frequency with time of an oscillator, i.e., drift is due to aging plus changes in the environment, power supply, etc. Aging can be due to several factors (Vig and Meeker, 1991). The main causes are mass transfer to or from the resonator surfaces (due to adsorption and desorption of contamination) and stress relief within the mounting structure or at the interface between the quartz and the electrodes. The observed aging is the sum of the aging produced by the various mechanisms and may be positive or negative.

The aging rate of a crystal unit is highest when it is new. As time elapses, stabilization occurs and the aging rate decreases. The aging observed at constant temperature often follows an approximately logarithmic dependence on time. When the temperature of a crystal is changed, however, a new aging cycle starts.

High-quality general-purpose crystals may typically age 1 ppm per year. If a lower aging rate is desired, overtone crystals in clean glass, metal, or ceramic enclosures should be used. Advanced surface-cleaning, packaging, and ultrahigh-vacuum fabrication techniques have resulted in units which age less than 1×10^{-10} per day after a few days of stabilization, or 1×10^{-8} per year.

2.1.4.3 Short-Term Stability. Crystal oscillators' frequency and phase also exhibit random fluctuations, i.e., short-term instabilities (Gerber and Ballato, 1985; Stein and Vig, 1992). Short-term instability, or "noise," in the time domain is usually expressed as the two-sample deviation of the fractional frequency fluctuations for a specified averaging time τ, and is denoted by $\sigma_y(\tau)$. The averaging times τ over which $\sigma_y(\tau)$ is specified generally range from 10^{-3} to 10^3 s. For a good oscillator, $\sigma_y(\tau)$ may range from 1×10^{-9} for $t = 10^{-3}$ s to 1×10^{-12} for $t = 10^3$ s. For $t > 10^4$ s, the stability is usually referred to as long-term stability or aging. For $t < 1$ s, the short-term instabilities are generally attributed to noise in the oscillator circuitry, although the crystal itself can also be a significant contributor.

When measured in the frequency domain, short-term stability is denoted by $\mathcal{L}(f)$, $S_\phi(f)$, or $S_y(f)$—phase noise, the spectral density of phase fluctuations, and that of frequency fluctuations, respectively, at a frequency separation f from the carrier frequency ν, and y is the normalized frequency $\Delta\nu/\nu$. The three quantities are related by $f^2 S_\phi(f) = S_y(f) = 2f^2\mathcal{L}(f)$. For a low-noise 5-MHz oscillator, $\mathcal{L}(f)$ may be -115 dBc at 1 Hz from the carrier, and -160 dBc at 1 kHz from the carrier, where dBc denotes decibels below the carrier.

2.1.4.4 Thermal Hysteresis and Retrace. When the temperature of a crystal unit is changed and then returned to its original value, the frequency will generally not return to its original value. This phenomenon, called thermal hysteresis for TCXOs and retrace for OCXOs, can be caused by the same mechanisms as aging, i.e., mass transfer due to contamination and stress relief (although the mechanisms are not fully understood) (Kusters and Vig, 1991).

For a given oscillator, the magnitude of the effect depends on the magnitude and direction of the temperature excursion, on the thermal history of the unit, and on the design and construction of both the crystal unit and the oscillator circuit. The effect tends to be smaller in OXCOs, where the operating temperature of the crystal is always approached from below, than in TCXOs, where the operating temperature can be approached from either direction. Thermal hysteresis can be minimized through the use of clean, ultrahigh-vacuum fabrication techniques (which minimize the mass-transfer contribution) and through the use of properly mounted *SC*-cut crystals (which minimize the stress-relief contributions). The magnitude of the effect typically ranges from several ppm in general-purpose crystals to less than 1×10^{-9} in the highest-stability crystals operated in OXCOs.

2.1.4.5 Drive Level. The amplitude of vibration is proportional to the current through a crystal. Because of the nonlinearities of quartz, the frequency of a crystal and the incidence of interfering modes are functions of the drive level. Therefore, the drive level must be stated when a crystal's parameters are specified. The oscillator designer's ability to improve signal-to-noise ratios by using a higher drive level is limited. In *SC*-cut crystals, the drive level effects can be significantly below those observed in *AT*- and *BT*-cut units. When the drive level is increased, the frequency of *AT*- or *SC*-cut crystals increases.

2.1.4.6 Acceleration, Vibration, and Shock. The frequency of a crystal unit is affected by stresses. Even the acceleration due to gravity produces measurable effects. When an oscillator using an *AT*-cut crystal is turned upside down along the worst direction, the frequency typically shifts about 4×10^{-9} because the acceleration sensitivity of the crystal is typically 2×10^{-9} per g. The sensitivity is the same when the crystal is subjected to vibration; i.e., the time-varying acceleration due to the vibration modulates the frequency at the vibration frequency with an amplitude of 2×10^{-9} per g. In the frequency domain, the vibration sensitivity manifests itself as vibration-induced spectral lines that appear at plus and minus the vibration frequency away from the carrier frequency (Vig *et al.*, 1992). The acceleration sensitivity of *SC*-cut crystals can be made to be less than that of comparably fabricated *AT*- or *BT*-cut crystals.

Shock places a sudden stress on the crystal. During shock, the crystal's frequency changes due to the crystal's acceleration sensitivity. If the elastic limits in the crystal's support structure or in its electrodes are exceeded during shock, the shock can produce a permanent frequency change. Crystal units made with chemically polished crystal plates can withstand shocks in excess of 30 000*g*. Such crystals have been successfully fired from howitzers.

2.1.4.7 Radiation. Ionizing radiation affects the frequency and resistance of a crystal unit. The degree to which high levels of ionizing radiation affect the frequency and resistance of a crystal unit depends primarily on the quality of quartz used to fabricate the device and on the dose (Gerber and Ballato, 1985; Stein and Vig, 1992). The frequency change per radian is higher at lower doses. When crystals made of natural quartz are subjected to ionizing radiation, their frequencies are changed permanently by approximately a few parts in 10^{11} per rad at a 1 Mrad dose. The resistance can increase to the point where oscillation stops because of insufficient gain in the oscillator. To minimize the effects of ionizing radiation, high-purity cultured quartz should be used. Pulse irradiation produces a transient frequency shift due to the thermal-transient effect. This effect can be minimized by using *SC*-cut crystals. Energetic neutrons change a crystal's frequency by about a few parts in 10^{21} per neutron per cm^2.

2.1.5 Filters Quartz-crystal units are used as selective components in crystal filters (Gerber and Ballato, 1985). With the constraint imposed by the equivalent circuit of Fig. 3, filter design techniques can provide bandpass or bandstop filters with a range of characteristics (see PIEZOELECTRIC FILTERS AND RESONATORS). Crystal filters exhibit low insertion loss, high selectivity, and excellent temperature stability.

Filter crystals are designed to have only one strong resonance in the region of operation, with all other responses (unwanted modes) attenuated as much as possible. The application of energy-trapping theory (Gerber and Ballato, 1985) can provide such a response. If electrode size and thickness are selected in accordance with that theory, the energy of the main response is trapped between the electrodes, whereas the unwanted modes are untrapped and propagate toward the edge of the crystal resonator, where their energy is dissipated. It is possible to manufacture *AT*-cut filter crystals with greater than 40-dB attenuation of the unwanted modes relative to the main response.

Filters made of piezoelectric ceramics, usually of PZT compositions, cover the range of about 50 Hz to above 10 MHz. As is the case for quartz filters, these devices range from simple resonators to multielectrode resonators to coupled sets of devices. PZTs, having a high coupling coefficient and moderate *Q*, allow the use of these devices in medium- to high-bandwidth applications. Ceramic filters have poorer frequency vs temperature and long-term stability than quartz crystal filters.

SAW bandpass filters are used in applications such as television-receiver intermediate-frequency circuits. Such filters can provide stop-band rejection of better than 60 dB and in-band response flat to 0.1 dB. SAW devices can also perform signal processing functions, such as pulse compression and side-lobe suppression that can be performed by dispersive filters and reflective-array-compressor (RAC) filters, and a chirp transform can provide the Fourier transform of an input signal.

2.2 Sensors and Transducers

Whereas in frequency control and timing applications of quartz-crystal devices the components are designed to be as insensitive to the environment as possible, quartz crystals and other piezoelectric materials can also be designed to be highly sensitive to environmental parameters such as temperature, mass changes, pressure, force, and acceleration (EerNisse *et al.*, 1988). Quartz-crystal transducers can exhibit unsurpassed resolution and dynamic range. For example, one commercial "quartz pressure gage" exhibits a 1-ppm resolution, i.e., 60 Pa at 76 MPa (0.01 lb/in.^{2} at 11,000 lb/in.^{2}), and a 0.025% full-scale accuracy. Quartz thermometers can provide millidegrees of absolute accuracy over wide temperature ranges. Quartz sorption detectors can detect a change in mass of 10^{-12} g. Quartz accelerometer/force sensors are capable of resolving 10^{-7} to 10^{-8} of full scale.

Piezoelectric ceramics are also used for sensors (Newnham and Ruschau, 1991). In some applications, ceramics (e.g., various compositions of lead zirconate titanate, PZT) are preferred over quartz and other single-crystal piezoelectrics because of their higher piezoelectric coupling, which can result in a larger signal when a force is applied. For example, ceramics are used in some accelerometers wherein the acceleration of a mass applies a compressional or shear force to the piezoelectric ceramic. The signal-conditioning circuitry, which must amplify what is usually a small signal from a high-impedance source, is often part of the device.

2.3 Actuators, Motors, Smart Materials and Devices

Piezoelectric actuators, devices that are capable of moving something electromechanically via electric-field–induced strain, can be classified into two categories, based on the type of driving field applied to the device:

1. rigid displacement devices, in which a dc field is applied, and
2. resonating strain devices, in which an ac field excites the device (Newnham and Ruschau, 1991).

Piezoelectric materials have conventionally been used in devices of the second type, e.g., as vibrators in oscillators, filters, buzzers, speakers, and ultrasonic generators. For rigid displacement devices, large electric fields (~1 kV/mm) have been needed in order to achieve sufficiently large stresses and strains. Therefore, the materials have had to be strong mechanically and electrically (i.e., with high insulation strength). Another problem has been the fact that when an electric field is applied to a piezoelectric ceramic such as PZT, at low fields the strain is proportional to the field, but at high (e.g., >100 V/mm) fields, the relationship becomes nonlinear, and significant hysteresis is exhibited. The hysteresis has limited the applications in areas that require a linear, nonhysteretic response.

In recent years, the need for precision displacement devices has increased in fields such as optics and semiconductor processing. Submicron-level precision is required in several of these applications, which has renewed interest in the use of improved piezoelectric (and electrostrictive) materials for fine positioning control.

Rigid displacement devices have been used for precision optical control, e.g., in deformable mirrors, and for mechanical control, e.g., in dot-matrix printer heads, piezoelectric relays, and cutting-error–correction devices. Deformable mirrors allow changing the focal length and adjustments for curvature imperfections, and can even compensate for telescope image distortions resulting from fluctuating airflow. Other applications in optics include variable diffraction gratings, microangle optical element adjustments, and precision microscope stages. Cutting-error–correction devices have been used in, for example, cutting tools used for the forming of large radius-of-curvature aspheric surfaces. A piezoelectric actuator synchronized to the rotation of the cutting tool can reduce the imperfections of the cutting tool 20-fold, to an accuracy of about 0.1 mm.

In dot-matrix printers, a printing ribbon is impacted by a multiwire array to form, e.g., a 9 × 9 dot matrix. In some such printers, the actuator consists of about 100 layers of a thin piezoelectric ceramic sheet. The displacement of the actuator is magnified via levers so that the total displacement is about 300 μm. The arrangement provides higher printing speeds than printers using conventional electromagnetic actuators, with lower energy consumption and less noise (as a result of easier shielding).

Resonating displacement devices include ultrasonic knives and scapels, piezoelectric fans, ultrasonic humidifiers, piezoelectric pumps, ultrasonic wire bonders, components in active vibration-damping systems, and ultrasonic motors. Ultrasonic wire bonders are used, for example, for bonding gold wire leads to semiconductor devices. The ultrasonic vibration of the bonding tip disperses the surface contamination at the bond interface and, thereby, improves the strength and reliability of the bond.

Ultrasonic motors of various rotary and linear types have been constructed. In a rotary device, the rotation of a rotor is caused by piezoelectric vibration of a stator instead of the conventional electromagnetic interaction. The driving force is transmitted directly from the stator to the rotor by friction. One linear stepping motor ("inchworm"), for example, consists of a pair of piezoelectric clutches, each at the end of a piezoelectric ceramic tube. The clutches alternately grab, move, and release a metal rod in a manner that moves the rod linearly, in steps. Such a motor can provide submicron resolution, and large (although slow) displacements. Both linear and rotational motors have been produced by means of surface-wave vibrations. A traveling elastic wave is induced by a piezoelectric driver. A slider in contact with the rippled surface of a body moves the body in the direction of the wave. Longitudinal, torsional, and bending multimode vibrators have also been employed in piezoelectric motors.

The name "smart material" has been used to describe some actuators (Newnham and Ruschau, 1992). Smart materials have the ability to be both sensors and actuators. Passively smart devices can sense a change in the environment and respond in a useful manner, automatically, without any assistance. Actively smart devices contain a feedback loop that allows them to recognize a change and initiate an appropriate response through an actuator. A passively smart material differs from an actively smart material in that no external fields, forces, or feedback systems are used to enhance its behavior (Newnham, 1992). "Very smart" materials have the additional ability to learn and alter their property coefficients in response to a changing environment. An example of an actively smart device is a videotape head positioner in which a PZT bilaminate bender (i.e., bimorph) with a segmented electrode pattern is used. The bender vibrates at 450 Hz. Voltage across the sensing electrodes is processed and applied to the positioning electrodes so as to follow the tape track path and keep the head perpendicular to the track. Modern "high-tech" automobiles use several piezoelectric sensor–actuator combinations. For example, in one system, a piezoelectric raindrop sensor senses the amount of rain falling and adjusts the windshield wipers to the optimum speed. Piezoelectric ceramics are also used in active noise cancellation and in smart shock absorbers (a bump in the road produces a voltage, which produces a displacement that changes the damping produced by the hydraulic system).

2.4 Optical and Acousto-optical Devices

Applying a strain to a solid can produce a deformation of the lattice that can change the solid's optical properties (Kino, 1987). Sound waves and light can thereby interact in a solid or fluid. The sound wave creates a periodic variation of the properties of the medium, which can result in scattering and diffraction. The coupling between light and sound can result from the photoelastic (or piezo-optic) effect, or the converse electrostrictive effect. In the photoelastic effect, strains due to the sound waves change the atomic lattice spacings, resulting in localized changes in the dielectric constant. In the converse electrostrictive effect, the presence of the electric field due to light causes a strain that is proportional to the square of the electric field.

When a light beam is deflected by sound waves, the amplitude of the deflected beam depends on the amplitude of the sound wave, and the angle of deflection depends on the frequency of the sound wave. The light pattern formed by the deflected beam can thereby provide the Fourier transform of the modulating acoustic beam. Using the acousto-optic interactions with two acoustic beams adds further possibilities that lead to a wide variety of signal-processing functions, such as the real-time wideband convolution and correlation of electrical signals.

2.5 Underwater Sound Systems, Ultrasonic Cleaners, Medical Ultrasonics, and Nondestructive Evaluation

Water is an excellent medium in which to transmit (compressional) sound waves, and piezoelectric ceramic transducers, e.g., PZTs and barium titanates, are excellent materials for generating and detecting such waves. The generator is usually called a source or projector, the detector is called a hydrophone, and the term sonar (derived from SOund Navigation And Ranging) is a major topic in the field of underwater acoustics. Arrays of transducers can be used to achieve directionality; the arrays can be steered mechanically or electrically, similar to the techniques used in radar. The functions performed by sonar are similar to those performed by microwave systems above water, i.e., detection, tracking, classification, communication, navigation, etc.

In ultrasonic cleaners, the vibration of an ultrasonic transducer produces compression (high pressure) during the half-cycle when the transducer moves toward the liquid, and rarefaction (low pressure) when it moves away from the liquid. If the amplitude of the ultrasonic vibration is high enough, then during the low-pressure part of the cycle, the pressure on the liquid will be below the liquid's vapor pressure at the temperature of operation, and a large number of minute bubbles are formed. One-half cycle later, the high pressure causes the vapor to recondense to liquid, thus forming tiny partial vacuum bubbles that implode with great force. Such a formation and implosion of vapor bubbles is called cavitation. The cavitation provides the ultrasonic scrubbing of surfaces. Use of a cleaning solution in the cleaners can enhance the cleaning action.

Medical ultrasonic (i.e., ultrasound) systems apply the principles of sonar to the visualization of internal organs. Lithotripsy is a treatment method wherein a patient is immersed in a liquid and very intense and highly directional ultrasonic waves are directed, through the liquid, at internal organs, e.g., to break apart kidney stones.

The reflection, scattering, and diffraction of ultrasonic waves at the boundaries of different materials (e.g., different tissue densities in medical ultrasonics) is also used in a nondestructive evaluation of materials and devices.

2.6 Other Piezoelectric Devices

That a dc potential can produce a displacement and an alternating electrical potential can produce vibration in a piezoelectric material has been exploited in a wide variety of devices. For example, piezoelectric ceramics (often in the form of bimorphs) and piezoelectric polymers are used in microphones, telephony, intruder alarm systems, audio tone generators in signaling devices, range finders, sensors for door openers, remote-control devices, loudspeakers, phonograph pickups, atomization devices, pulverization devices, welders (for ultrasonic welding of plastics and metals), ultrasonic soldering, ultrasonic drilling and machining of brittle materials, valves, pumps, optical choppers and scanners, grippers, cooling fans, and actuators in pinball games, and as transducers that produce sonochemical reactions.

That a force on a high-coupling piezoelectric ceramic material can produce a high dc potential has been exploited in, for example, high-voltage generators used for ignition purposes—for lighting a fire in gas appliances, in cigarette lighters, and in charcoal grill lighters; fuses for explosives; for triggering flash bulbs, in push buttons, and in keyboards.

That the velocity of ultrasonic waves is far smaller than the velocity of electromagnetic waves in solids has been exploited in a variety of subminiature BAW and SAW delay lines for replacement of electromagnetic delay lines.

Highly sensitive uncooled infrared detector arrays are based on ferroelectric materials (Dereniak and Sampson, 1992; Andresen and Shepherd, 1993). In one detector array, for example, bolometer elements are made of ferroelectric barium strontium titanate ($BaSrTiO_3$). Near the ferroelectric phase transition, i.e., near the Curie point, the pyroelectric coefficient is large, and the dielectric constant varies rapidly. In the dielectric bolometer, as the temperature of the elements changes on account of incoming infrared radiation, the capacitance changes are sensed. In the pyroelectric mode, the temperature-change–induced polarizations are sensed. A new type of uncooled infrared detector array of potentially superior performance consists of an array of quartz microresonators. This recent invention utilizes the steep frequency-vs-temperature characteristics of resonators made of certain cuts of quartz, the low noise characteristics of quartz crystal oscillators, and the small thermal mass and high thermal isolation capability of microresonators (Vig, 1995).

GLOSSARY

Aging: The systematic variation of frequency with time due to internal changes in an oscillator, i.e., while all environmental parameters are held constant.

Crystal Unit: An electrical component consisting of a quartz-crystal plate of appropriate orientation with respect to the crystallographic axes of quartz, electrodes on or near the quartz plate, a mounting structure, and an enclosure. The component is sometimes also referred to as a "crystal" and as a "resonator."

Drift: The systematic change in frequency with time of an oscillator, i.e., drift is due to aging plus changes in the environment, power supply, etc.

Electromechanical Coupling Factor: A number describing conversion efficiency of energy between electric and elastic forms in a piezoelectric material.

Ferroelectric: The description given to those polar crystals capable of having the spontaneous polarization along the polar axis reversed or reoriented, usually in response to an applied electric field.

Frequency Deviation $y(t)$: The instantaneous normalized frequency deviation at time t from a mean frequency.

Oven-Controlled Crystal Oscillator (OCXO): A type of oscillator in which the crystal unit and the temperature-sensitive components of the oscillator are placed in a stable oven, the temperature of which is set to the crystal's turnover temperature.

Phase Noise $\mathscr{L}(f)$: The measure of short-term stability in the frequency domain (see IEEE Standard 1139-1988 for definition and discussion).

Piezoelectricity: The phenomenon in which an electric polarization couples to a mechanical strain. In the direct piezoelectric effect, the electric polarization results from mechanical strain; in the converse effect, a mechanical strain is produced in a material by a polarizing electric field. The polarization is proportional to the strain, and changes direction with it.

Point Group: One of 32 possible geometric symmetry arrangements of atoms in a crystalline material determining which properties (e.g., piezoelectricity) exist, and their relations with the crystal axes.

Pyroelectricity: The phenomenon in which a temperature change produces a charge separation, and consequently an electric field. When the crystals are subjected to a uniform change of temperature, electric charges accumulate on the ends of the polar axes.

Quartz Crystal: Single-crystal silicon dioxide, SiO_2. Alpha quartz is the crystalline form of quartz at temperatures below 573 °C. Cultured quartz is quartz produced in a factory, as opposed to natural quartz, which is mined.

Stability: Sensitivity to a frequency change as a result of changes of parameters such as time, temperature, shock, and the like. Stability is usually expressed as a dimensionless, normalized frequency change from a nominal or mean frequency.

Temperature-Compensated Crystal Oscillator (TCXO): A type of oscillator in which the crystal unit's frequency-vs-temperature behavior is compensated by varying a load reactance in the oscillator circuit.

Two-Sample Deviation $\sigma_y(\tau)$: The square root of the two-sample variance. Also called the Allan deviation, or the square root of the Allan variance.

Two-Sample Variance $\sigma_y^2(\tau)$: The time average over the sum of the squares of the differences between successive readings of the frequency deviation sampled over a sampling time τ, under the assumption that there is no dead time between the frequency deviation samples. Also called the Allan variance.

Ultrasonic: A modifier to indicate a device or system employing, or pertaining to, frequencies above the audio range.

Continuing Series

The *Proceedings of the International IEEE Ultrasonics Symposium* is published annually by the IEEE. These volumes contain research and review papers on a wide variety of piezoelectric ultrasonic devices.

The *IEEE Transactions on Ultrasonics, Ferroelectrics, and Frequency Control* reports on topics dealing with piezoelectric materials, nondestructive evaluation, biological and medical ultrasonics, imaging, ferroelectricity, sensors, optical interactions, underwater sound, measurement and control applications, ultrasonic motors, and frequency control.

The *Proceedings of the IEEE International Frequency Control Symposium*, and its predecessor, the *Proceedings of the Annual Symposium on Frequency Control*, are the primary fora for publishing research results and review papers on piezoelectric materials for frequency control, and on resonators and oscillators for frequency control, selection, and timing applications. These have been published since the Tenth Symposium in 1956. The latest volumes are available from IEEE, 445 Hoes Lane, Piscataway, NJ 08854. The earlier volumes are available from the National Technical Information Service, Sills Building, 5285 Port Royal Road, Springfield, VA 22161.

PIEZOELECTRIC RESONATORS AND APPLICATIONS

INTRODUCTION

Early theoretical treatments and experimental observations of the electrical properties of piezoelectric resonators have been reviewed. Also reviewed were early publications on potential applications of piezoelectric resonators in oscillators, filters, and circuit couplers (Cady, 1964, Vol. 1, Chap. 1, pp. 1–8).

An important purpose of the present article is to review some developments in the understanding of the theory and application of piezoelectric resonators. Some possible mode types in piezoelectric resonators and associated mode characteristics are described in this article. Although some applications of piezoelectric resonators can be based on a quasistatic linear theory, many important applications need to use a nonlinear theory (Gagnepain and Besson, 1975; Tiersten and Sinha, 1978). In some cases, an approximate linear theory can be used in place of the more accurate nonlinear theory. The nonlinear behavior of the piezoelectric resonator often produces undesired resonator performance, which needs to be understood (at least approximately) in order to optimize the use of resonators in particular applications. In Appendix A, a quasistatic theory of thickness-excited thickness-mode piezoelectric resonators is described as an example. Three general kinds of applications of piezoelectric resonators described in this article are frequency control (i.e., filters), frequency generation (i.e., oscillators), and measurement of various environmental conditions (i.e., sensors). Filters, oscillators, and sensors using crystal and ceramic resonators all have considerable commercial significance.

Most sections of this article are based on published surveys and review articles. References to specific topics are included if suitable reviews are not available. Except in special cases, references found in recent papers or reviews are not repeated in this article. Throughout this article, differentiation with respect to a system variable is indicated by the comma notation, i.e., $u_{1,3} = du_1/dx_3$ or $u_{2,t} = du_2/dt$. The summation convention (Jeffreys, 1931) is used for repeated indices. Quantities are called tensors if they change like tensors when the coordinate system is rotated (Nye, 1957, 1960).

1. A QUASISTATIC LINEAR MODEL FOR PIEZOELECTRIC RESONATOR MODES

Useful background material for this section can be found in the literature (Tiersten, 1969, Part I, pp. 11–61; Part II, pp. 65–93).

1.1 Basic Variables and Equations

The stress differential equations that govern the mechanical motion of elastic or piezoelectric materials are

$$T_{ij,i} + f_j = \rho u_{j,tt}, \tag{1}$$

where the T_{ij} are the nine components of the mechanical stress tensor, the f_j are the three components of the body force vector, ρ is the material density, and the u_j are the three components of the mechanical displacement vector. This equation of motion can be derived from the conservation of linear momentum for the system. It is also Newton's second law that describes the mechanical motion of elastic or piezoelectric materials.

The electrical differential equations that govern the polarization of electric charge-free dielectrics or piezoelectric materials are

$$D_{i,i} = 0, \tag{2}$$

where the D_i are the three components of the electrical displacement vector. Equation (2) is one of Maxwell's equations that describes the electrostatic behavior of charge-free dielectrics.

For linear piezoelectric materials, the components of mechanical stress and electrical displacement are proportional to the components of mechanical strain and electric field:

$$T_{kl} = c^E_{klmn}S_{mn} - e_{mkl}E_m \tag{3}$$

and

$$D_j = e_{jkl}S_{kl} - \epsilon^S_{jk}E_k, \tag{4}$$

where $S_{ij} = 0.5(u_{i,j} + u_{j,i})$ are the nine components of the mechanical strain tensor, $E_k = -\phi_{,k}$ are the three components of the electric field vector, the c^E_{klmn} are material constants called the 81 components of the stiffness tensor at constant E, the e_{jkl} are material constants called the 27 components of the piezoelectric constant tensor, and the ϵ_{jk} are material constants called the nine components of the dielectric permittivity tensor at constant S.

Equations (3) and (4) are called constitutive equations. The definitions of the quantities in the constitutive relations allow expressing the components of the mechanical stress and electric displacement in terms of the electric potential and the components of the mechanical displacement. Other forms of the constitutive equations may be useful in describing particular systems (Berlincourt *et al.*, 1964; Meeker, 1985, pp. 60–61).

Under some conditions, it is useful to allow the material constants in a linear theory to depend on environmental conditions such as temperature, pressure, acceleration, etc. These environmental conditions are more accurately treated as nonlinear effects. For some external conditions, such as inhomogeneous heating, the linear constitutive equations are not accurate, and approximate or nonlinear theories are needed (Tiersten and Sinha, 1978).

Boundary and initial conditions that insure a unique solution of Eqs. (1) and (2) have been derived. A specific example states boundary specification of three mechanical stress components and the electric potential on all surfaces for all time and initial specification of the components of mechanical velocity, mechanical displacement, and electric field at all points in the body (Tiersten, 1969, Chap. 5, pp. 33–39). Practical resonator designs are usually based on zero values for the mechanical stress components and a specified electric potential as the boundary conditions. Components of mechanical velocity and the electrical current at the surfaces can be calculated directly from the final solution.

After a desired direction in the crystal lattice has been selected, four types of mechanical stress and two types of electrical boundary conditions lead to nearly all practical resonator designs. Many other types of boundary conditions, which might lead to useful resonator designs for particular applications, will not be considered in this article.

For thickness-mode transducers (as contrasted to resonators), useful boundary conditions are the specification of three mechanical stress components, three mechanical velocity components, and an electric potential and electric current at each of the two surfaces of the transducer. Details for a single-mode thickness transducer with infinite length and width have been reported (Meeker, 1985, Chap. 2.1, pp. 47–110, and Chap. 2.2, pp. 110–119).

Expressing the differential equations, boundary conditions, and initial conditions in other coordinate systems is often useful in the development of theories for resonators with special symmetries, such as circular plates or cylindrical rods (Meitzler *et al.*, 1973).

For the quasistatic case, the free electric charge within the body is zero, and resonator properties do not depend on magnetic effects. The material density, electric charge, and electric potential are scalars or zero-order tensors; the mechanical displacement, the acceleration, the electric field, and the electric displacement are vectors or first-order tensors; and the strain and stress are second-order tensors. Physical quantities are called tensors because of the way they change when the coordinate axes are rotated (Nye, 1957, 1960).

The coupled second-order differential equations are solved, subject to the boundary conditions, for the dependence of the distribution of mechanical motion on time and position within the resonator body (Tiersten, 1969, Chap. 8, pp. 65–80; Chap. 9, pp. 81–93). The general solution process would yield mechanical displacement distributions for all possible modes of motion of the resonator. Except for some idealized resonators, the solutions are not easily expressed as analytical functions and have to be determined numerically for particular boundary conditions on the surfaces of the resonator body (Holland and EerNisse, 1969).

Other choices of dependent and independent field quantities can be useful in developing theories for particular resonator geometries (Berlincourt *et al.*, 1964; Meeker, 1985). The superscripts on ϵ_{ik}^{S} and c_{klmn}^{E} can only signify a particular choice of independent and dependent field quantities, because the constants defined for other choices can be calculated directly from those defined above; i.e., all alternative sets of these constants pertain to the resonator material at all times and at all places and are not related to specific boundary condition choices (Meeker, 1985).

1.2 The Elasto-Piezo-Dielectric Matrix

A compressed notation (Halliburton *et al.*, 1985) allows the tensor constitutive equations in Sec. 1.1 to be rewritten as

$$T_m = C_{mn}^{E} S_n - \epsilon_{km} E_k \tag{5}$$

and

$$D_i = e_{in} S_n + \epsilon_{ik}^{S} E_{ik}, \tag{6}$$

where $m = 1$ to 6, $n = 1$ to 6, $k = 1$ to 3, and $i = 1$ to 3. The 9×9 symmetric matrix of the coefficients of S_n and E_k is called the *elasto-piezo-dielectric matrix.*

1.3 Coordinate-System Transformations

By selecting a proper orientation for a resonator blank in the material coordinate system, the temperature coefficient, acceleration sensitivity, or some other desired property can be optimized. The arbitrary orientation of a plate or bar with respect to the material coordinate system can be described by three rotations, starting with a plate or bar thickness, edge, or length along one of the standard axes. This system for specifying the orientations of rectangular plates (or of plates with other shapes with orientation marks on the surfaces or edges) is described in standards (Hafner, 1985, Chap. 16, pp. 297–304), to provide better communication between theoreticians, designers, suppliers, and customers on plate and bar specifications. Effects of plate or bar orientation in the crystalline lattice and the symmetry of the crystal lattice on the elements of the elasto-piezo-dielectric matrix can be found in the literature (Halliburton *et al.*, 1985).

1.4 Comments on Piezoelectric Resonator Theories

The deceptively simple equations in Sec. 1.1 have never been solved in closed form for an actual physically realizable piezoelectric resonator. Exact solutions for idealized resonators such as infinitely wide and long thickness-mode plate resonators or infinitely narrow and thin length-mode bar resonators have been reported (Cady, 1964, Chap. 5, pp. 84–115; Berlincourt *et al.*, 1964). Approximate solutions for thickness shear-mode plate resonators with finite width and length and for extensional and flexural length-mode bar resonators with finite thickness and width have been reported (Sykes, 1982, pp. 214–219; Meeker, 1985, Chap. 2.1, pp. 47–110, and Chap. 2.2, pp. 110–119). In Secs. 2 and 3, some of the more useful modes of piezoelectric resonators are briefly described. For each resonator, a few modes (usually only one or two) are desired, and the other modes are unwanted. Both desired and unwanted mode activities must be controlled by the design of the resonator. This means that the designer must understand the properties of all the active modes in the resonator of interest in order to optimize the performance and cost of the resonator.

To optimize some important resonator properties, such as the electrical impedance level of unwanted resonator modes, it is necessary to have adequate models for each mode of interest. For particular applications, these models may have to include couplings between various modes. Until the required models are developed, considerable experience is required to design resonators with desired low activities of unwanted modes.

Many piezoelectric resonators made of crystalline quartz have been named with one or two letters to designate the desired mode (Sykes, 1982, pp. 211–214). Some characteristics of several of these quartz-crystal resonators are described in Sec. 3.

Piezoelectric resonators can be classified in terms of mode type (i.e., bulk or surface acoustic) and resonator material (i.e., crystal, polarized ceramic, polarized film, etc.). Each mode type refers to a particular distribution of the motion (direction and magnitude) of the individual volume elements of the piezoelectric resonator body. All volume-element motions have the same frequency and phase (Cady, 1964, Vol. 1, Chap. 5, pp. 86–87; Hildebrand, 1965). In some cases, the actual motion is a complicated combination of several simple types of motion.

Each mode type may also be characterized by a resonance frequency, an antiresonance frequency, an electrical impedance level, and a dissipation factor (Hafner, 1985, Chap. 7, pp. 1–44). These mode characteristics depend on the shape, dimensions, and crystal orientation of the piezoelectric body and on the electrode material, thickness, orientation, and spatial distribution. The electrodes may be inside the body, on the body surfaces, or outside the body in the surrounding space.

Some details of using the linear theory to derive electrical impedances per unit area for thickness mode resonators are given in Appendix A.

In Secs. 2 through 5, many of the modes that can exist in a piezoelectric resonator are discussed briefly.

2. BULK ACOUSTIC-WAVE RESONATOR MODES

2.1 Shear and Dilatation Thickness Modes in Plates and Disks

2.1.1 Infinite Length, Width, and Radius: Completely Electroded Several theories of piezoelectric thickness-excited thickness-mode resonators with infinite width and length, using only exact solutions for the equations in Sec. 1.1, have been reviewed (Meeker, 1985, Chap. 2.1, pp. 47–110, and Chap. 2.2, pp. 110–119). Electrical and mass surface-loading effects are included in some of these theories. By use of the appropriate mechanical displacement components and elasto-piezo-dielectric matrix elements, this theory can be used for both shear and dilatational mode resonators (Meeker, 1985, Chap. 2.1, pp. 47–110, and Chap. 2.2, pp. 110–119). As an example of these theories, some detailed results are given in Appendix A for thickness-mode resonators. Appendix A also includes a brief discussion of the effects of nonuniform spatial distributions of mechanical motion in physically realizable thickness-mode resonators.

Figure 1 shows mechanical displacement components for the fundamental lowest-frequency thickness shear and dilatational

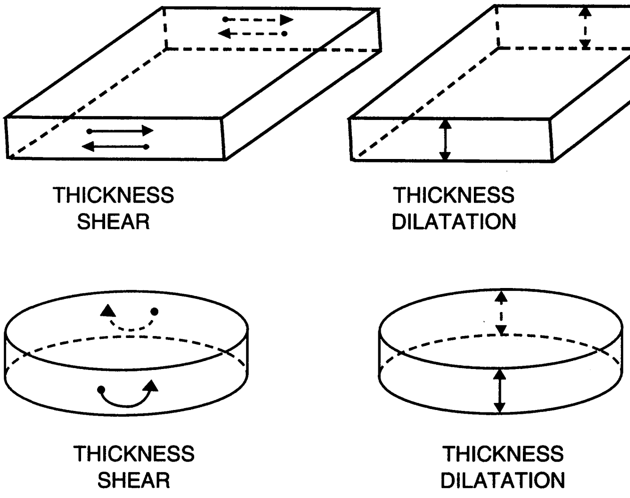

FIG. 1. Mechanical displacement components for thickness modes in plates and disks with infinite length, width, and radius.

modes in plates and disks with infinite lateral dimensions. The lateral boundaries shown in Fig. 1 only serve to draw attention to a localized region of the infinitely extended plate or disk. An infinite number of overtone higher-order thickness modes have more than one phase reversal of mechanical displacement between the major surfaces of the plate or disk. The plate or disk major surfaces are either completely electroded or completely unelectroded. In Fig. 1, the circular thickness shear is a torsion (Sec. 2.3.2).

For well-designed thickness-mode resonators, the modes described by Eq. (7) in Appendix A will be the resonator modes with the lowest values of Z. Many other modes not described by Eq. (7) of Appendix A will have impedances that are higher and are called weaker modes, because in most circuits they will have a lower amplitude. In some cases, coupling between the stronger modes and the weaker modes produces unacceptable resonator properties.

Applications of thickness-mode piezoelectric resonators depend on resonator electrical impedances, as described by equations like Eq. (7) in Appendix A. Some general and specific applications are discussed in Sec. 8.

For some crystals at certain orientations, thickness modes in plates or disks can be excited by electric fields along a direction in the plane of the plate (Meeker, 1985, Chap. 2.1, pp. 47–110, and Chap. 2.2, pp. 110–119; Ballato *et al.*, 1986).

2.1.2 Finite Length, Width, and Radius: Completely Electroded For the discussion in Sec. 2.1.1, the thickness is the only finite dimension of the plate or disk. Each of the three possible modes (one quasidilatational and two quasishears) has an infinite series of thickness modes, each characterized approximately by the number of half-wavelengths of mechanical motion through the plate thickness. The antiresonance frequencies of these modes are evenly spaced (harmonic); the resonance frequencies are not evenly spaced (anharmonic).

Each finite lateral dimension of the completely electroded or completely unelectroded plate or disk leads to an infinite series of anharmonic thickness modes with frequencies that are not evenly spaced and that are associated with the number of half-wavelengths of mechanical motion along the lateral dimension. Thus, three numbers signify the number of half-wavelengths of mechanical motion along the three dimensions of the resonator plate. For the circular disk, the three dimensions are the thickness, radius, and a rotation angle in the plane of the disk. The relationships among the resonance frequencies of these three sets of thickness modes are shown in Fig. 2, in which dispersion relations for plate mode propagation have been converted into frequency equations by a wave-number approximation (Meeker, 1985). There are relations, as shown in Fig. 2, for each of the two finite lateral dimensions of the plate. Figure 3 shows how the plate deforms in shear for three combinations of half-wavelengths in two dimensions (Sykes, 1982, Fig. 6.5, p. 211). A low-order mode not shown in Fig. 3 has two half-wavelengths in the plate thickness direction. Lateral anharmonic modes are found on fundamental and overtone resonance and antiresonance mode branches.

2.1.3 Infinite Length, Width, and Radius, with Finite Electrode Dimensions: Partially Electroded When finite-area

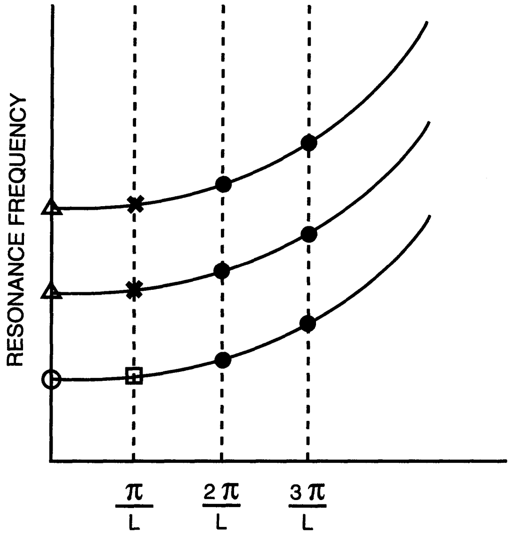

FIG. 2. Thickness-mode resonance frequencies in plates with infinite width. Open circles, fundamental thickness-mode frequency (infinite length). Triangles, overtone thickness-mode frequencies (infinite length). Squares, fundamental thickness-mode frequency (finite length). Crosses, overtone thickness-mode frequencies (finite length). Solid circles, two lowest anharmonic mode frequencies of thickness fundamental modes and overtone modes (finite length).

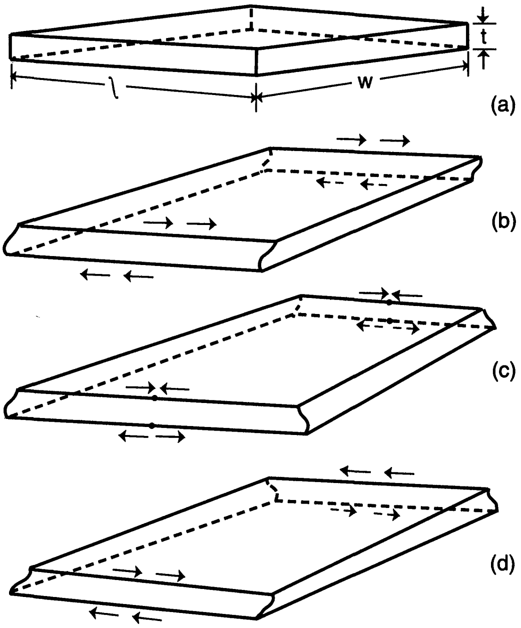

FIG. 3. Thickness-shear motion of plates: (a) undeformed plate, (b) fundamental thickness mode, (c) lowest-frequency length anharmonic thickness mode, (d) lowest-frequency width anharmonic thickness mode. From Sykes (1982); reproduced by permission of Van Nostrand Reinhold Company.

electrodes are placed on a plate or disk with infinite lateral dimensions, the mechanical motion depends on the frequency lowering of the electroded region relative to the unelectroded region (the relative frequency lowering is called plateback) and on the lateral electrode dimensions. The frequency lowering depends on the electrode mass and on the external electrical elements connecting the electrodes (open or short circuited, etc.). Electrodes with a given plateback and with lateral dimensions larger than a critical value (different for fundamental and each overtone) excite mechanical displacement components under the electroded area that are similar to those shown in Fig. 1, except that the motion amplitude will not be uniform across the electroded region. The motion amplitude in the unelectroded regions of the plate decays exponentially with distance away from the edges of the electrodes. This situation is called energy trapping (Holland and EerNisse, 1969, Chap. 5, pp. 179–244; Spencer, 1972; Smythe, 1985). For anharmonics of fundamental thickness modes and for electrode lateral dimensions smaller than the critical value, the entire plate has mechanical displacement components similar to those shown in Fig. 1. In this case, the motion amplitude is more uniform everywhere in the plate than the motion amplitude for the completely energy-trapped case. Trapped-energy thickness-mode resonators have higher quality factors and unwanted modes with reduced amplitudes (Meeker, 1985).

When partially electroded plates or disks have finite lateral dimensions, the mechanical motion is not completely trapped in the region of the electrodes and becomes a sinusoid with decaying amplitude in the unelectroded region of the plate. Resonance and antiresonance frequencies and the extent of the trapping depend on the lateral dimensions of the electrode and plate or disk, as well as on the electrode mass (Spencer, 1972).

These effects of lateral boundaries (edges of plate or electrodes) on the solutions for the piezoelectric resonator can be understood in terms of waves propagating in the plane of piezoelectric plates (Lee and Syngellakis, 1975; Wagers, 1977). Important basic concepts can be obtained from the theory of mechanical wave propagation in the plane of elastic plates (Meeker and Meitzler, 1964).

Important and widely used theories of elastic and piezoelectric plates and electrodes with both length and width finite have been developed (Tiersten, 1969). Coupling between the thickness and contour (flexure, extension, face shear) modes of the plate is included in some of these theories. These approximations have had considerable success in providing an understanding of lateral boundary conditions on the properties of piezoelectric resonators (Meeker, 1985).

2.1.4 Thickness-Mode Resonators Using Contoured Plates Properly designed finite electrodes offer one way of confining the vibrational motion of a thickness-mode resonator to a desired region of the plate. Another way of confining the motion is to make the plate thicker in the desired region of the plate (usually the central region). Resonators with very high quality factor and reduced undesired modes can be made by properly contouring the plate in this way. Many references to the desirable properties of contoured thickness mode resonators can be found in the literature (*Proceedings of the*

Annual Symposium on Frequency Control). Further discussion of the properties of contoured thickness mode resonators is beyond the scope of this article.

2.2 Contour Modes in Bars, Cylinders, Plates, and Disks

In this section, some of the characteristics of modes in plates, bars, disks, and cylinders with resonance frequencies that depend mostly on length, width, and radius are reviewed. For rectangular plates, a wave-number–type approximate theory that couples thickness, extension, flexure, and face-shear modes has been published (Meeker, 1985).

2.2.1 Extension in Bars and Cylinders

For length extension in bars or cylinders, the word "longitudinal" is sometimes used in place of the word "extensional." Bars with small enough width and thickness and cylinders with small enough radii have modes with resonance frequencies that depend mostly on the length dimension. The associated wave motions are one dimensional but not plane. Electric field excitation along the length or along one of the lateral dimensions can be used. Excitation along diameters of cylinders requires special electrode geometries (Meeker, 1985). Figure 4 shows the mechanical displacement components associated with extensional modes. An infinite number of resonance frequencies are associated with mechanical displacement component phase reversals along the length. Figure 5 shows how bars with two free ends deform for the fundamental length mode and the next two overtone length modes (Sykes, 1982, Fig. 6.3, p. 208).

The mechanical motion has components parallel and perpendicular to the length direction. A neutral surface separates regions with oppositely directed motions perpendicular to the length direction. Motion components parallel to the length direction are in the same direction on both sides of the neutral surface. Both the cross section (rectangular, circular, elliptical, etc.) and the lateral dimensions (length, width, diameter, etc.) have a small effect on the resonance frequency. The effect of the shape of the cross section is usually small; the effects of lateral dimensions increase with increasing lateral dimensions as bars or cylinders become plates or disks (Holland and EerNisse, 1969, Chap. 3, pp. 96–124; Chap. 4, pp. 125–178). These modes can be excited by electric fields along the directions of the length, width, radius, and thickness.

Many characteristics of these resonators depend on the direction of the electric field excitation (Berlincourt *et al.*, 1964; Meeker, 1985). For thickness electric fields, this is the desired mode in the quartz *E* resonator and

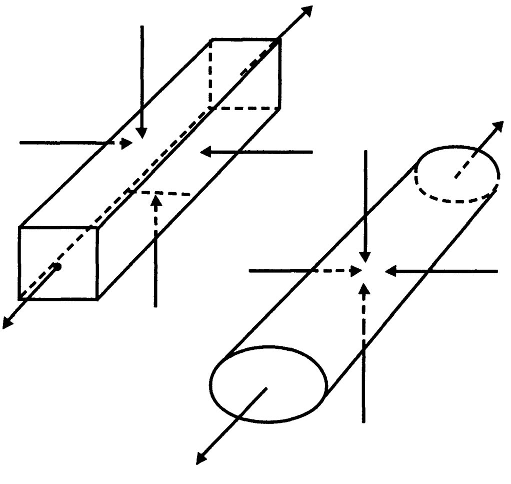

FIG. 4. Mechanical displacement components for fundamental extensional mode in bars and cylinders.

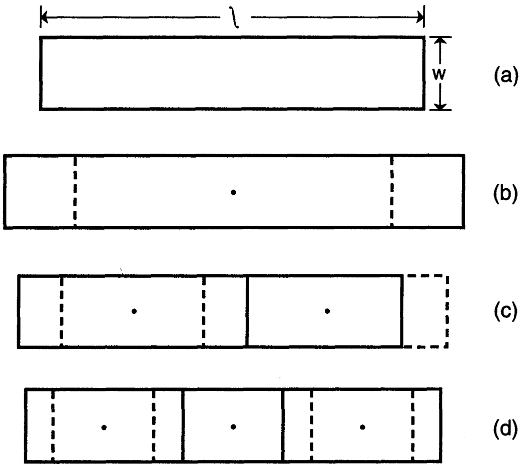

FIG. 5. Extensional deformations for three lowest-frequency modes of a bar with stress-free ends: (a) undeformed bar, (b) fundamental mode, (c) first overtone mode, (d) second overtone mode. From Sykes (1982); reproduced by permission of Van Nostrand Reinhold Company.

the −18°-rotated *X*-cut quartz resonator (Sykes, 1982, pp. 211–214).

2.2.2 Extension in Plates and Disks

The word "longitudinal" is sometimes used in place of the phrase "plate extensional." The mechanical motion is an extension in the direction of one lateral dimension accompanied by a contraction in the direction of the other lateral direction. Bars and cylinders with larger lateral dimensions have mechanical displacement components along the two lateral dimensions (Sykes, 1982, pp. 214–219). Phase reversals of mechanical displacement components along both lateral directions are associated with mechanical motions identified by three numbers. For the cylinder the three numbers denote the number of phase reversals along length, radius, and a rotation angle in a plane perpendicular to the length axis. A review of the wave motions for isotropic plates and cylinders with infinite lateral dimensions (Meeker and Meitzler, 1964) shows the detailed mechanical displacement components for four independent mode types called longitudinal, flexural, symmetric shear, and antisymmetric shear. For longitudinal and flexural modes, the mechanical displacement components lie in a sagittal plane defined by the propagation direction and the normal to the plate surfaces. The two shears have mechanical displacement components in the plane of the plate. For cylinders, the four mode types are longitudinal, flexural, symmetric torsion, and antisymmetric torsion. For piezoelectric plates, the four types of waves are similar to those in the isotropic plate for some materials and for some propagation directions. In the general case, the four simple motion types are not independent, and the actual motion can be considered to have contributions from each of the four simpler types.

Longitudinal modes in isotropic plates have mechanical displacement components in the sagittal plane, as shown in Fig. 6. When the shear modes contribute to the actual motion, the mechanical motion is not planar. Higher-order longitudinal modes can be named with three numbers denoting the approximate number of phase reversals of mechanical displacement along all three coordinate directions. For isotropic cylinders, families of longitudinal modes are characterized by phase reversals of mechanical displacement along the length, radius, and a rotation in the plane normal to the length axis.

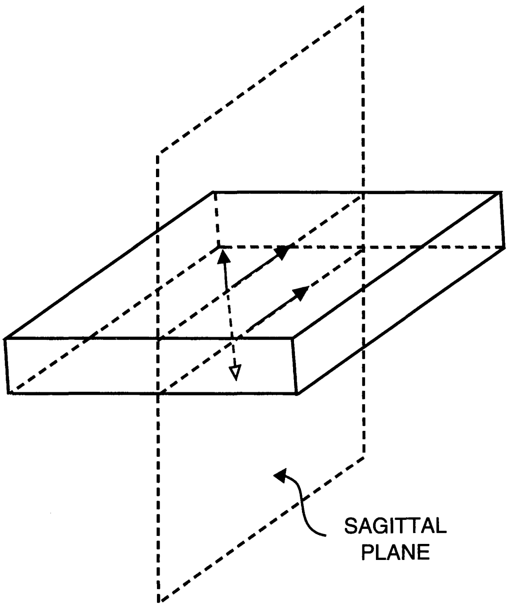

FIG. 6. Mechanical displacement components for longitudinal modes in isotropic plates.

For nearly square plates, coupled two-dimensional extension is the mechanical motion of quartz *GT* elements, for which lengths and widths can be adjusted to give a very small dependence of resonance frequency over a wide range of temperatures (Sykes, 1982, pp. 211–214). Extension is the desired mode in the *X*-cut rotated quartz *MT* element (Sykes, 1982, pp. 211–214). Extension in a plate with circular lateral shape is called a radial mode (Berlincourt *et al.*, 1964).

2.2.3 Flexure in Bars and Cylinders

Flexural mechanical displacement components produce a rotation of the cross section of the bar or cylinder length direction about an axis that is perpendicular to the length direction, as shown in Fig. 7. The resulting bending of the bar or cylinder is accompanied by an expansion on one side of the neutral surface and a contraction on the other. Figure 8 shows deformations for the three low-order flexural modes of a bar with two free ends (Sykes, 1982, Fig. 6.1, p. 206). Because of the antisymmetry, these modes must be excited by specially placed electrodes, by using a composite material, or by

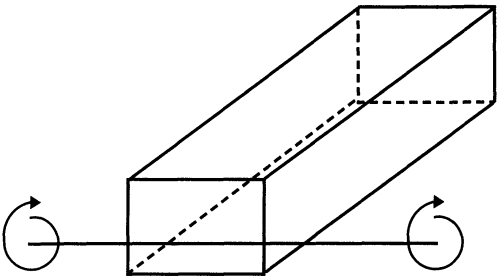

FIG. 7. Flexural deformations in bars.

modifying the material (viz., in ceramics, using inhomogeneous polarization) to provide the necessary asymmetry to couple the motion to the electric field. The quartz *J* element uses a thickness-excited composite quartz material (two extensional bars glued together so that one bar expands and the other contracts with the same direction of electric field). Examples using special electrode distributions to excite these modes are the +5° *X*-cut and the rotated quartz *NT* element (Sykes, 1982, pp. 211–214; Meeker, 1985).

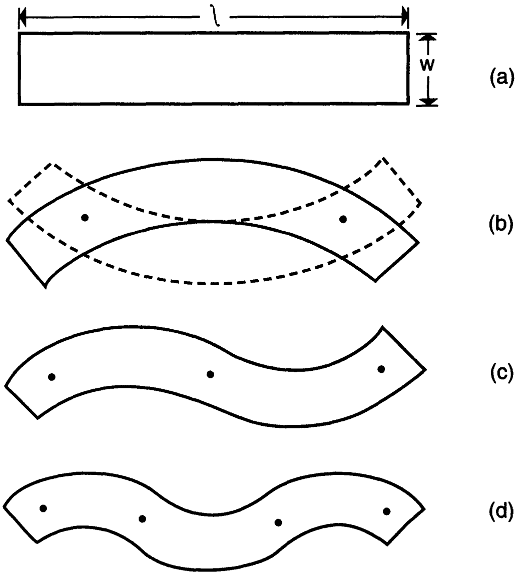

FIG. 8. Flexural deformations for the three lowest frequency modes of a bar with stress-free ends: (a) undeformed bar, (b) fundamental mode, (c) first overtone mode, (d) second overtone mode. From Sykes (1982); reproduced by permission of Van Nostrand Reinhold Company.

2.2.4 Flexure in Plates and Disks For isotropic plates, mechanical displacement components lie in the sagittal plane, as shown in Fig. 9. The mechanical motion has components parallel to and perpendicular to the length direction. A neutral surface separates regions with parallel motion components in opposite directions. Perpendicular motion components are in the same direction on both sides of the neutral surface. Figure 10 shows deformations of a flexural plate with four free edges (Sykes, 1982, Fig. 6.2, p. 207). The mechanical motion is in the direction of the plate length, width, or radius. A small thickness motion, antisymmetric about the width-length plane, accompanies the motion (Sykes, 1982, pp. 214–219). The motion is a twist of a cross section about an axis in the plane of the plate and normal to the direction of the plate length, width, or radius. This is the desired mode in the *X*-cut rotated quartz *NT* element (Sykes, 1982, pp. 211–214).

2.2.5 Face Shear in Plates Two-dimensional motions of thin face-shear plates with different numbers of phase reversals along the length and width directions are shown in Fig. 11 (Sykes, 1982, Fig. 6.4, p. 210). The mechanical motion is a shear in

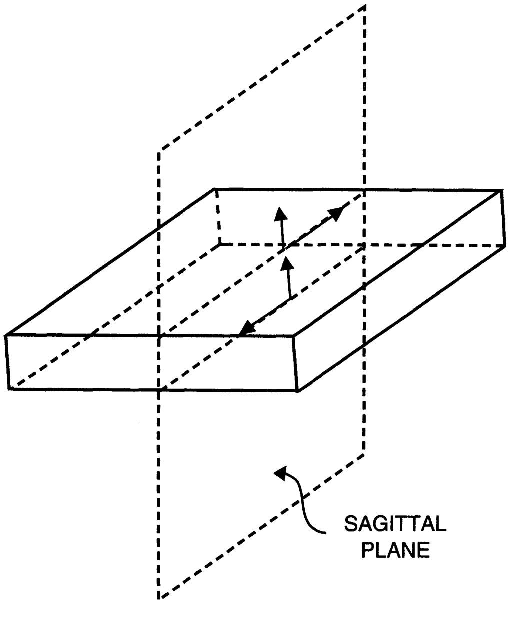

FIG. 9. Mechanical displacement components for flexural modes in isotropic bars and plates.

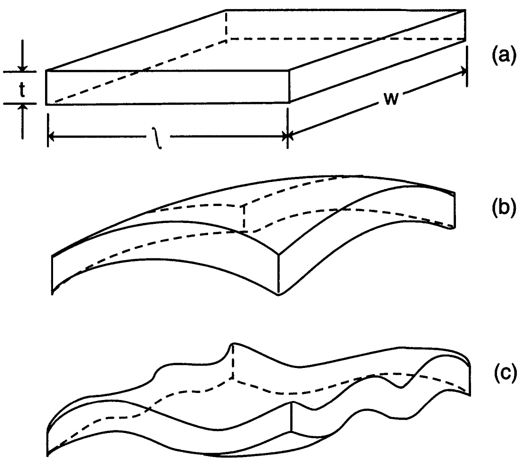

FIG. 10. Deformations for two flexural modes of a plate with four stress-free edges. (a) Undeformed plate, (b) fundamental plate mode with no phase reversals along length or width, (c) overtone plate mode with one phase reversal along the length and three phase reversals along the width. From Sykes (1982); reproduced by permission of Van Nostrand Reinhold Company.

the plane determined by the directions of the length, width, or radius of the plate. Face-shear modes can be excited by electric fields in the direction of one of the lateral dimensions or the thickness (Meeker, 1985). For thickness excitation, this is the desired mode in the quartz *CT* and *DT* resonators (Sykes, 1982, pp. 214–219). The corresponding mode in circular disks is a torsion (Sec. 2.3.2).

2.3 Torsional Modes

2.3.1 Torsion in Bars and Cylinders

The only mechanical displacement component is a twist around the length axis in a plane normal to the length axis, as shown in Fig. 12. For simple torsion, phase reversals along the length characterize an infinite number of modes. For higher-order modes and larger lateral dimensions, mechanical displacement components have phase reversals along the length and radius (Mason, 1964a, Chap. 6, pp. 78–113; Meeker and Meitzler, 1964; Timoshenko *et al.*, 1974; Meeker, 1985). The bar cross section can be circular, elliptical, or rectangular.

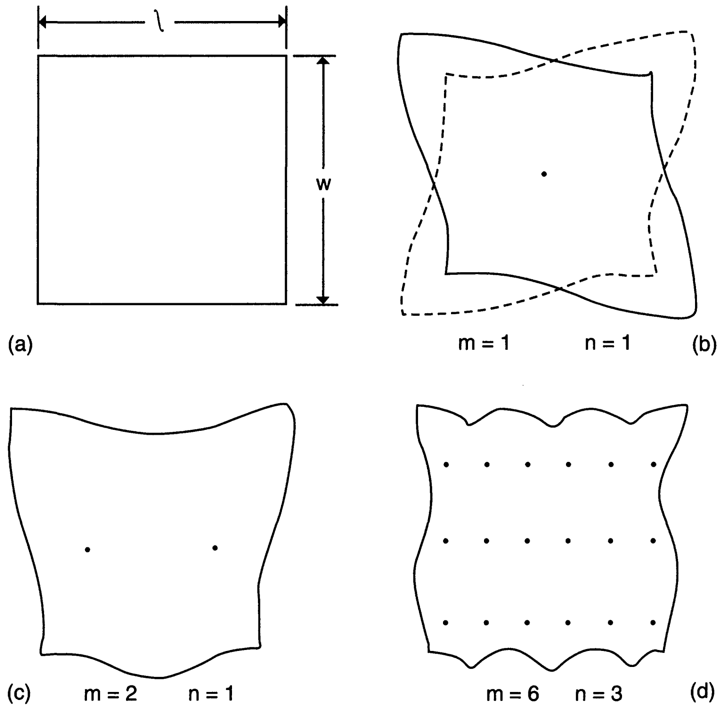

FIG. 11. Face-shear deformations in a plate: (a) undeformed plate, (b) fundamental plate mode with one phase reversal along the length and one phase reversal along the width, (c) overtone plate mode with two phase reversals along the length and one phase reversal along the width, (d) overtone plate mode with three phase reversals along the width and six phase reversals along the length. From Sykes (1982); reproduced by permission of Van Nostrand Reinhold Company.

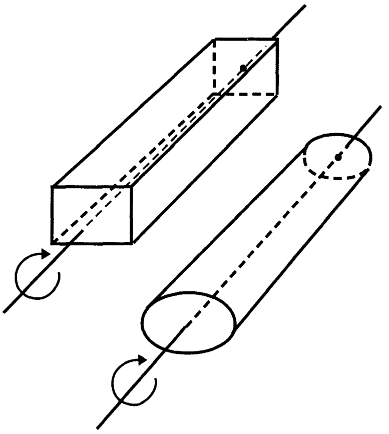

FIG. 12. Torsional motions in bars and cylinders.

2.3.2 Torsion in Disks Thickness torsion is a circular shear or twist in the plane of the plate, which is normal to the direction of the plate thickness. The plate lateral shape can be circular, elliptical, rectangular, etc. This mode corresponds to plate face shear in plates. Phase reversals of mechanical displacement along the thickness direction define overtone modes. Phase reversals of mechanical displacement along the radius and in rotation angle produce circular deformations similar to those shown in Fig. 11 for plates.

3. BULK ACOUSTIC-WAVE RESONATORS

3.1 Quartz-Crystal Resonators

As practical examples of the properties of resonators using the modes discussed in Sec. 2, several properties of quartz resonators have been tabulated (Meeker, 1985). Many piezoelectric crystalline quartz resonators have had a short name (usually one or two letters) assigned to designate the mode. These names, orientations of the resonator in the quartz crystalline lattice, modes of vibration, and useful resonance frequency ranges are shown in Table 1. Table 2 shows the approximate dependence of resonance frequency, series motional capacitance, and series motional inductance on the dimensions of quartz resonators. Also shown in Table 2 are ratios of capacitances (clamped dielectric capacitance to motional capacitance) and series motional resistances. The ratios of capacitances, series motional capacitances, series motional inductances, and series motional resistances refer to electrical elements of the simple lumped-element equivalent circuit for the various resonator types. This simple electrical equivalent circuit is shown in Fig. 13. Equivalent electrical circuits are described in Sec. 6. For quartz-crystal resonators, Figs. 14 and 15 show the dependence of resonance frequency on mode type and temperature. Resonator orientations in the right-hand alpha-quartz crystal lattice are shown for several types of quartz resonator modes in Fig. 16.

3.2 Resonators Using Other Materials (Ceramics, Crystals, Films)

Piezoelectric ceramics and crystals are selected for use in resonators for reasons of cost and performance. Ceramics and some crystals have high piezoelectric coupling factors that are useful in resonators for wide-bandwidth or low-impedance filters. Al-

though piezoelectric films are flexible and not likely to break during processing into high-frequency resonators, most of the reported work involves transducer applications (Meeker, 1988). Examples of ceramic materials are lead zirconate titanate and lead titanate (Fujishima *et al.*, 1984). Examples of crystal materials are lithium tantalate, lithium niobate, and berlinite (Sheahan and Johnson, 1977; Smythe, 1985). Studies on many other useful ceramic and crystal materials have been reported (Meeker, 1985).

4. COMPOSITE ELECTROMECHANICAL RESONATORS

For many applications, it is desirable to make resonators from nonpiezoelectric materials such as glasses or metals, which can be excited by piezoelectric transducers attached to a particular place on the resonator body. The thickness asymmetry required to excite flexural-mode resonators can be achieved by fastening two properly oriented plates of piezoelectric material together. Some applications of composite electromechanical resonators are discussed in Sec. 8. Proprietary iron–nickel alloys with small amounts of other metals, such as chromium or molybdenum, can have compositions adjusted to give a low-temperature coefficient of resonance frequency and a sufficiently low dissipation for particular modes of interest (Sheahan and Johnson, 1977). Film transducers have potential applications as composite resonators (Linville, 1988; Meeker, 1988).

5. SURFACE ACOUSTIC-WAVE RESONATOR MODES ON PLATES

The theory for a single-surface semi-infinite half-space is useful for the practical case of a plate that is many wavelengths thick. When the propagation direction of the assumed mechanical wave motion is parallel to a stress-free surface, solutions to the equations of Sec. 1.1 have been found for several different cases. Depending on the direction of the mechanical displacement and the orientation and nature of the surface, two different types of surface wave motion can be identified. Rayleigh and Gulyaev–Bleustein Waves are discussed in Secs. 5.1 and 5.2.

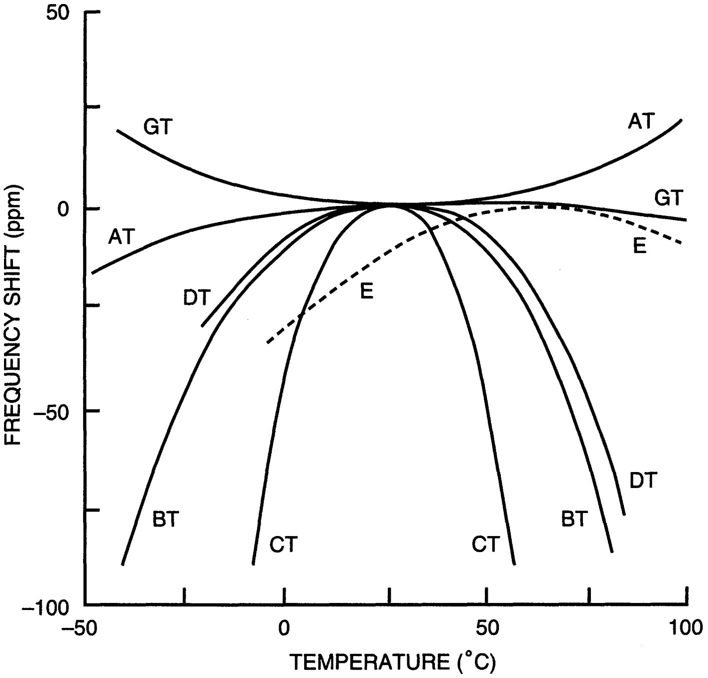

FIG. 14. Dependence of resonance frequency on temperature for quartz-resonator types *GT*, *AT*, *E*, *DT*, *CT*, and *BT*. From Meeker (1985); reproduced by permission of Academic Press.

5.1 Rayleigh Waves

For isotropic elastic materials, Rayleigh surface waves (Meeker and Meitzler, 1964) have mechanical displacements entirely in the sagittal plane that contains the directions of the wave propagation and the normal to the surface. The mechanical displacement has components along the directions of the propagation and the normal to the surface. There is no coupling to modes with displacement components normal to the sagittal plane. The wave motion has a propagation vector with a real component in the propagation direction and an imaginary component in the plate normal direction. The surface-wave mechanical displacement amplitude decays exponentially away from the surface. The imaginary wave number along the direction perpendicular to the surface means that no acoustic energy is propagated into the elastic medium; the major

portion of the mechanical energy of the surface wave is within a few wavelengths of the surface.

For anisotropic piezoelectric materials, the existence and velocity of the mechanical surface wave depends on the orientations of the surface in the crystal lattice, on the propagation direction in the plane of the surface, and on the mechanical and electrical boundary conditions at the surface. The electrical boundary conditions can involve a relationship between the electric displacement and the electric potential at the surface. Furthermore, transverse surface or bulk modes may be coupled to the Rayleigh wave motions. The coupling to the transverse modes may also depend on the orientations of the surface and the wave propagation in the crystal lattice and on the mechanical and electric boundary conditions on the surface (Farnell, 1970).

5.2 Gulyaev–Bleustein Waves

Transverse or shear-type surface acoustic waves cannot exist alone for a piezoelectric medium unless a layer of material with a lower shear wave velocity is placed on the surface. This lower-velocity layer produces the required condition for the existence of

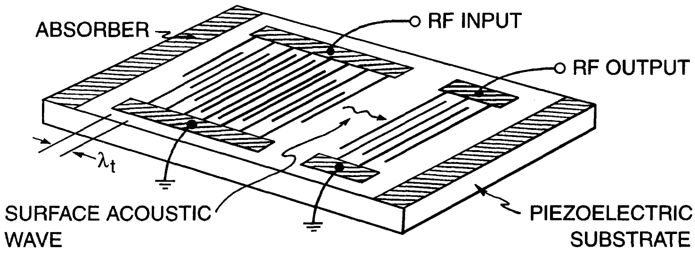

FIG. 17. Schematic of a surface acoustic wave filter with two interdigital transducers. From Shreve and Cross (1985); reproduced by permission of Academic Press.

exponential decay of the transverse wave motion along the direction of the surface normal. The mechanical displacements are in the direction of the plane of the surface and normal to the propagation direction (Farnell and Adler, 1972).

5.3 Devices

Surface acoustic-wave devices became much more useful when the interdigital transducer and reflector were invented (White, 1970; Shreve and Cross, 1985, Chap. 2.3, pp. 119–145; Wagers, 1985). The interdigital transducer has alternate electrodes spaced one half-wavelength apart and driven 180° out of electrical phase. The interdigital transducer can be made of metal deposited on the surface or in grooves etched into the surface. The interdigital reflector can be made of metal strips or other material deposited on the surface or in grooves in the surface; empty grooves can also be used. These elements preserve the planar advantages of surface-wave devices and allow the design and implementation of transversal filters, resonators, and resonator filters. These filters and resonators have found uses in many different applications, which are discussed in Sec. 8.

Figure 17 shows two interdigital transducers used in a transversal filter with a bandwidth mostly determined by the reciprocal of the number of electrode elements. The position and length of the electrode elements can be changed to optimize the performance of the filter (Shreve and Cross, 1985, Chap. 2.3, pp. 119–145; Wagers, 1985). The transversal filter can also be used in oscillator applications. Figure 18 shows how a surface acoustic-wave resonator can be made by exciting the surface wave with a broadband interdigital transducer with a small number of electrode elements and by providing surface-wave reflectors on each side of the transducer to define a resonant cavity (Shreve and Cross, 1985, Fig. 2.3-2, p. 122). The reflectors can be carefully prepared plate edges, grooves, or metal (or other material) elements on the surface. Useful resonator *Q*'s can be attained with a large number (>1000) of reflectors. A two-port resonator can be made from two reflectors and two properly positioned interdigital transducers, each with a small number of elements. Many different electrode configurations have been reported as ways to optimize various performance criteria of the surface-wave device (Shreve and Cross, 1985, Chap. 2.3, pp. 119–145). These resonators can be used in oscillators and filters. Some applications of surface acoustic-wave devices are discussed in Sec. 8.

6. EQUIVALENT ELECTRICAL CIRCUITS

Impedance equations [such as Eq. (7) in Appendix A for the thickness-excited thickness-mode resonator] for the particular mode of interest can be represented approximately by a very useful and intuitive equiv-

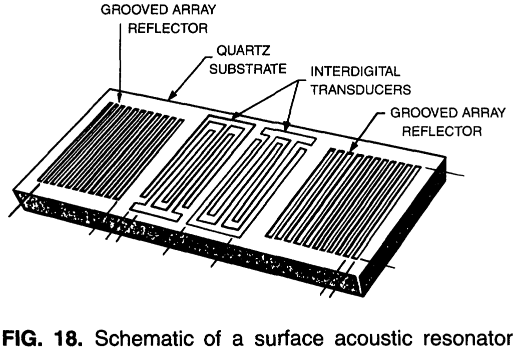

FIG. 18. Schematic of a surface acoustic resonator with two interdigital transducers and two grooved reflectors. From Shreve and Cross (1985); reproduced by permission of Academic Press.

alent electrical circuit with four physically realizable electrical elements (a capacitor in shunt with a series resonant circuit), as shown in Fig. 13 (Cady, 1964, Vol. 1, Chap. 14, pp. 333–383; Hafner, 1985, Chap. 7, pp. 1–44). An important advantage of this approximate equivalent circuit is its simplicity. For many applications, this representation is accurate enough for design purposes or even for final system analyses. This representation can be placed directly in most standard circuit-analysis computer programs, so that the circuit–resonator interfaces can be modeled conveniently. Most piezoelectric resonator specifications include a resonance frequency, an inductance, a ratio of capacitances, and a quality factor (Q) or a series resistance. These terms relate directly to the simple equivalent circuit and are readily understood by the circuit-design users of the piezoelectric resonator. For many applications, the advantages of expressing the characteristics of the piezoelectric resonator in terms of a small number of simple electrical elements far outweigh any disadvantages associated with the reduced accuracy of the representation. For some purposes, the simple equivalent circuit is not accurate enough, and exact equivalent circuits or physical electrical impedance relations must be used to represent resonator characteristics (Ballato, 1977, pp. 126–129; Meeker, 1985).

7. MATERIALS

The selection of a material for a piezoelectric resonator to be used in a particular application involves a number of complex and sometimes contradictory ways in which the material characteristics affect the performance of the resonator. For a given frequency, the size and shape of the desired resonator depend on the choice of resonance mode and on the associated material constants. The dependence of resonance frequency and other resonator characteristics on temperature, pressure, acceleration, drive level, time, etc. are controlled by the resonance mode, by the orientation of the resonator body in the crystal lattice, and by the dependence of the relevant elasto-piezo-dielectric material constants on the appropriate environmental variables. The mechanical and dielectric dissipations (Berlincourt *et al.*, 1964; Ballato, 1977, Chap. 5, pp. 115–181) and material nonlinearities vary considerably from material to material. Zeros in the elasto-piezo-dielectric matrix for a particular orientation of the resonator body in the crystal lattice depend on the choice of material and can be used to control the activity of particular unwanted mode resonances. For applications requiring very low dissipation and narrow bandwidth, quartz has been the material of choice because of the general resonator stability that can be achieved over temperature and time. Other applications, in which wide bandwidth and low resonator impedance are the most important resonator properties, use piezoelectric ceramics such as lead zirconate titanate (PZT) (Fujishima *et al.*, 1984). Other materials, such as berlinite, lithium niobate, and lithium tantalate have properties that lie between those of quartz and the ceramics (Meeker, 1985). Piezoelectric plastic film resonators have advantages for some applications (i.e., higher material linearity and mechanical flexibility), but the scope of applications has not been fully defined (Meeker, 1988). Composite electromechanical resonators (Sec. 4) can be made of metal with bonded piezoelectric transducers (Sheahan and Johnson, 1977) or deposited piezoelectric films. These resonators have been used in many commercial applications (Sec. 8). The material properties of deposited metal film electrodes, metal or glass enclosures or seals, and gases packaged with the device all affect the performance of the resonator or filter.

8. APPLICATIONS OF PIEZOELECTRIC RESONATORS

Table 3 gives some reasons for the popularity of piezoelectric resonators in certain applications. Some disadvantages of piezoelectric resonators are also shown in Table 3.

8.1 Piezoelectric Filters

A common method of designing a piezoelectric filter is to design an electric filter with inductors, capacitors, and resistors to meet the desired requirements. Lattice and ladder filter designs are often used (Mason, 1964b; Smythe, 1985). The lattice filter has the topology of a bridge and can be balanced

Table 3. Comparison of some characteristics of piezoelectric and electrical (inductance–capacitance) resonators.

	Piezoelectric	Electrical
Electromagnetic radiation and absorption	Smaller	Larger
Temperature coefficient of frequency	Smaller	Larger
Time drift and aging	Smaller	Larger
Resonance frequencies	Many	One
Antiresonance frequencies	Many	None
Unwanted resonance modes	Many	None
Useful frequencies	Higher	Lower

for stop-band attenuation (reflection) and unbalanced for pass-band transmission. Ladder filters have circuit sections in series; more circuit sections provide greater stop-band attenuation. In the next four sections, discrete crystal filters, monolithic crystal filters, electromechanical filters, and surface acoustic-wave filters are discussed.

8.1.1 Discrete Crystal Filters After a suitable electric filter is designed, piezoelectric resonators are substituted for the electric resonators formed from the appropriate inductor–capacitor combinations. The resonator couplings are left in electrical form. This kind of filter is called a discrete crystal filter, since the resonant elements of the filter are discrete crystal resonators. The piezoelectric resonator is equivalent to an inductor–capacitor electrical resonator over a narrow range of frequencies. The frequency difference between resonance and antiresonance frequencies of the piezoelectric resonator restricts the bandwidth of simple piezoelectric discrete crystal filters. Electrical inductances can be used in parallel with the piezoelectric resonator to widen the useful electrical bandwidth of the filter, especially at lower frequencies. For smaller electrical bandwidths at higher frequencies, the quality factor of the piezoelectric resonator can be much higher than the quality factor of the inductor–capacitor electrical resonator. Higher-frequency discrete crystal filters can have lower midband insertion losses than filters using discrete electrical components. The filter can be called a discrete crystal filter, a discrete ceramic filter, a discrete composite filter, or a discrete film filter, depending on the type of resonator used. Both lattice and ladder discrete-component piezoelectric filters have been widely used in numerous applications for many years (Smythe, 1985). These applications include voice channel and signaling filters in analog communication systems and intermediate-frequency filters for radio and television.

Filters that contain at least one coupled resonator pair on a piezoelectric plate and have no electrical coupling elements are called monolithic crystal filters because popular examples use crystal plates. Monolithic crystal filters are discussed in Sec. 8.1.2.

8.1.2 Monolithic Crystal Filters When two or more trapped-energy (Sec. 2.1.3 for thickness shear) piezoelectric resonators occupy the same piece of piezoelectric material and the resonator coupling is a mechanical interaction between the resonators, the filter is called a monolithic crystal filter. A popular type of monolithic crystal filter uses more than one mechanically coupled monolithic crystal filter section with electrical coupling between the sections. Sometimes, parasitic electrical elements between sections can be used to provide the electrical coupling required by the design (Spencer, 1972; Sheahan and Johnson, 1977; Smythe, 1985).

These filters have been used in voice channel and signaling in communication systems, as front-end filters for cellular and mobile radio, as intermediate filters for radio and television, and for clock-recovery filters for timing extraction in repeatered digital transmission systems (Sheahan and Johnson, 1977; Fujishima *et al.*, 1984; Smythe, 1985).

8.1.3 Electromechanical Filters Electromechanical filters are mechanical filters for which input and output resonators are electrically (electrostrictively or piezoelectrically) or magnetically coupled to the use system. Only piezoelectrically coupled electromechanical filters are considered in this article. Except for the input and output resonators, the interior resonators are usually mechanical resonators. The input and output resonators are often composite resonators made from mechanical resonators with an attached (cemented, deposited, etc.) piezoelectric film or transducer (Sec. 7). Resonators can be rods, bars, plates, disks, tuning forks, etc. Couplers can be wires, ribbons, bars, etc. Resonator and coupler modes can be flexure, torsion, extension, etc. Piezoelectric ceramic has usually been the material selected for the piezoelectric part of the composite input and output resonators.

Although other materials, such as glass, could be used for the resonators, metal seems to offer advantages of lower processing cost with adequate performance for most applications. Several useful reviews contain many details of design, manufacture, and application for these filters (Mason, 1964b; Sheahan and Johnson, 1977; Smythe, 1985). Other filters are mechanical filters with mechanical resonators and mechanical coupling.

8.1.4 Surface Acoustic-Wave Filters Reviews of several consumer communication applications discuss filters for radar pulse compression, television intermediate-frequency control, television video–audio signal separation, and mobile communication radio frequency control. Detailed design and performance evaluations are presented (White, 1970; Ruppel *et al.*, 1993).

8.2 Piezoelectric Crystal or Electromechanical Oscillators

A crystal or electromechanical oscillator is a closed-loop circuit that contains an amplifier and a crystal or electromechanical resonator (Cady, 1964, Vol. 2, Chap. 19, pp. 489–509). The frequency at which the total loop phase shift is an integral number of cycles is the oscillator frequency. At the oscillator frequency, the amplitude grows until the circuit nonlinearities reduce the total loop gain to unity. If the starting low-amplitude circuit gain is less than unity at the oscillator frequency, oscillation will not occur. Oscillation will not occur if the loop gain and phase requirements are not satisfied simultaneously. Usually, the loop gain and phase shift of the oscillator circuit are so sensitive that computer modeling of a simple oscillator circuit is not sufficient to arrive at a useable design (Frerking, 1978; Parzen and Ballato, 1983; Frerking, 1985; Smith, 1985), and some experimental adjustments are necessary.

Applications include clocks, computers, household appliances, analog and digital communications systems, radios, and televisions.

8.3 Piezoelectric Sensors

Many sensor applications use a piezoelectric resonator to convert some environmental change into a change of resonance frequency. Two very important advantages of using a piezoelectric-resonator sensor are the large frequency shifts associated with small changes in the resonator environment and the availability of very accurate frequency-measurement equipment at a reasonable cost. In some cases, hysteresis in the characteristic frequencies limits the applicability of the sensor. For all cases, the availability of relatively inexpensive microprocessors allows rapid and on-line calculations using the measurements and a display of the desired information.

Sensor applications (Walls and Gagnepain, 1985; EerNisse *et al.*, 1988) include temperature measurement, pressure measurement (Besson *et al.*, 1993), thin-film mass measurement, thin-film stress measurement, bulk mass measurement, gas or vapor identification and concentration measurement (Frye *et al.*, 1991; Watson *et al.*, 1991), acceleration measurement, force measurement, and measurement of liquid viscosity and liquid–solid phase transitions (Hoummady *et al.*, 1991).

APPENDIX A: THICKNESS-EXCITED THICKNESS MODES IN PLATES

A.1 Infinite Length and Width

The condition of infinite plate length and width is met by setting all derivatives in the differential equations (Sec. 1.1) with respect to the length and width directions equal to zero for all time and for all points in space. Trial plane-wave mechanical displacement solutions of the differential equations are expressed in terms of $\cos(\text{arg}^+)$, $\sin(\text{arg}^+)$, $\cos(\text{arg}^-)$, and $\sin(\text{arg}^-)$, where

$$\text{arg}^+ = \omega t - m_r x_r \quad \text{and} \quad \text{arg}^- = \omega t + m_r x_r,$$

with m_r as the wave number for the selected propagation direction x_r and ω the angular frequency. Substituting the trial wave solutions into the differential equations converts them into four algebraic equations.

The quasistatic approximations in Sec. 1.1

allow a separation of the four coupled algebraic equations into three coupled algebraic equations in the mechanical displacements and a fourth equation for the electric potential in terms of the same mechanical displacement components. The three coupled equations can be solved for the mechanical displacement components, which can then be used to calculate the electric potential from the fourth equation. The three coupled homogeneous algebraic equations have wave-type solutions when the determinant of the coefficients is zero. There are three values of wave velocity (the products $v_r^{(n)} \times v_r^{(n)}$ are the eigenvalues of the coefficient matrix) for which the determinant is zero. Associated with each of the three eigenvalues is an eigenvector, with a component along each of the coordinate axes. Normalized eigenvector components are $U_{qr}^{(n)}$. Each value of $v_r^{(n)}$ gives a linear dependence of the frequency on the associated wave number m_r. These linear relations between frequency and wave number are called dispersion relations.

The three eigenvectors are orthogonal and can be normalized. One of the eigenvectors has the largest component along the chosen propagation direction (quasidilatational), and the other two eigenvectors have largest components normal to the chosen propagation direction and to each other (quasishears). Of these two, the one with the smaller v_r can be called the slow quasishear, and the other can be called the fast quasishear. The four homogeneous equations are the same for trial solutions that are antisymmetric and symmetric in the plate thickness coordinate. The electrical equation can be integrated over x_r in terms of two integration constants.

The general solution is the sum of the six solutions (three antisymmetric and three symmetric) with arbitrary coefficients, along with the integral of the electrical equation. There are eight coefficients to be determined from the three zeros of T_{ir} and one ϕ on each of the two surfaces of the plate. Components of mechanical displacement, velocity, strain, and stress and of electric field, displacement, and current can be calculated directly from the general solution.

When the boundary conditions are either symmetric or antisymmetric, the symmetric solution set and the antisymmetric solution set are independent of each other and can be obtained separately. Furthermore, the solution set that has symmetric mechanical displacement components is not driven by the applied electric potential.

If the boundary conditions are neither symmetric nor antisymmetric, i.e., different layer mass per unit area on the two surfaces, then the symmetric and the antisymmetric solution sets are dependent and the symmetric solution modes are excited directly by a thickness electric field.

A.2 Electrical Impedance per Unit Area

For the resonator with zero thickness electrodes, the surface stresses are zero and the antisymmetric solution can be expressed as an electrical impedance as

$$Z = \frac{1}{jB_0}\left\{1 - \sum_n \left[2(k_r^{(n)})^2 \frac{T_h^{(n)}}{m_r^{(n)}H}\right]\right\}, \tag{7}$$

where n identifies the three eigensolutions, j is the imaginary number identifying the phase angle or reactive nature of the impedance, $B_0 = \omega C_0$ is the susceptance of the resonator when no mechanical motion is allowed (clamped), ω is the angular frequency,

$$C_0 = \frac{WL}{H}\epsilon_{rr}^S \tag{8}$$

is the clamped capacitance, W is the plate width, L is the plate length, H is the plate thickness,

$$m_r^{(n)} = \omega / v_r^{(n)}, \tag{9}$$

$$k_r^{(n)} = \frac{\sum_q U_{qr}^{(n)} e_{rqr}}{v_r^{(n)}[\rho\epsilon_{rr}^S]^{1/2}}, \tag{10}$$

and

$$T_h^{(n)} = \tan(0.5Hm_r^{(n)}). \tag{11}$$

At any given frequency, the impedance of Eq. (3) is defined by C_0, three $k_r^{(n)}$, and three $m_r^{(n)}$. This impedance has three sets of modes, each with a resonance frequency ($Z = 0$) and an antiresonance frequency ($Y = 1/Z = 0$). These three mode sets are one quasidilatational mode and two quasishear modes. For each set, there is a fundamental and an infinite number of thickness overtones. The separation between corresponding resonance and antiresonance frequencies depends on the associated $k_r^{(n)}$, which are called piezoelectric coupling factors.

A.3 Resonators with Loaded Surfaces

A.3.1 Frequency Shifts due to Electrical Loading The open-circuit (or high-driving-impedance or small-electrical-current) resonance frequency is nearly equal to the antiresonance frequency. The short-circuit (or low-driving-impedance or small-electrical-voltage) resonance frequency is nearly equal to the resonance frequency.

A.3.2 Frequency Shifts due to Mass Loading The mechanical loading of two electrode layers that are thin enough can be represented by a mass per unit area. For this case, the effect of the electrode mass is to change $[k_r^{(n)}]^2$ in Eq. (7) to

$$\frac{[k_r^{(n)}]^2}{1 - (\rho_e H_e/\rho \mathrm{H}) \times 0.5 H m_r^{(n)} T_h^{(n)}}, \tag{12}$$

where ρ_e is the density of the electrode material and H_e is the combined thickness of the two electrode layers. For small H_e, both resonance and antiresonance frequencies are shifted downward (Ballato, 1977, pp. 126–129).

A.3.3 Frequency Shifts due to Nonuniform Mechanical Motion Thickness-mode resonance frequencies and piezoelectric coupling depend on the uniformity of the spatial distribution of mechanical motion. Antiresonance frequencies do not depend on the uniformity of mechanical motion. This means that the effects of nonuniform distribution of mechanical motion can be incorporated into the theory by multiplying the coupling {$[k_r^{(n)}]^2$ in Eqs. (7) and (10)} by a factor that depends on the spatial distribution of mechanical motion (Kosinski *et al.*, 1993).

GLOSSARY

Antiresonance Frequency: The high-impedance frequency of zero reactance.

Discrete Crystal Filters: Filters with discrete crystal resonators for resonant elements.

Electrical Differential Equations: $D_{i,i} = 0$, where D_i are the three components of the electrical displacement.

Ladder Filters: Filters with sections in series; more sections provide greater stop-band attenuation.

Lattice Filters: Filters with the topology of a bridge that can be balanced for stop-band attenuation (reflection) and unbalanced for pass-band transmission.

Linear Constitutive Equations: $T_{kl} = c_{klmn}^E S_{mn} - e_{mkl} E_m$ and $D_j = e_{jkl} S_{kl} - \epsilon_{jk}^S E_k$, where $S_{ij} = 0.5(u_{ij} + u_{j,i})$ are the nine components of the mechanical strain; $E_k = -\phi_{,k}$ are the three components of the electric field, with ϕ the electric potential; c_{klmn}^E are the 81 components of the stiffness at constant E; e_{jkl} are the 27 components of the piezoelectric constant; ϵ_j^S are the 9 components of the dielectric permittivity at constant S; and ω is the angular frequency, equal to $2\pi \times$ frequency.

Piezoelectric Effect: Direct: Electric displacement produced by mechanical strain. Converse: Mechanical strain produced by electric displacement.

Resonance Frequency: The low-impedance frequency of zero reactance.

Stress Differential Equations: The equations $T_{ij,t} + f_j = \rho u_{j,tt}$, where T_{ij} are the nine components of mechanical stress, f_j are the three components of the body force, ρ is the material density, and u_j are the three components of the mechanical displacement.

INTRODUCTION

A plasma is an electrically energized gas that consists of electrons, ions, neutral atoms, molecules, and molecular fragments. Etching is selective removal of material from a surface by chemical reactions and/or physical sputtering. Plasma etching is a process wherein chemically reactive species and ions produced in a gas discharge (plasma) are used to remove selectively a film from a substrate or portions of such a film or substrate. Plasma etching has also come to be known as dry etching because the chemically reactive medium is a gas instead of a liquid such as an acid or a base solution. Plasma etching is widely used in manufacturing of electronic and optoelectronic devices and integrated

circuits, which are made layer by layer through patterning of thin films on the surface of a semiconductor substrate such as a Si or a GaAs wafer (Manos and Flamm, 1989; Gottscho, 1993).

A plasma (or gas discharge) is obtained by applying an electromagnetic field to a volume of gas under vacuum. Although extremely high temperatures and gases at atmospheric pressure can be used to produce a plasma, these methods do not find applications in plasma etching. Electrons in the plasma are accelerated by an electric field induced by the electromagnetic excitation and gain energy from the applied field. These energetic electrons collide with the neutral-gas species and dissociate them into reactive radicals and molecular fragments. Plasma etching makes use of the chemical reactivity of the various molecular fragments produced in the plasma combined with energetic action of the electrons and the ions to etch various materials. This combined action of charged particles and reactive neutral species provides the means to etch very small features on thin films and enables the integrated-circuit (IC) manufacturers to pack more solid-state electronic devices into smaller areas. This article is intended to provide an overview of plasma etching and to serve as an introduction to the field, as well as a reference to some more advanced topics.

1. PLASMAS AND PLASMA ETCHING

1.1 Reasons for Plasma Etching and Applications

Plasma etching is used mainly for two purposes:

1. to transfer a pattern from a mask into an underlying layer of material by selectively removing the unmasked portions of that layer, and
2. to remove a layer completely from on top of a substrate.

The use and advantages of plasma etching in patterning thin films are illustrated in Fig. 1, which shows a schematic of a film to be etched on top of a substrate. The film is unmasked in places where it is to be removed. A mask is a material that is chemically and physically resistant to the etchant in order to protect the desired parts of the film. Common mask materials include polymers (photoresist), oxides (e.g., SiO_2), nitrides (Si_3N_4), and metals. The unmasked part of the film can be removed by exposing the surface to a chemically reactive medium such as an acid solution or a plasma. Wet etching (i.e., removal of the film by using an acidic solution) and plasma etching are the two major techniques to transfer the pattern defined by the mask to the underlying film. At present, plasma etching is the method of choice for etching thin films of electronic materials in the microelectronics industry.

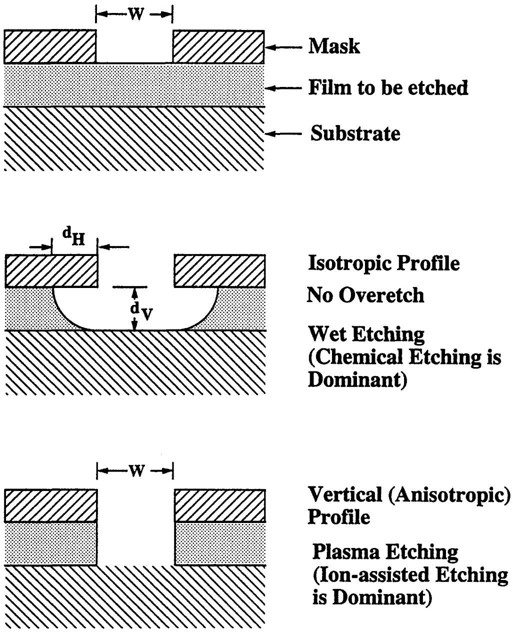

FIG. 1. (a) Cross section of film to be etched, with mask. (b) Cross section of film etched using wet etching, showing the profile resulting from etching rates equal in vertical and horizontal directions. (c) Cross section of film etched using plasma etching, for which the etch rate in the horizontal direction is negligible compared with the rate in the vertical direction.

One of the major reasons for preferring plasma (dry) etching over wet etching is depicted in Figs. 1(b) and 1(c), which compare the resulting patterns in the films when wet and plasma etching techniques are used, respectively. When wet etching techniques are used, the etching reactions proceed at equal rates in vertical and horizontal directions and the profile shown in Fig. 1(b) results.

Since the film is removed isotropically (i.e., independent of direction), the resulting profile has the characteristic quarter-circle shape. Isotropic etching in this manner results in an etched feature that is larger than the original feature in the mask. This undesirable and unintentional enlargement of the original feature size in transferring the pattern from the mask to the underlying film is called linewidth loss. The horizontal ingression as a result of etching under the mask is called mask undercutting. In order to pack more or smaller features in same area, linewidth loss or undercutting should be minimized. In fact, in order to replicate the mask pattern onto the film exactly and to reduce linewidth loss, the etch profile depicted in Fig. 1(c) is desired. The etched feature in Fig. 1(c) has straight vertical sidewalls and is the preferred profile in microelectronics manufacturing.

The etch profile shown in Fig. 1(c) can be obtained when the etch rate in the horizontal direction is zero or negligible compared to the etch rate in the vertical direction. Using a plasma provides the means to enhance the etch rate in the vertical direction relative to the etch rate in the horizontal direction thereby enabling one to obtain etch profiles like the one shown in Fig. 1(c). This type of etch profile is called an anisotropic etch profile and the etching method that produces such profiles is called anisotropic etching. The directionality in etching arises from anisotropic transport of ions from the plasma to the wafer surface. The reasons behind directional ion transport from the plasma to the surface are discussed later. Plasma etching has become the dominant technique for patterning thin films in microelectronics manufacturing because of its ability to etch anisotropically in a dry environment. This ability enables the integrated-circuit manufacturers to pack more solid-state devices such as memory elements into smaller areas, which reduces the unit production cost and increases processor speeds and memory capacity.

1.2 History of Plasma Etching

Glow discharges and reactions in plasmas have been studied for many years. It is difficult to pinpoint the first use of plasmas for etching. However, credit is generally given to Irving (1968), who suggested that an oxygen plasma can be used to remove photoresist films that are used as masks in production of microelectronic devices. Shortly thereafter fluorine-containing plasmas were used to etch silicon films (Coburn and Winters, 1983). Positive results from these experiments combined with the advantages of plasma etching over wet chemical etching methods stimulated the commercialization of plasma etching reactors. As of the early 1990s, 30% of the integrated-circuit manufacturing equipment had become plasma based (Proud and Gottscho, 1991).

Advances in the IC manufacturing technology are a direct result of advances in plasma etching technology. Features with sizes (e.g., the width W of the trench shown in Fig. 1) 5–10 μm could be etched during the initial years of development. It is now possible to etch 0.5–1-μm size features routinely with plasmas, and the goal is to reduce this dimension below 0.25 μm by the turn of the century. The submicron electronic device fabrication was made possible by plasma etching. Plasma etching played and continues to play an important role in the electronics and communication revolution.

1.3 Plasma Physics and Chemistry

A plasma is a partially ionized gas produced by applying an electric field to a volume of gas at low pressure (10^{-4}–100 Torr). Thus, it is composed of electrons, ions, and a variety of neutral species. Plasmas used for thin-film etching are low-pressure glow discharges excited usually by radio-frequency (0.1–100 MHz) or microwave fields (usually 2.45 GHz). The gas pressure and temperature in typical plasma etching reactors range from 10^{-4} to 10 Torr and 300 to 500 K, respectively. Although temperatures as high as 800 K have been reported, plasma etching is not a high-temperature process, and for most etching processes the gas temperature remains near ambient.

The electrons are accelerated by the applied field and can only lose energy when they collide with the neutral gas species elastically or inelastically. Elastic collisions preserve the internal energy of the colliding partner. Inelastic collisions, on the other hand, can leave the colliding partner in an excited state. Electrons lose only a small fraction (10^{-4}) of their energy during elastic collisions because of the three orders of magnitude mass difference between the electrons and typical neutral species. However, electrons can lose energy in inelastic collisions. Compared to elastic collisions, inelastic collisions occur relatively infrequently at low energies and occur in sufficient frequency only when the electron energies are high (more than a few electron volts). In addition, at low pressures, the mean free path of the electrons is large. Because of the low energy-loss rate and long mean free paths, the electrons can reach high energies compared to the more massive ions and neutral species. Typically, the average electron energies are between 1 and 10 eV, which correspond to temperatures of 10^4–10^5 K! On the other hand, ion and neutral temperatures are closer to the ambient temperature. Thus, the glow discharge is a highly nonequilibrium environment characterized by species that can have drastically different velocity-distribution functions and temperatures. The electron and ion densities range from 10^8 to 10^{13} cm^{-3} depending on the excitation method employed, power, pressure, etc. However, the ratio of ion or electron density to the neutral-species density remains in the range of 10^{-7}–10^{-1}; the upper ratio is reached only in high-density discharges, and for most processes the discharge consists of relatively few electrons and ions in a sea of neutral species. The basic physics of glow-discharge processes are discussed by Chapman (1980) and by Lieberman and Lichtenberg (1994) in detail.

The characteristics listed above imbue glow discharges with unique and useful properties. Energetic electrons are capable of breaking chemical bonds via collisions with gas molecules, thereby overcoming kinetic limitations or energy barriers that exist in thermal dissociation processes. In this way, very reactive chemical species can be produced by dissociating the process gasses even at low temperatures (e.g., at ambient temperature). The low process temperature allows etching of temperature-sensitive materials in a plasma environment.

Since the first use of a gas discharge for etching, different types of plasma reactors have been utilized (Manos and Flamm, 1989; Flamm, 1991; Lieberman and Gottscho, 1993; Mucha *et al.*, 1994; Graves, 1994). These reactors differ in method of excitation, reactor geometry, or other operational parameters (e.g., power, pressure, and so forth). Today, a wide variety of plasma etching reactors exists. Despite the variations in reactor configuration and operation, the key physicochemical phenomena that enable plasma etching remain the same. The plasma performs two basic functions. First, chemically reactive species are generated by electron-impact collisions. Second, the discharge is a source of energetic particles—ions, electrons, and photons—that bombard the surfaces immersed in the plasma and alter the surface chemistry during etching (Hess, 1990). The bombardment of the film or substrate surface by energetic ions, primarily in the direction normal to the surface, increases the etch rate in the vertical direction and is responsible for anisotropic etching.

In the following discussion of plasma physics and chemistry, the parallel-plate single-wafer plasma etching reactor shown in Fig. 2 is taken as an example to describe the key phenomena that make plasmas useful for etching. In the parallel-plate plasma reactor (also known as the diode reactor), the plasma is sustained between two electrodes, as shown in Fig. 2, by applying radio-frequency power to either one or both of the electrodes. The process gases are usually introduced uniformly through a showerhead, which also serves as the upper electrode. The gases are pumped out from the periphery of the electrodes. This type of reactor is discussed in detail in Sec. 3. Table 1 lists typical operating conditions and dimensions of a parallel-plate plasma reactor.

Electrons are the heart of the plasma and are responsible for ionizing and dissociating the process gasses. Free radicals, metastable species, ions, and electrons themselves are generated by homogeneous gas-phase collisions such as the ones shown in Fig. 2 and Table 2. Depending upon the electron energy, an electron–neutral collision can result in a number of different reactions. Table 2 gives a representative but by no means a complete list of possible electron-impact reactions in a plasma; in this list chlorine is taken as an example but analogous reactions can be written for other species as well. Of these reactions, dissociation is one of the most important reactions for etching. In the

FIG. 2. Schematic of a parallel-plate plasma reactor showing the sheath and important phenomena occurring in plasmas of chemically reactive gas. Chlorine plasma etching of silicon is depicted as an example. The plasma is sustained between two electrodes by application of radio-frequency power to either or both of the electrodes. Gases are usually introduced through the top electrode using a shower head and pumped out from the periphery of the electrodes.

Table 1. Typical operating parameters and properties of a rf parallel-plate (diode) plasma etching reactor and a high-density plasma reactor.

Parameter	rf parallel-plate reactor	High-density plasma reactor
Pressure	0.001–10 Torr	0.0001–0.1 Torr
Power	50–1 000 W	100–5 000 W
Frequency	0.1–100 MHz	0.1–20 MHz or 2.45 GHz
Gas flow rate	10–3 000 sccm	10–200 sccm
Electron temperature	1–10 eV	1–10 eV
Plasma density	10^8–10^{11} cm^{-3}	10^{10}–10^{13} cm^{-3}
Fractional ionization	10^{-7}–10^{-4}	10^{-4}–10^{-1}
Ion bombarding energy	50–1000 eV	10–500 eV
Ion bombarding flux	0.01–5 mA/cm^2	1–50 mA/cm^2
Magnetic field	0 (except in magnetically enhanced reactive ion etching, MERIE)	0–1200 G
Plasma volume (for 8-in.-diameter wafers)	300–5000 cm^{-3}	1000–10 000 cm^{-3}

case of Cl_2, this reaction produces the etchant, reactive Cl radical. Via this reaction, Cl_2 gas can be dissociated close to 100% in a plasma at room temperature. Without the energetic electrons, even 10% dissociation would require a gas temperature above 1000 K. The excitation reaction and subsequent deexcitation of the excited species creates photons. Thus, electromagnetic radiation in the visible, ultraviolet, infrared, or even the x-ray region is emitted from the excited molecules and ions as they relax to a lower energy state. This is what makes a plasma glow. The rates of the reactions in Table 2 depend on the electron energy-distribution function, the density of the electrons, the density of the colliding partner in the reactor, and the collision cross section for the reaction (Mucha *et al.*, 1994; Lieberman and Lichtenberg, 1994).

Table 2. A list of representative electron impact reactions in a Cl_2 plasma.

Electron-impact ionization	$e^- + Cl_2 \rightarrow 2e^- + Cl_2^+$
Dissociative ionization	$e^- + Cl_2 \rightarrow 2e^- + Cl^+ + Cl$ $e^- + Cl_2 \rightarrow e^- + Cl^- + Cl^+$
Dissociative attachment	$e^- + Cl_2 \rightarrow Cl^- + Cl$
Electron-impact dissociation	$e^- + Cl_2 \rightarrow e^- + 2Cl$
Electron-impact excitation (rotational, vibrational, electronic)	$e^- + Cl_2 \rightarrow e^- + Cl_2^*$

The energy and trajectory of the ions bombarding the substrate surface are determined by the potential distribution established in the plasma, particularly near the substrate surface. Since electrons are lighter and more mobile than heavier ions, it is expected that they would be lost to the walls of the plasma reactor in larger numbers than ions. This exodus of electrons would in turn deplete the plasma of electrons, leaving a space charge behind. In fact, this is exactly what happens during the first moments of plasma initiation. However, within a short period of time electrons are depleted next to the walls and the electrodes and a space-charge layer forms next to the surfaces in contact with the plasma. In order to stop the electron depletion, an electric field is established to repel the electrons away from the walls. At steady state, the ion flux and electron flux equilibrate to satisfy the overall current continuity and charge balance. The majority of the electrons are repelled and excluded from the region near the walls by the high electric field created by the space charge. Thus, the plasma is separated from the walls of the vessel and the electrodes (in fact, any surface that is immersed in a plasma) by a space-charge region called the sheath. The sheath appears relatively dark as a result of lack of electrons and hence electronic excitation in this region. One consequence of this space-charge formation is that the potential distribution in the discharge is such that the plasma is at a higher potential than all surfaces it is in contact with. In other words, an electric field near the walls always points toward the electrodes and repels the electrons from the sheath. The same electric field that repels the electrons away from the walls accelerates the oppositely charged ions toward surfaces. The ions are accelerated by the sheath electric field and bombard the film and substrate surfaces predominantly at normal incidence. This bombardment is responsible for enhancing the etch rate in the vertical direction and for inducing anisotropic etching, which produces etch profiles such as the one shown in Fig. 1(c). The etch rate with simultaneous bombardment with ions and reactive neutrals is higher, sometimes by more than an order of magnitude, than the sum of the etch rates with ions and reactive neutrals alone (Coburn and Winters, 1979). This synergistic enhancement and resulting etching is called ion-assisted etching.

1.4 Key Steps in Plasma Etching

The mechanism of plasma etching can be broken down into six steps, as depicted in Fig. 3 (Mucha *et al.*, 1994). First, reactive species are generated by electron-impact reactions in the plasma. This step is crucial in etching because many of the gases do not react spontaneously with the film to be etched without dissociation. The reactive etchant species are transported to the surface by gas flow and diffusion and adsorb onto a surface site on the film that is being etched. In general, reactive radicals (Cl) have higher adsorption and reaction probabilities than the parent molecule (Cl_2) even at low surface temperature. Details of what happens on the surface are often unclear and provide an active area for research. Ion-assisted surface reactions take place and volatile reaction products are formed on the surface. Product formation is followed by desorption, another crucial step in the etch process. A free radical can react rapidly with a solid surface, but unless the product species has a appreciable vapor pressure so that desorption occurs, no etching takes place. Desorbed products diffuse into the bulk and are pumped out of the reactor.

1.5 Ion-Assisted Etching

Depending on the reactor and operating conditions the energy of the ions incident onto the surface can range from a few to

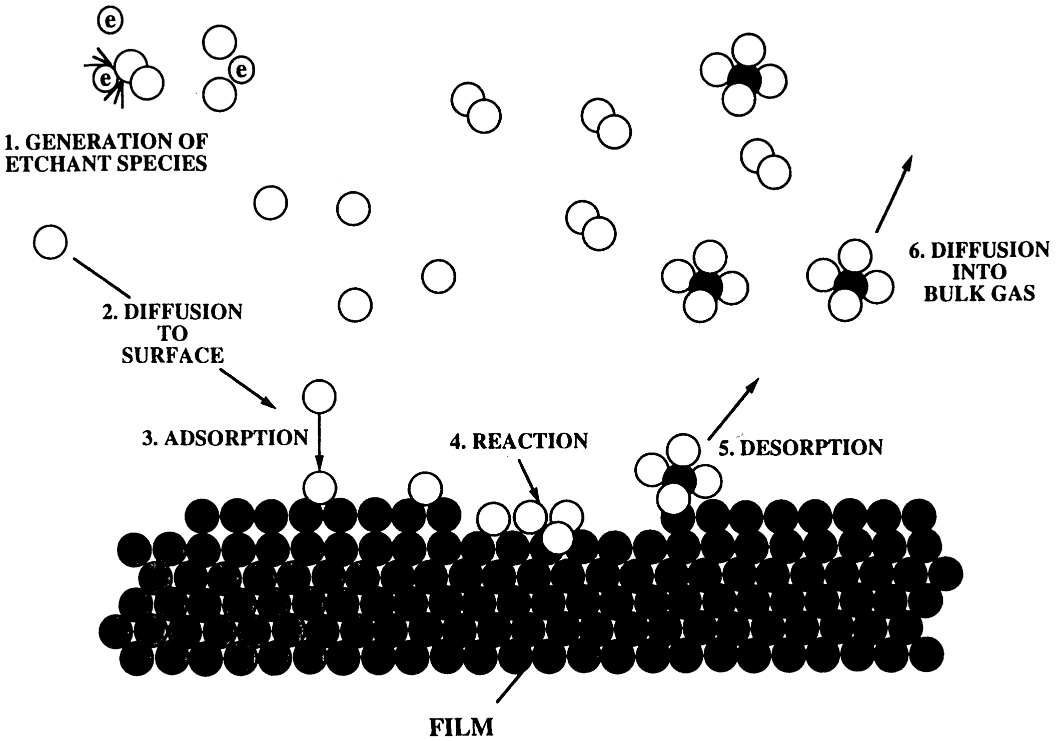

FIG. 3. General mechanism of plasma etching (reprinted from Mucha *et al.*, 1994, with permission).

hundreds of electron volts, more than enough to break bonds and effect surface reactions. The enhancement of etch rate due to particle bombardment can be envisaged by referring to Figs. 3 and 4. Steps 3–5 are heterogeneous reactions with kinetics that depend on the temperature and the nature of the surface. Increasing the temperature is one way of increasing the energy of the reactants and surface species to facilitate reactions. Particle bombardment is another way that energy can be imparted to the surface. Particle bombardment can break chemical bonds on the surface, thereby creating reactive sites for adsorption or creating reactive surface species that can react to form volatile products. Much like the electrons in the gas phase, ion bombardment can cause new reaction pathways that the surface chemistry can evolve through. Ion bombardment can also assist product desorption, facilitating step 5 in Fig. 3 in cases where the etching product is not very volatile. Which of these steps is responsible for enhanced etch rates in the vertical direction is not clear and most likely depends on the specific case.

Ion-assisted etching was demonstrated by Coburn and Winters in 1979 in a classic experiment. In their experiment, Coburn and Winters observed that Si could be etched chemically with XeF_2 at $\approx$5 Å/min and could be physically sputtered by Ar^+ at $\approx$2 Å/min. However, when both XeF_2 and Ar^+ were used, an etch rate of 55 Å/min, an order of magnitude higher than both the chemical and physical etching rates, was observed. This experiment demonstrated the existence of a synergy between chemical etching and ion bombardment. It turned out that these effects are very general in plasma etching and are encountered in etching of other materials with other gases.

Two simple mechanisms for ion-assisted anisotropic etching are depicted in Fig. 4. In the ion-induced damage mechanism shown in Fig. 4(a), the ion bombardment breaks the bonds on the crystal surface and leaves the film more reactive and more accessible to the chemical etchant. For example, this could happen via formation of a reactive layer that is mixed and removed by ion bombardment. The sidewalls, on the other hand, do not receive ion bombardment and etching is unaccelerated. Consequently, material removal proceeds faster in the ion flux direction, normal to the film surface, resulting in anisotropic etching. In the surface inhibitor mechanism, the second scenario shown in Fig. 4(b), the sidewalls are protected from etching by an inhibitor. This protecting layer can be a thin layer of polymer film or oxide, which can readily form in a plasma environment. The inhibitor may also form at the bottom surface but will be removed quickly by ion bombardment, exposing the bare surface to etchants that in turn can remove the film.

2. PLASMA ETCHING CONSIDERATIONS

The general goal of any plasma etching process is to achieve high etch rate, high degree of anisotropy (vertical sidewalls), good uniformity on a single wafer as well as from wafer to wafer, and selective etching of the film relative to the mask and the underlying film or substrate (Sawin, 1994) with minimal radiation damage to the devices on the wafer. Unfortunately, many of these goals are mutually exclusive. For example, the ion bombardment of the surface that provides the anisotropic etching also causes damage. The relative importance of these goals and objectives depends on the application. Given the numerous combinations of process gases, process conditions, and plasma reactor configurations, the difficulty of designing, developing, and optimizing a process to achieve a given set of objectives is the major limitation of plasma etching processes. In this section, important factors and considerations that affect the design and development of plasma processes are described briefly.

2.1 Process Parameters and Reactor Choice

Plasma reactors are notoriously complex systems because of strong coupling of physical and chemical phenomena occurring in the gas phase and on surfaces. At present, it is impossible to predict theoretically the optimum operating parameters for a given plasma etching application. For this reason, reactor and process parameters are chosen empirically, after laborious trial-and-error experimentation and optimization.

One can distinguish between two different

kinds of parameters in plasma etching: externally controlled variables and internal plasma variables. The externally controlled variables are those that can be manipulated directly by turning a knob or pushing a button. These parameters include power, pressure, excitation frequency, flow rate, and gas composition. These operating parameters dictate the outcome of a plasma process, the "figures of merit," through their effect on the internal properties of the plasma. These internal properties include the electron energy distribution function, reactive species concentrations, ion flux, ion-bombardment energy and angular distribution, and their spatial variations. The difficulty in controlling and developing plasma etching processes arises from the fact that these key internal properties cannot be controlled independently but are determined by the externally set operating parameters. Often, the relationship between the external parameters and the internal properties is not known. Furthermore, changing one external parameter may affect more than one internal property. For example, increasing the power may result in an increase of ion bombardment flux and energy, as well as etchant concentration.

In summary, there are no simple guidelines for chosing process parameters and designing reactors. Usually, choices are made on the basis of scientific as well as economic reasons, which are different for each application. Thus, each individual process should be considered on the basis of its own objectives. At present, process complexity and the large number of parameters that affect the process are the most serious impediments to routine use of plasma etching.

2.2 Etch Rate and Selectivity

Etch rates determine the processing time in the plasma, and the throughput. Process economics and the thicknesses of the films to be etched dictate the magnitude of an acceptable etch rate. Typically, etch rates should be and are on the order of several thousand angstroms to a few microns per minute for a manufacturing process. Wafer throughput rates on the order of 20 wafers/h are typical. The ratio of the etch rates for two different materials immersed in the same plasma determines the selectivity of removing one film without significantly etching the mask or the selectivity of removing one film without etching an underlying film or the substrate. Selectivities in excess of 1:10 are generally desirable. High etch rates and selectivity can be achieved by judicious selection of feed gases to a plasma reactor. For a given material, the gas selection is generally made by trial and error and by using guidelines based on previous experience with similar materials. Numerous materials have been etched using plasmas. Table 3 is a list of materials frequently encountered in IC manufacturing and the etchants used to pattern these films.

2.3 Uniformity

Uniformity refers to uniformity of etching not only from wafer to wafer but also over a single wafer as well. For example, if the etch rate is higher at one position on the wafer than at another position, the film will be removed in that location before complete removal of the film in locations where the etch rate was not as high. However, the wafer must remain in the reactor to allow for complete removal of the film everywhere. This results in overexposure of some areas to the plasma. This is called overetching. Overetching can result in undercutting and etching or damage of the underlying films and structures. Uniformity on a single wafer is particularly important because uniform etching over a wafer is required in order to minimize the necessity to overetch.

Nonuniform etching can be on a macroscopic or a microscopic scale. Macroscopic uniformities are on the length scale of the wafer dimensions and are caused by radial gradients in the etchant concentration (Economou *et al.*, 1991; Aydil and Economou, 1993), ion-bombardment flux and energy, and/or wafer temperature. Uniformity is usually characterized by reporting the maximum percentage deviation of the etch rate from an average etch rate or from the etch rate at the center. Today's plasma etching processes require a uniformity that is better than ±5%.

Etchant concentration gradients can exist at the wafer edge where two surfaces with different reactivities meet. The etchant is depleted by etching reactions and the etchant concentration is lowered over the wafer with respect to the surrounding electrode. This

concentration gradient will cause the etch rate to decrease from the edge of the wafer toward the center, causing the film to be removed from the edges first.

Since the surface reactions are ion-bombardment driven, the radial uniformity of ion-bombardment flux and energy also affect the uniformity of etching. In this case, the important factors that determine the uniformity are the power absorption profile and ion transport in the reactor (Stevens *et al.*, 1992; Economou *et al.*, 1991; Aydil and Economou, 1991).

Another factor that may affect macroscopic uniformity is the temperature profile across the wafer. Chemical reactions depend on the temperature exponentially, and even very minute temperature differences on the surface can lead to unacceptable uniformity. Nonuniform etching may result if the wafer is not cooled or is in poor thermal contact with the cooled electrode (Aydil and Economou, 1993).

Microscopic uniformity refers to uniformity of etching on the scale of the feature size (Gottscho *et al.*, 1992). For example, features with different shapes and sizes are know to etch at different rates. This creates a situation where the etch rate varies from hole to hole or from trench to trench even when they are next to each other (within several micrometers). This phenomenon has been called microloading, RIE (reactive ion etching) lag, and aspect-ratio–dependent etching. Generally, it is observed that smaller features etch at a slower rate than larger ones as a result of transport limitations for ions and neutrals. There are several possible mechanisms that have been put forth to explain microscopic nonuniformities. Generally, microscopic nonuniformities result from differences in ion and neutral transport rates within the feature. The topic has been reviewed by Gottscho *et al.* (1992).

2.4 Profile Control

The goal of pattern-etching processes is to transfer the exact replica of the features on the mask to the underlying film. The most useful metric for profile control is the ratio of lateral undercutting, d_H, to vertical etching, d_V, as depicted in Fig. 1. The ratio d_H/d_V is inversely related to the quality of replication. In anisotropic etching, $d_H/d_V = 0$, and high-quality replication of the mask pattern is obtained. On the other hand, for isotropic etching, $d_H/d_V = 1$, which results in linewidth loss and poor pattern replication. Anisotropic etching is desired for high-density, fine line patterning.

It should be clear from the discussion in Sec. 1 that the degree of anisotropy depends critically on the ion energy and angle distribution. For anisotropic etching, a very narrow angular distribution about the normal to the surface is desired. A narrow angular distribution is obtained when the ions are accelerated through the sheath without undergoing collisions that will randomize their velocity distribution function, and when the velocity acquired in the sheath is much larger than the random velocity that the ions possess before entering the sheath (Liu *et al.*, 1990). Since the mean free path of the ions increases with decreasing pressure, anisotropic etching is usually obtained at low pressures (<50 mTorr). The desired energy distribution is less clear. The ions must be energetic enough to cause anisotropic etching but not so energetic that they damage the substrate.

It has been shown that deliberate sidewall inhibition can be used as a strategy to achieve anisotropic etching (Donnelly and Flamm, 1981). This strategy relies on the sidewall-inhibition mechanism described previously. Polymer-forming halocarbons are added to the plasma to form protecting layers on the sidewalls. Ion bombardment maintains a cleared bottom surface where the etching can take place. Sidewall passivation layers can be formed in plasmas even without the polymer-forming species. For example, a silicon dioxide inhibitor layer can be formed on the sidewalls by adding O_2 to the etching mixture (e.g., BCl_3/Cl_2 or BCl_3/HCl) for etching silicon.

Another strategy for controlling anisotropy is to mix two etchant gases where one etchant is known to etch anisotropically and the other isotropically. Control of anisotropy by changing the composition of the plasma has been demonstrated in this manner by mixing ClF_3 with Cl_2 (Flamm *et al.*, 1982).

Other major factors in profile control in etching are the mask material and the rate of mask erosion. The masks shown in Fig. 1 represent an ideal case where the mask is not eroded by the etchant or the ion bombardment. Inevitably, mask erosion, particularly near the edges, can result in linewidth loss.

Finally, it should be noted that vertical walls are not always desirable. For example, if the etched pattern is going to be filled with another material, using a deposition method, a slightly tapered profile may be desired to reduce shadowing during deposition.

3. PLASMA ETCHING REACTORS

A general plasma etching system has several basic components: a vacuum chamber and pumping system to maintain the desired low process pressures, a gas handling system to deliver, meter, and control the flow of reactant gases, and a power supply to create a glow discharge. Pressure in the reactor is measured and controlled using a pressure transducer and a throttling valve. The electrode or the platen that the wafer is placed on is usually cooled to prevent it from heating by ion bombardment. In addition to basic equipment, commercial plasma reactors include automated wafer and process handling systems. Some reactors also employ plasma diagnostic equipment to measure etching rates and etchant concentrations. Detailed assembly of a plasma etching system is subject to variations depending on the desired operating parameters and application. On account of the large variety of existing plasma etching reactor configurations, a simple categorization is not possible. The objective in the following subsections and the associated figures is to describe briefly the most common reactor configurations and to emphasize differences and similarities among them. References are given for more detailed information. Summaries of different reactor configurations are also given in Mucha *et al.* (1994), Lieberman and Lichtenberg (1994), and Lieberman and Gottscho (1993).

3.1 Barrel Reactor

The barrel reactor is the earliest plasma apparatus constructed for etching. In this reactor, several wafers are placed on a "boat,"

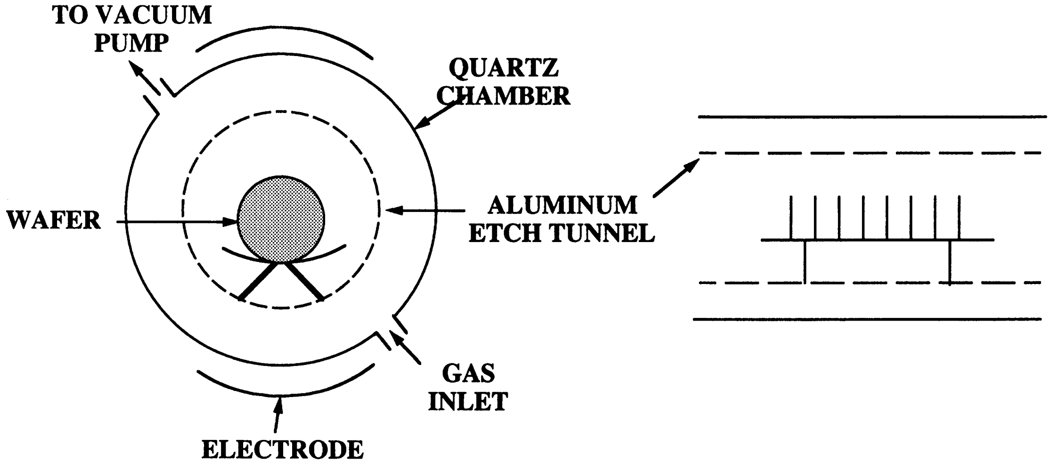

FIG. 5. Barrel reactor (reprinted with permission from Mucha *et al.*, 1994).

which in turn is placed in a cylindrical evacuated chamber. Usually the chamber is made out of quartz and a perforated metal shield is placed around the wafers to protect them from radiation damage, heating, and energetic ion bombardment. The plasma is maintained in the annulus by applying rf power to coils or electrodes placed outside the chamber as shown in Fig. 5. The wafers receive little or no ion bombardment because of the shield: only reactive radicals reach the wafer, resulting in purely chemical etching and isotropic etching profiles. For this reason, barrel systems are used in noncritical etching steps where undercutting can be tolerated, or in applications such as photoresist mask removal where anisotropic etching is not needed.

3.2 (Parallel Plate) Diode Reactor

The diode reactor, already mentioned in Sec. 1, is one of the most widely used plasma reactors. The plasma is created by applying a rf field between two electrodes. Usually 13.56 MHz is used in order not to affect communications. However, frequencies ranging from 100 kHz to 100 MHz have been employed. The electrodes can be large to accommodate many wafers or small to process a single wafer (Mathad, 1985). At present, most parallel-plate reactors are designed to etch one wafer at a time in order to provide better wafer-to-wafer control. As discussed earlier, this geometry results in ion bombardment of the substrate. Etching is by both physical (ion bombardment) and chemical (reactive radicals) processes, which makes it possible to etch high–aspect-ratio (ratio of depth to width, d_V/W) features such as holes and trenches.

The diode reactor is usually operated in two modes. In one configuration, the wafers are placed on the grounded electrode while the opposite electrode is powered. The processes using this configuration are termed "plasma etching." When substrates are placed on the powered electrode, a reactive ion etching (RIE) mode results (Coburn, 1982). In the RIE configuration (see Fig. 6), the chamber walls are grounded and act as the counter electrode. Although no exact de-

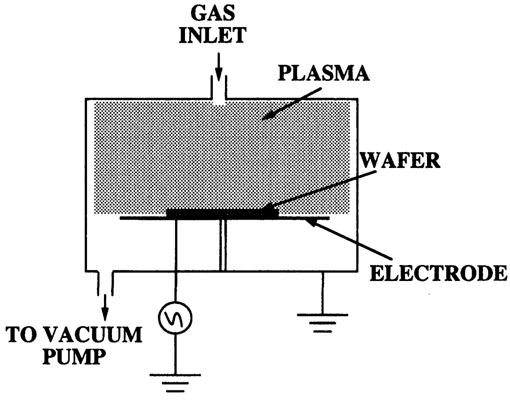

FIG. 6. Diode reactor in RIE configuration (reprinted with permission from Mucha *et al.*, 1994).

marcation in pressure exists, RIE is typically conducted at pressures less than 100 mTorr (typically 1–100 mTorr) and plasma etching is carried out at pressures above 100 mTorr (typically 0.1–5 Torr). The RIE arrangement exposes the wafers to higher-energy ion bombardment than in the plasma etching mode because higher potentials are established next to the powered electrode when compared to the sheath next to the grounded electrode. Another reason for higher-energy ion bombardment in RIE is the lower operating pressure. Ion bombardment in RIE mode is more energetic and more directional (narrower incident angle distribution about the normal to the surface) than in plasma etching because the ions do not collide with the neutrals and lose energy and directionality as they are accelerated in the sheath.

3.3 Magnetically Enhanced Reactive Ion Etching Reactor (MERIE)

The magnetically enhanced reactive ion etching reactor (see Fig. 7) is one of the variations of the RIE configuration (Leahy and Kaganowicz, 1987). The MERIE reactor is an RIE reactor that employs a static magnetic field applied parallel to the powered electrode. The purpose of the magnetic field is to confine the electrons and increase the plasma charge density by reducing the electron loss rate.

3.4 Hexode Reactor

The hexode reactor is another variation of the RIE reactor. In this reactor, the wafers are mounted around the periphery of a hexagonal electrode as shown in Fig. 8. The hexagonal electrode is powered and the reactor walls are grounded to serve as the counter-electrode. The plasma is sustained in the annular volume and etches the substrates placed on the hexagonal electrode. The region around each wafer locally resembles a diode reactor. The hexode increases the capacity of RIE configuration by extending the powered electrode into "the third dimension."

3.5 Downstream (Remote) Plasma Reactor

In a downstream plasma etching reactor (see Fig. 9), the plasma is sustained away from the wafer to be processed (Cook, 1987). For this reason, this reactor configuration is also referred to as the remote plasma or the afterglow reactor. As in the barrel reactor, etching is isotropic because only long-lived reactive radicals transported via diffusion and gas flow make it to the wafer surface. Depending on the distance between the plasma and the wafer, very few or almost no ions and electrons reach the surface. The plasma is sustained in a quartz tube either by external electrodes or coil as in the barrel

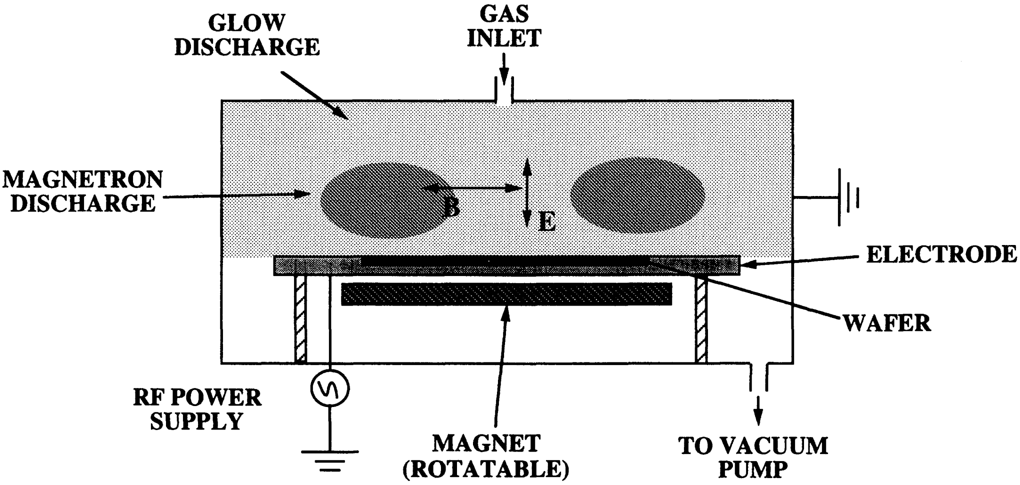

FIG. 7. Magnetically enhanced reactive ion etching reactor (MERIE) (reprinted with permission from Mucha *et al.*, 1994).

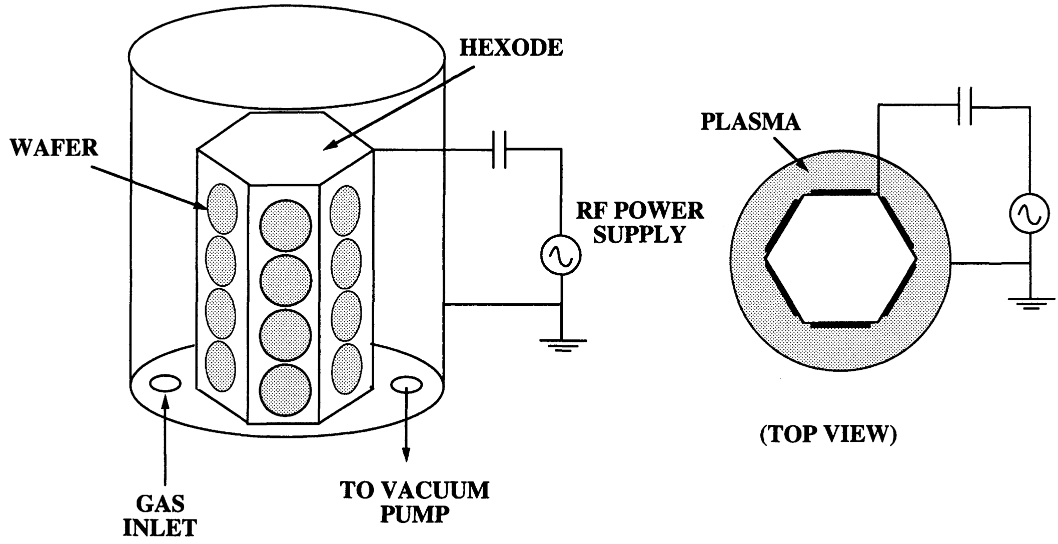

FIG. 8. Hexode plasma reactor (reprinted with permission from Mucha *et al.*, 1994).

reactor or by enclosing the plasma tube in a microwave cavity. Often the tube is bent to minimize line-of-sight radiation incident onto the wafer.

3.6 Triode Reactor

The triode reactor, shown in Fig. 10, is another variation of the diode configuration but employs three electrodes. As in the diode reactor, two of the electrodes are used to create ionization and to sustain the plasma by applying rf power to one of them. However, the wafer is placed on a third electrode, which is biased by an independent, and often different (lower) frequency, power supply in an effort to provide independent control of the ion-bombardment energy from the ion flux. A major limiting feature of the diode reactor is that the ion-bombardment flux and energy cannot be controlled independently from each other. For instance, an attempt to increase the ion flux by increasing the rf power can cause an increase in the sheath potential and thus the ion-bombardment energy in addition to an increase in the ion flux. To a certain extent, the triode arrangement decouples the power needed to sustain the plasma from the power needed to accelerate the ions across the sheath toward the wafer.

3.7 High-Density Plasma Reactors

These plasma sources were developed in the late 1980s to surmount the problems of the diode etcher and its variations, particularly to enable the independent control of the ion-bombardment flux and energy over a wide range of operating parameters. Thus, these reactors all operate like the triode reactor, where the plasma generation is decoupled from the substrate biasing so that the ion-bombardment energy can be controlled by separately biasing the workpiece. The difference between the high-density reactors and the triode reactor is that two of the electrodes used to energize the plasma have been replaced by very efficient high-power plasma sources. In fact, aside from hardware, the major differences among the different high-density plasma sources are in the mechanisms by which the applied field is coupled to electrons in the plasma. The high-density sources provide high ion densities (10^{11}–10^{13} cm^{-3}) at low pressure (1–10 m-Torr) that enable anisotropic etching at high rates. In addition, high-density plasma sources use efficient noncapacitive coupling of power to the electrons, thereby providing high ion fluxes (1–50 mA/cm^2) at low energies. In the next sections, each of the high-density sources is briefly described. Typical operating parameters for high-density discharges are listed in Table 1. A comprehen-

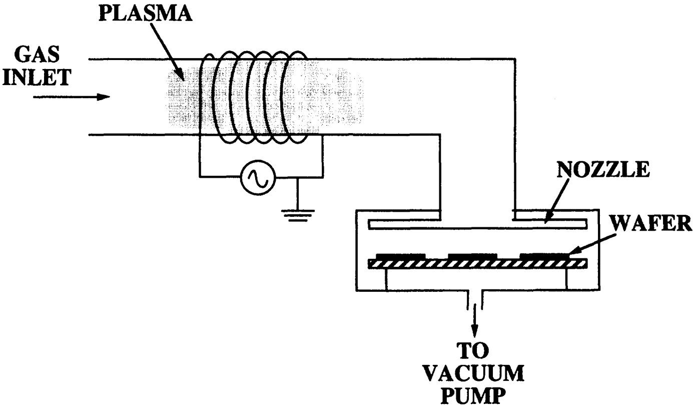

FIG. 9. Downstream (remote) plasma reactor (reprinted with permission from Mucha *et al.*, 1994).

sive review of the high-density sources is given by Lieberman and Gottscho (1993).

3.7.1 Electron Cyclotron Resonance Plasma Reactor ECR reactors (Asmussen, 1989) are conceptually separated into two regions: a source region where the power is absorbed by the electrons and a reactor region downstream from the source. However, ECR plasma reactors are not downstream reactors. The wafer is placed in the reactor region on a substrate platen that can be biased with a rf power supply. The process gases are injected into the source region. The plasma extends out of the source region into the reactor region and both reactive species and energetic ions impinge onto the wafer. The plasma is maintained by coupling microwave power at 2.45 GHz to the electrons in presence of a static magnetic field B, such that the microwave frequency ω is in resonance ($\omega = \omega_{ce}$) with the electron cyclotron frequency, $\omega_{ce} = eB/m_e$, where e and m_e are the electron charge and mass, respectively ($B = 875$ G for resonance at $\omega = \omega_{ce} = 2.45$ GHz). Electrons gain energy from the microwave electric field as they rotate in phase with the microwaves. Microwaves generated by a magnetron are guided to the reactor and launched through a dielectric window into the source region. One or more electromagnets surround the source and the reactor

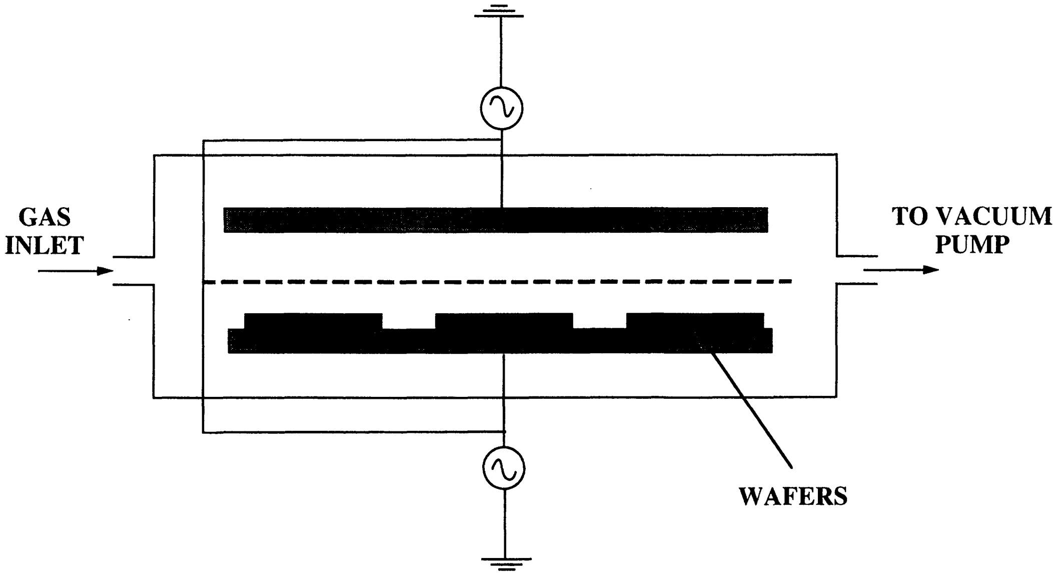

FIG. 10. Triode reactor (reprinted with permission from Mucha *et al.*, 1994).

to create the magnetic field necessary for resonance. ECR plasma reactors operate at pressures 0.1–100 mTorr and utilize 0.5–2 kW of power to generate a very dense (10^{11}–10^{13} ions/cm^3) plasma. There are different types of ECR plasma reactors. They differ in geometry, in the manner in which the microwaves are introduced into the reactor, and in the magnetic field profiles used to achieve resonance. One is shown in Fig. 11.

3.7.2 Helicon Plasma Reactors As in ECR reactors, helicon reactors can also be separated into a source region and a reactor region. The reactor region is similar to that of an ECR reactor. However, helicon plasma reactors utilize helicon waves to sustain a plasma in the source region rather than microwaves (Boswell, 1970, 1975; Chen, 1992). Helicon waves are right-hand circularly polarized whistler waves that can propagate in axially magnetized plasma columns. The helicon waves have complex modes characterized by radial, axial, and azimuthal variation, and they are called helicon waves because the electric and magnetic field components of the wave trace out a helical locus in space. Application of helicon-wave–excited plasmas to etching is relatively recent (Boswell and Henry, 1985; Perry *et al.,* 1991). Helicon waves are excited in the plasma by an appropriately shaped rf-driven (13.56 MHz) antenna placed concentrically outside the quartz tube that contains the discharge (see Fig. 12). There are several different helicon antenna shapes that can be used to excite helicon waves. A static magnetic field is also necessary to produce helicon waves and is created by coils placed around the source. As the helicon waves are excited and propagate through the plasma, energy is thought to be absorbed by the electrons through collisional or Landau damping. Process gases are injected from the top of the quartz tube and are ionized and dissociated as they flow through the source. Helicon sources produce a plasma with parameters that are comparable to those produced by ECR sources. Ion densities are in the range of 10^{11}–10^{13} ions/cm^3. However, the hardware required for helicon plasma excitation is much simpler than ECR sources.

3.7.3 Helical Resonators As in ECR and helicon plasma reactors, helical resonators can also be separated into a source region and a reactor region. Helical resonators use an entirely different method to excite the plasma. A helical resonator consists of a coil surrounded by a grounded shield as shown in Fig. 13. The plasma is sustained inside the dielectric tube placed inside the coil. One end of the coil is grounded while the other is left floating. Power is applied to a position in between the two ends. The structure becomes resonant when an integral number of quarter waves of the rf field fit between the two ends of the helix (Cook *et al.,* 1990). Large currents flowing through the coil at resonance create high fields inside the dielectric tube, which in turn accelerate the electrons in the discharge. Compared to the ECR

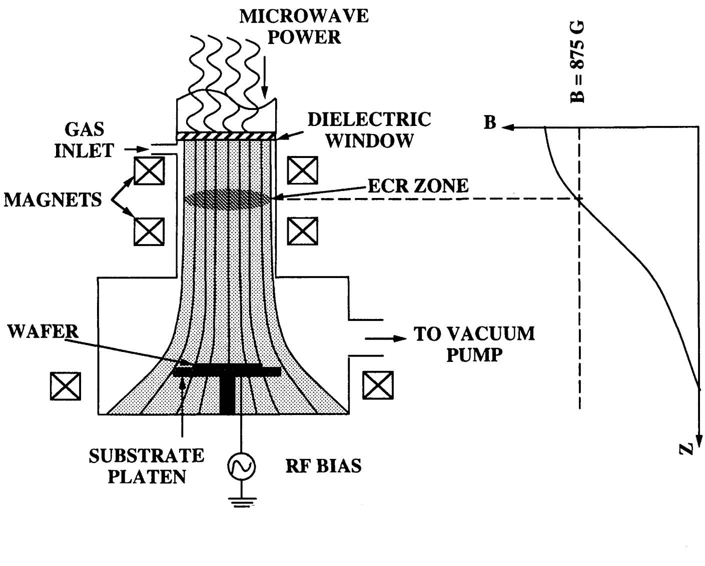

FIG. 11. High-profile electron cyclotron resonance (ECR) plasma reactor (reprinted with permission from Mucha *et al.,* 1994).

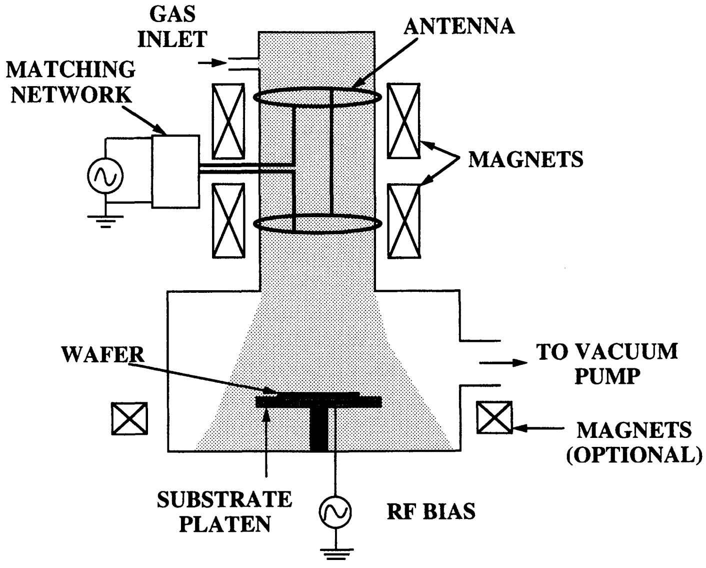

FIG. 12. Helicon plasma reactor (reprinted with permission from Mucha *et al.*, 1994).

and helicon reactors, helical resonators require very simple hardware but create a plasma with similar properties.

3.7.4 Inductively Coupled Plasma (ICP) Reactors—Radio-Frequency Induction (RFI) or Transformerly Coupled Plasma (TCP) Reactors In its simplest form, an inductively coupled plasma consists of a coil wrapped around a tube very much like the helical resonator. However, the name inductively coupled plasma reactor is generally associated with a new class of sources invented in the late 1980s that utilized the planar configuration shown in Fig. 14 (Hopwood, 1993). The planar coil used to excite the plasma is a cylindrical spiral that resembles a stove-top heater element. Radio-frequency (13.56 MHz) power is applied to the outer end of the coil, which is grounded at the center. The coil is placed on top of a quartz window, which forms one of the walls of the reactor. Radio-frequency inductive electric fields created inside the reactor sustain the plasma. ICP sources create high-density plasmas with properties similar to those of ECR, helicon, or helical resonator plasmas. As in other high-density sources, the wafer is placed on a platen that can be biased separately. The hardware required for TCP sources is as simple as helical resonators. Hopwood (1992) has reviewed the design and principles of RFI reactors.

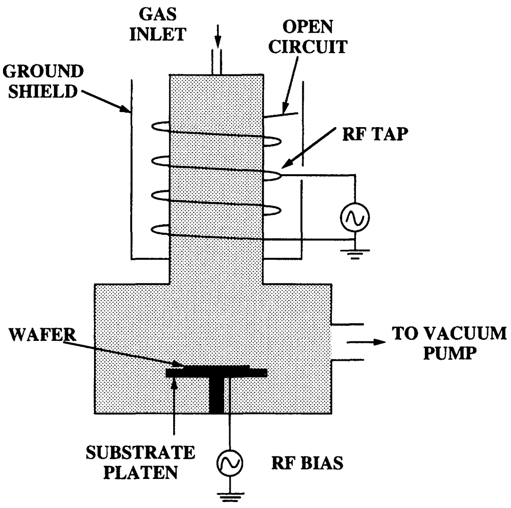

FIG. 13. Helical resonator (reprinted with permission from Mucha *et al.*, 1994).

4. MODELING OF PLASMA ETCHING REACTORS AND PLASMAS

There has been a growing interest in modeling of chemically reactive plasmas in order to improve our understanding of gaseous discharges and to develop more rational procedures for plasma reactor design. Modeling can give insight into many aspects of plasma etching. The models developed so far range from microscopic scale to reactor scale. One of the goals of plasma reactor

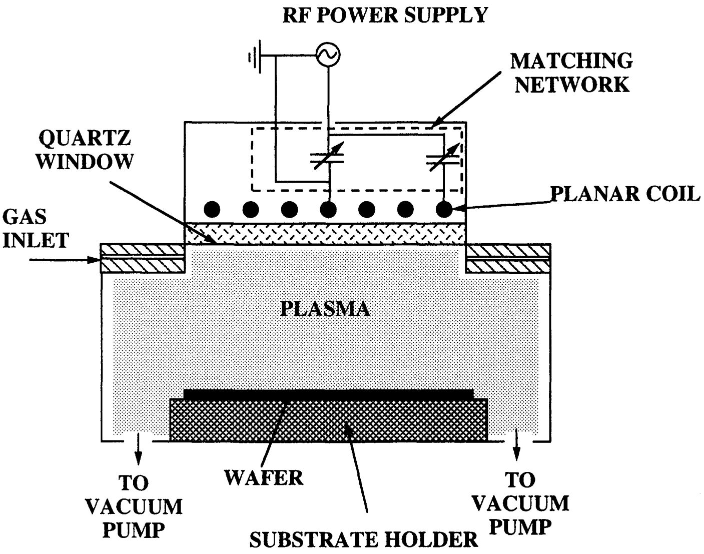

FIG. 14. Radio-frequency induction plasma reactor.

modeling has been to reduce the dependence of the technology on costly trial-and-error process development methods by developing predictive plasma reactor simulators and computer-aided design tools. A chemical reactor model fulfilling this need requires modeling of both the discharge physics and the discharge chemistry. The discharge-physics models can predict the charged-particle densities and energies, the electric field strength, and their distributions in the reactor. These variables are important in generating chemically reactive species and altering surface reactions primarily through the ion bombardment. Discharge-chemistry models include gas-phase and surface reactions of neutral species along with the transport of these species by convection and diffusion.

A common approach to plasma reactor modeling is to subdivide the reactor model into more manageable, simpler submodels as depicted in Fig. 15. Initial models of the plasma etching reactors concentrated on studying each submodel in isolation, despite the fact that the submodels are strongly and nonlinearly coupled to each other. Several investigators have conducted modeling studies of low-pressure chemically reacting plasmas in this manner. In each of the investigations, different aspects of the problem were emphasized. Some researchers focused on understanding the discharge physics (Graves and Jensen, 1986) while others emphasized neutral transport and reaction phenomena (Economou and Alkire, 1988). For detailed reviews of the plasma reactor literature the reader is referred to articles by Graves (1989), Lister (1992), and Kline and Kushner (1989), and review chapters by Meyyappan (1994) and Mucha *et al.* (1994). In this section, a brief overview of the plasma etching reactor modeling literature is given.

Herein, plasma models in the literature are summarized by separating them into five categories according to approach and focus:

1. electron-kinetics modeling—Boltzmann transport equation;
2. continuum glow-discharge models;
3. neutral transport and reaction models;
4. sheath models; and
5. particle-in-cell and Monte Carlo simulations.

Clearly there is an overlap between the different topics. There are two approaches to discharge modeling: the fluid (continuum) approach and the kinetic (particle simulation) approach. In the fluid approach, the plasma is treated as a continuum and as a mixture of neutral, ion, and electron fluids. In particle or Monte Carlo simulations, temporal behavior of large numbers of electrons, ions, or neutrals is computed as they move under the influence of the existing electric and/or magnetic fields and undergo collisions. Hybrid models where fluid and particle simulation approaches are combined have also been used.

FIG. 15. Schematic representation of a common way of dividing the plasma etching reactor model into several submodels and the interrelationship between these submodels.

4.1 Electron-Kinetics Modeling

The first step in plasma modeling is the computation of the electron energy-distribution function (EEDF), which is done either by solving the Boltzmann transport equation (Cherrington, 1979) or by resorting to Monte Carlo techniques. The product of the EEDF with the collision cross section for any of the electron-impact reactions shown in Table 3 determines the rate of that reaction. EEDF also determines the transport properties such as the mobility and diffusivity of the electrons in the plasma. A recent article by Jiang and Economou (1993) is an example of such a computation and contains a brief review of the literature related to solving the EEDF.

4.2 Continuum Glow-Discharge Models

Many investigators have simulated plasmas by using continuum models with emphasis on the discharge structure and physics. It is assumed that the mean free paths of the particles that make up the plasma are much larger than the reactor dimensions. In these models, electron- and ion-transport coefficients are treated phenomenologically, preferably by using functions determined after computing the EEDF. Transport and reaction of the charged particles are modeled by solving the material balances for the electrons, positive ions, and negative ions, the energy balance for the electrons, and Poisson's equation with the appropriate boundary conditions. In continuum models of the discharge, the focus is the discharge structure, and usually gas and surface chemistry are de-emphasized. The output of the continuum models comprises the self-consistent spatial and temporal distributions of all the charged species, ionization and electron-collision reaction rates, fluxes to the surfaces, and the electric field (potential) distribution.

4.3 Neutral Transport and Reaction Models

Neutral transport and reaction models emphasize the species transport, and gas-phase and surface reactions, although the surface reactions are treated phenomenologically. The purpose is to predict the spatial distribution of the reactive radicals in the reactor and their fluxes to the substrate. The neutral transport models are coupled to the continuum discharge models through the radical generation rates by the electron-impact reactions, which in turn are coupled to the EEDF. On the other hand, the calculation of the EEDF requires the knowledge of the plasma composition. This shows the intricate coupling between different phenomena occurring in plasma reactors.

In neutral transport models, the emphasis is on understanding the phenomena that control the spatial distribution of reactive radicals by solving the diffusion–convection–reaction equations (i.e., differential material balances) for the neutral species. The gas-flow field is obtained by solving the Navier–Stokes equations. The output of the neutral transport models includes the spatial variation of the etchant and its flux to the wafer surface. If the etching kinetics are known, the etchant flux can be used in conjunction with the ion flux to calculate the etch rate and its spatial distribution across the wafer.

4.4 Sheath Models

The goal of modeling the sheath is to predict the flux and the energy and angular distributions of ions bombarding the substrate. Ion transport in the sheath has been studied using both continuum and Monte Carlo models. Details of collision processes occurring in the sheath are difficult to incorporate into continuum models. The Monte Carlo models can treat details of ion–neutral collisions and conveniently yield the energy and angular distribution of ions impinging onto the film surface (Liu *et al.*, 1990). For this reason, Monte Carlo models are preferred over continuum models in modeling the sheath. In Monte Carlo techniques, the trajectory of an ion in the sheath is determined by solving the equations of motion. The calculations are repeated for many thousands of ions and the desired distributions are determined from the histograms.

4.5 Particle-in-Cell and Monte Carlo Simulations

The Monte Carlo simulation techniques used in modeling the sheath can also be used to model the plasma itself. This approach is an alternative to the continuum models of the discharge. Discharge physics and even chemistry can be modeled using the so-called particle-in-cell Monte Carlo (PIC-MC) simulations. The particle-in-cell simulations involve solving the equations of motion for thousands of electrons, ions, and neutrals with each particle representing millions of particles in reality. These particles used in the simulations are called superparticles. Particle density distributions and currents are determined on a grid and Maxwell's equations are solved simultaneously for the electric and magnetic fields. Collisions are modeled by allowing the superparticles to collide with other species or among themselves during their motion. Birdsall and Zangdon (1985) and Birdsall (1991) give an introduction to PIC-MC simulation methods and a comprehensive list of references.

5. SPECIFIC PLASMA ETCHING APPLICATIONS

In plasma etching, many materials may be present in the reactor and on surfaces simultaneously. Even in the simplest system, consisting of a mask and a film to be etched, there are two different materials on the substrate exposed to the plasma. In choosing etchants, one must be aware of the important aspects of the chemistry of each material. Over the past three decades many materials have been etched using plasmas. Guidelines for choosing etchants for plasma etching of various materials, particularly those encountered in IC manufacturing, have been reviewed numerous times. Table 3 is a summary of etchants used in plasma etching for different materials. References are also listed for more information.

Isotropic and anisotropic etching of silicon and polycrystalline silicon has been studied the most. Plasmas that produce F, Cl, and Br radicals can etch Si at rates ranging from 0.01 to several μm/min depending on the plasma density, pressure, etc. In fact, halogen atoms can etch many materials including metals, oxides, nitrides, silicides, III–V semiconductors, and III–V alloys, with a few exceptions. The difficulty in choosing an etchant is encountered when it is desired to etch one material selectively over another material. For example, F-containing plasmas can be used to etch silicon dioxide and nitride. However, if one desires to etch these materials selectively over silicon, plasma chemistry must be adjusted. Although adjusting plasma chemistry and conditions to achieve good selectivity remains an art, high selectivity is achievable and selective etching of oxides and nitrides over Si has been demonstrated. It has been empirically established that high selectivities can be achieved in F-deficient and apparently CF_3-rich plasmas. It is believed that Si etching is inhibited by formation of a polymer film on Si while the nitride and the oxide remain uncovered and etched.

Plasma etching of metals requires more care than etching of other materials since metals are readily oxidized with O_2 and water vapor to form stable oxides, which may act as an inhibitor as in the case of Al. In some cases where the metal oxide forms volatile chlorides or fluorides (Cr, W), O_2 may be intentionally added to the plasma to promote formation of an oxide. In etching some metals—for example, aluminum—an initiation or "lag time" is encountered at the beginning of plasma etching. This slow etching is due to a native oxide layer that must be removed before the underlying metal can be etched. The inhibiting properties of metal oxides can be used to one's advantage to promote anisotropic etching of holes and trenches. For example, oxidation can be delicately balanced by small additions of O_2 so that an inhibitor oxide forms on the sidewalls but not on the bottom of the features where the oxide can be removed by ion bombardment.

Polymeric organic films are usually present in almost all plasma etching processes because they are widely used as mask materials. The organic films are readily etched by O_2 or O_2-containing plasmas. Since O_2 is also used as an additive to plasmas for other purposes, selective etching of the film with respect to the mask may become an issue. Too much O_2 addition can result in mask etching. Plasma etching of organic films has been reviewed in detail by Hartney *et al.* (1989).

6. PLASMA PROCESS MONITORING: PLASMA DIAGNOSTICS

Discussions in the previous sections have established that plasma etching involves a wide variety of feed-gas compositions, and operating variables such as rf power, pressure, gas-flow rates, and reactor configurations. Although the black-box approach of changing these variables and observing the effects can be used in developing etching processes, it is far better and far more cost effective to identify and understand fundamental processes occurring in a gas discharge. To this end, a variety of plasma diagnostic techniques have been developed and used in determining the key plasma properties. These diagnostic techniques include various optical spectroscopy methods and mass spectroscopy to monitor gas-phase species, laser interferometry to measure, *in situ* and in real time, thicknesses of the films being etched, and Langmuir probes to determine the ion density and electron temperature. Some of these techniques are simple and robust enough to be used in manufacturing environment and have been used for process control. Because of its utility, plasma diagnostics in itself is a large field. Plasma diagnostic methods have been reviewed by Auciello and Flamm (1989). Below, some of the common diagnostic methods are summarized briefly. Of the diagnostic methods reviewed here, very few are actually used in manufacturing. This, however, has been changing rapidly in the last few years as the diagnostic equipment hardware becomes more inexpensive and robust. Still, some of the more complex diagnostics, such as laser-induced fluorescence and attenuated total-reflection Fourier-transform infrared spectroscopy, are only used in process development and research but not in manufacturing.

6.1 Optical Emission and Optical Diagnostic Techniques

Probably the most widely used diagnostic technique is optical-emission spectroscopy. In this technique, plasma-induced emission from the discharge is collected and analyzed in a spectrometer. Spectra from ultraviolet to near infrared have proven most useful for identifying the species in the plasma. Optical emission is well suited for species identification because the spectra, complex as they may be, provide a fingerprint of each atomic or molecular species. In addition, optical emission is a nonintrusive method and does not disturb the plasma. Optical emission can be collected as a function of spatial position and time, thus allowing one to follow spatiotemporal changes in the plasma. Obtaining concentrations of species in the plasma is more difficult since emission intensity depends not only on species concentration but also on electron temperature and density. An approximate technique called actinometry (Coburn and Chen, 1980; d'Agostino *et al.*, 1981) has been discovered to overcome this difficulty. Although actinometry does not provide absolute species concentrations, it has been used to map relative etchant concentrations as a function of position and operating parameters in a variety of reactors.

Optical emission can also be used to determine the end of etching of a film. This is commonly called "end-point" detection. The technique makes use of the fact that the etchant or etching-product concentrations undergo abrupt changes when the film being etched is removed. For example, in etching of a polysilicon film, Cl is depleted in the discharge by etching reactions. When the Si film is totally removed from the surface, a rise in Cl concentration will be observed because the reactions that eliminate Cl have been completed. Thus, by monitoring Cl concentration in Si etching, one can detect the end of the etching process. This technique is not unique to Cl and has been used in many plasma etching processes to detect the end point. Optical emission and other end-point detection techniques have been reviewed by Roland *et al.* (1985).

Optical emission has also been used to map out etchant concentrations in a plasma during etching (Economou *et al.* 1991). Since uniformity of etching is related to etchant distribution over the wafer, this method provides an *in situ* method for monitoring the uniformity.

Another optical technique that has been used to obtain the spatiotemporal variation of species concentration in plasma reactors is laser-induced fluorescence (LIF). In this technique, ground-state species are excited to a higher energy level by a laser and emission arising from the subsequent deexcitation to a lower energy level is detected. Since one has a control over the excitation and emission wavelengths, spectra obtained are simpler than plasma-excited emission and highly selective with respect to the species being monitored. However, hardware for these experiments is less robust and more expensive than in optical emission spectroscopy. Thus, LIF is not a suitable candidate for monitoring plasmas in a manufacturing environment but can be and has been used as a process development tool. Optical emission, laser-induced fluorescence, and other optical diagnostic techniques have been reviewed by Gottscho and Miller (1984) and by Donnelly in the book edited by Auciello and Flamm (1989).

6.2 Mass Spectroscopy

Mass spectroscopy, like optical emission, also provides a method for identification of species in a discharge and products in the effluent from a reactor. Mass spectroscopy is most commonly used to monitor vacuum integrity and process-gas purity. Mass spectroscopy does not give spatially resolved information but can be used for end-point detection in a similar manner to optical emission.

One use of mass spectroscopy in plasma etching research is in identification of species and ions bombarding the surfaces immersed in a plasma. This is done by making a sampling orifice on the substrate platen. The species incident onto the electrode pass though the sampling orifice and are analyzed by a mass spectrometer. There are many subtleties involved with these types of experiments; the technique is reviewed by Coburn (1989) and discussed in Auciello and Flamm (1989).

6.3 Langmuir Probes

A Langmuir probe is a thin wire or wires immersed in a plasma and biased with respect to a reference electrode. The current *I* collected by the probe as a function of the bias voltage *V* carries information about the electron and ion density, the electron temperature, and the plasma potential. Extraction of these values is done by using a model for current collection by the probe. For this reason, Langmuir-probe data interpretation may be difficult. Furthermore, Langmuir-probe measurements involve placing the probe into the plasma and therefore are intrinsically intrusive. To minimize the disturbance fast-injection probes have been invented in which the probe is pneumatically injected into the plasma and remains in the discharge only for a limited amount of time (≈100 ms). Langmuir probes can be used to collect spatially resolved information and are mostly used for determining the uniformity of ion density in a plasma. Langmuir-probe operation and theory have been reviewed in a number of publications (Auciello and Flamm, 1989; Swift and Schwar, 1969; Chen, 1965).

6.4 *In Situ* Film-Thickness Measurements: Laser Interferometry and Reflectometry

Monitoring plasma etching using optical reflection from surfaces has proven to be a very simple and useful technique. Optical reflection can be used for *in situ,* real-time film-thickness measurements and end-point detection. In these techniques, light from a source, such as a laser, is reflected off the etching surface and the reflected photons are collected using a detector. If the film being etched is an absorbing material such as metal, a change in the reflectivity will be observed at the interface between the film and the substrate because of a change in the refractive index. Although this is a useful method of determining the end point, films of known thickness must be etched in order to determine the etch rate.

Reflectivity measurement becomes even more powerful if the film is a nonabsorbing dielectric such as SiO_2 or Si_3N_4. In this case, the reflected intensity varies periodically as a function of the film thickness because of constructive and destructive interference produced by the reflections from the front and the rear (substrate–film interface) surfaces of the film. For this reason, this technique is called interferometry. As the film is etched and its thickness decreases, the reflected intensity undergoes oscillations with a period related to the film thickness. The etch rate can be calculated from the period of oscillations and the refractive index of the film. Interferometry and end-point detection using reflection-based techniques have been reviewed by Busta *et al.* (1979), Marcoux and Foo (1981), and Roland *et al.* (1985). More recently, interferometry has been extended to measure uniformity of etching in plasma reactors (Economou *et al.,* 1991; Dalton *et al.,* 1994) as well as substrate temperature (Donnelly and McCaulley, 1990).

6.5 Surface Diagnostic Techniques

Standard surface analysis techniques such as Auger and x-ray photoelectron spectroscopy provide a wealth of information on surfaces after etching but cannot be used *in situ* during plasma processing. Two *in situ* techniques have emerged to monitor surfaces: these are ellipsometry and attenuated total-reflection Fourier-transform infrared spectroscopy (ATR-FTIR). ATR-FTIR spectroscopy is one of the possible arrangements for performing surface infrared spectroscopy and is particularly well suited for studying surface adsorbates on nonabsorbing substrates with relatively high index of refraction such as semiconductors (Chabal, 1988). In ATR-FTIR spectrometry, infrared radiation from a Michaelson interferometer is focused onto one of the beveled edges of a semiconductor sample that is shaped as a trapezoid. The infrared beam is trapped inside the sample and undergoes multiple total internal reflections at the vacuum–semiconductor interface. The beam finally exits the sample from a second beveled edge. The transmitted beam is collected and Fourier analyzed. In this manner, an evanescent electric field is created at the vacuum–semiconductor interface and the interaction of this field with the surface adsorbates and thin films can be studied. ATR-FTIR spectroscopy provides the means to study the infrared absorption spectra of surface species and thin films. Use of ATR-FTIR in plasma processing has been reviewed by Aydil *et al.* (1994).

In ellipsometry, the substrate surface is illuminated by light with a known polarization and the change in polarization upon reflection is measured. The change in polarization provides information about the substrate and its overlayers. The optical properties can in turn be related to the nature of the overlayers and thus ellipsometry can provide information on surface processes. *In situ* ellipsometry has been used from the ultraviolet to the infrared region of the spectrum to diagnose surfaces exposed to plasmas (Drevillon, 1988). Principles of ellipsometry are reviewed in a collection of papers by Azzam (1991) and Azzam and Bashara (1977).

7. SUMMARY

Plasma etching is a crucial process for patterning thin films, particularly in manufacturing of integrated circuits and electronic devices. This article describes the basic principles behind plasma etching and properties of glow discharges as they relate to thin-film etching. Plasma etching is a very fast-evolving field and any introductory article is bound to be dated. This article is an attempt to assimilate the information currently available on plasma etching and present a framework within which plasma etching can be viewed. This article and the literature cited should serve as an entry point to the field of plasma etching.

GLOSSARY

Actinometry: An approximate calibration technique used to determine relative concentration of species in a plasma using optical emission spectroscopy.

Anisotropic Etching: Etching that proceeds at a higher rate in a direction normal to the substrate surface.

End Point: End of etching of a film.

Etchant: Collective name given to the reactive radicals, molecular fragments, and ions that participate in etching in a plasma.

Glow Discharge: A term used synonymously with low-pressure plasmas. It implies nonequilibrium among the ions, electrons, and neutrals.

Integrated Circuits (ICs): A collection of solid-state electronic devices built on a semiconductor substrate and interconnected together to form a working unit capable of performing complex electronic functions.

Ion-Assisted Etching: Etching that results from the combined synergistic action of bombardment by ions and reactive radicals in a plasma.

Isotropic Etching: Etching that proceeds at equal rates in all directions into the film or substrate.

Loading: A decrease in etchant concentration in a plasma due to depletion by etching reactions.

Overetching: Etching for a time longer than required to remove a given thickness.

RIE: Reactive ion etching.

Selective Etching: Preferential etching of one material over another.

Selectivity: Ratio of etch rates of two materials. Usually one material is the material to be etched and the other is a mask.

Sheath: A thin, dark, space-charge region that forms next to any surface that is brought in contact with a plasma.

INTRODUCTION

The most common type of plasma is a gas of such high temperature that it is ionized; that is, an appreciable number of atoms have been stripped of at least one electron and have become positive ions (Plates 1 and 2). Because of its free electrical charges, a plasma differs from ordinary gases because it is subject to electric and magnetic forces. Indeed, the science of plasma physics mostly concerns those plasmas in which the usual molecular forces are negligibly small compared with the electromagnetic forces. Plasma has been called the "fourth state of matter," after solid, liquid, and gas. All matter goes into this electrified state above temperatures of 10 000 K or so, at which point the fastest particles in the thermal distribution undergo collisions energetic enough to ionize an atom.

Plasmas can also exist at room temperature in metals and semiconductors in which there are free charge carriers. At the other extreme, in the vacuum of outer space, hydrogen atoms are ionized by photoionization by starlight. Once ionized, the ions and electrons do not recombine easily because, at a density of about 1 ion/cm^3, collisions are rare. Consequently, perhaps 99% of all the matter in the universe is in the plasma state. On Earth, however, the temperatures and atmospheric densities that are consistent with life cannot support plasmas, and these can be studied only in laboratory vacuum chambers.

Within the framework of physics and engineering, plasma physics is an interdisciplinary science that affects many other fields. It is an extension of electromagnetics that can treat conducting gases that exist in stellar interiors and in nuclear-fusion devices constructed to reproduce the conditions there. It describes the motion of charge carriers in semiconductor devices and in the machines used to make them. It is used in the design of gas lasers and microwave generators. Plasma physics is essential to the understanding of the behavior of matter under conditions of high energy density, such as in quasars and pulsars, and in targets bombarded by intense laser or particle beams. It has applications even to chemistry through the use of electrons to form new compounds and polymers. The development of femtosecond lasers to probe chemical and surface reactions in real time will be aided by the knowledge of how intense radiation interacts with matter in the plasma state.

Plasmas are more complicated than ordinary fluids for several reasons. First, they are subject to long-range electromagnetic forces. Second, plasmas have a particulate nature, unlike fluids, which are continuous media. At high temperatures, collisions are so rare that plasmas can be treated as collisionless fluids; and in the absence of randomizing collisions, the individual particles of the fluid must be taken into account. Third, since the charged-particle motions are greatly affected by magnetic fields, the plasma is a highly anisotropic dielectric and supports a rich variety of possible wave motions.

Though plasmas have been known for a much longer time, plasma physics as a science did not begin to advance rapidly until the late 1950s, when the search for an infinite energy source through controlled hydrogen fusion began. The principles of plasma science are now considered to be indispensable in many other disciplines besides controlled fusion: in astrophysics and space physics, in particle accelerators and radiation generators, in solid-state devices and lasers, in the understanding of turbulence and chaos in nonlinear dynamics, and, most recently, in manufacturing sciences.

1. HISTORY

Plasma physics had its beginnings in two disparate disciplines: gaseous electronics and cosmic electrodynamics. In the 1920s, Irving Langmuir and his colleagues, in their studies of gas discharges used in electron tubes, laid out the principles of plasma measurements with the electrostatic probes that bear his name. In the 1930s, Chapman and Cowling (1939) worked out the theory of nonuniform gases, and Mott and Massey (1933) contributed the theory of atomic collisions. During World War II, research on isotope separation using plasma discharges at Los Alamos led David Bohm to invent the infamous "Bohm diffusion" law whose origin is still shrouded in mystery. Gaseous electronics took a leap after the war as electrical engineers at Massachusetts Institute of Technology and Stanford University competed to understand beam–plasma interactions and to develop better klystrons and other microwave generators for radar. The theory of radio-wave propagation in the ionosphere was worked out simultaneously by V. L. Ginzburg (1964) and others in Russia. Experiments were still limited to Langmuir-probe measurements in weakly ionized discharges. It was also in the late 1950s and early 1960s that the other stem of plasma physics began its growth. H. Alfvén (1950), S. Chandrasekhar (1961), and other astrophysicists became aware of the role of plasmas in deep space and worked out the principles of magnetohydrodynamics, now known as hydromagnetics, including the discovery of "Alfvén waves." Astronomers tended to view plasmas as conductive fluids like mercury, whereas the gaseous electronics community treated plasmas from the particle point of view. These opposing views of the dual nature of plasmas were not merged until the era of nuclear-fusion research.

Following World War II, dense, hot plasmas were produced by the "pinch" effect at the Harwell military laboratories in England; these experiments foreshadowed the scramble for fusion power. Attempts to produce thermonuclear reactions in the laboratory and thus to "tame the H-bomb" were started in England, in Russia, and at four sites in the United States: at the national laboratories at Livermore, Los Alamos, and Oak Ridge, and at Princeton University. All of these programs were classified. The project at Princeton was code-named Project Matterhorn by its mountain-climbing leader, astrophysicist Lyman Spitzer, Jr. The leader of the Los Alamos Project was James Tuck, and this connection to Friar Tuck of Robin Hood fame led to the code name "Project Sherwood" for the U.S. fusion program. Classification was removed and international cooperation began at the 1958 Atoms for Peace conference in Geneva, where each nation displayed its best results. The United States unveiled two mirror-confinement programs (at Livermore and Oak Ridge), a pinch program at Los Alamos, and a "Stellarator" program at Princeton. The United Kingdom exhibited a large toroidal pinch called "Zeta," which produced copious neutrons, but which was later discredited when the neutrons were found to be of nonthermonuclear origin. The Russians exhibited an unglamorous piece of hardware that they dubbed a "tokamak," a Russian acronym for "toroidal magnetic chamber." This concept not only survived but has become the dominant one by far.

Spurred by the race for controlled fusion, plasma physicists progressed rapidly on both theoretical and experimental fronts. To generate power from fusing heavy hydrogen into helium requires heating a plasma to over 10^8 K and confining it for longer than 1 s. The principles of confining plasmas with the magnetic walls needed to withstand such temperatures were worked out on the basis of classical physics concepts for both closed (toroidal) and open (mirror) systems, but the unexpectedly fast leakage out of such magnetic "traps" or "bottles" was a huge problem. To solve it required going back to basic principles and establishing a new science, which barely resembles its precursors. The instabilities that a magnetized plasma can support required new theoretical and experimental methods. An elegant variational-principle formulation of the problem in a paper by Bernstein *et al.* (1958) is generally credited with establishing the respectability of plasma physics as a new and viable field. Also in 1958, the *Physics of Fluids* was established as the plasma journal, and the Division of Plasma Physics was founded in The American Physical Society to give plasma physics a home.

When the exploration of space started in the early 1960s, a need for plasma diagnostics arose, and Langmuir probes were quickly adapted for the Earth's ionosphere and the interplanetary environment. Exploration of the plasmas in the magnetospheres of the planets, as well as of the solar wind and other solar phenomena, have greatly expanded our knowledge of the solar system in the past three decades. The advent of radio astronomy has led to observations of plasma phenomena in deep space. Most recently, the importance of dusty plasmas has been realized in the understanding of comet tails and planetary rings.

In the early 1970s, high-power pulsed lasers were invented, and the concept of inertial confinement was born. The idea was to do away with magnetic fields altogether, using laser beams to compress a small pellet of deuterium–tritium fuel to 10^4 times solid density, and hence to speed up the fusion reaction time to the order of picoseconds. In that case, the inertia of the imploding pellet would confine the fuel long enough for fusion to occur. Unfortunately, the unexpected effects of plasma physics could not be avoided. When intense laser light strikes a solid object, the surface material is immediately ionized into a plasma cloud. A new type of instability, called a parametric instability, was driven by the laser beam; and this had the effect of reflecting the laser light before it could reach the solid surface of the pellet. Inertial confinement spawned a new branch of plasma physics, which required extensive development of nonlinear and computational techniques. Simultaneously, it was found that intense electron and proton beams of order 1 MA at 1 MV could be produced by storing electrical energy in capacitor banks and discharging it into a diode in a short pulse. Pulsed power became yet another branch of plasma physics, permitting the study of matter subject to terawatts of power, and leading to the invention of new plasma switches and x-ray generators.

Until recently, most plasma-physics research fell into one of the four areas described above: magnetic fusion, inertial fusion, space plasma physics, and pulsed power. In the 1990s, the use of partially ionized plasmas in manufacturing began to expand rapidly, along with the prevalent use of semiconductor ULSI (ultralarge-scale integrated) circuits and personal computers. Plasma etching and deposition are essential in the fabrication of computer chips with millions of internal features. It is anticipated that the production of flat-panel displays will ultimately also depend on plasma processing. Surface hardening of turbine blades, tools, construction materials, medical prostheses, and so forth is already a large commercial application of plasma physics. Plasma treatment of plastics and fibrous materials can be used, for instance, to make plastic containers more leakproof; to make paint adhere to plastic bags, clothing, currency, and automobile parts; to make fabrics absorb or repel water; and to tailor the refractive indices of optical fibers. In summary, though the original impetus for developing plasma physics was the lofty goal of an inexhaustible energy source for mankind, fusion power plants will not be commercially viable for several more decades. In the near future, however, plasma physics is likely to have a large impact on our daily lives because of its utility in the manufacture of a diverse variety of common materials.

2. BASIC PLASMA PHENOMENA

2.1 Methods of Treatment

2.1.1 Fluid Description At the simplest level, a plasma can be treated as an electrified fluid, without regard for its particulate nature. A common approach is to consider the positive ions and negative electrons of the plasma to be two interpenetrating fluids, which interact via the electric and magnetic field that they each generate in their motions (Chen, 1983). The equation of motion for fluid elements of each species j can be written

$$m_j n_j\left(\frac{\partial \mathbf{v}_j}{\partial t} + \mathbf{v}_j \cdot \nabla \mathbf{v}_j\right) = q_j n_j(\mathbf{E} + \mathbf{v}_j \times \mathbf{B}) - \nabla p_j - m_j n_j \nu_{jk}(\mathbf{v}_j - \mathbf{v}_k), \quad (1)$$

where q_j and m_j are the charge and mass of species j; n_j, p_j, and $\mathbf{v}_j$ are the fluid density, pressure, and velocity of that species; and ν_{jk} is its average collision frequency with species k. The pressure p_j is given by $p_j = \gamma_j n_j K T_j$, where K is Boltzmann's constant, T_j is the temperature of the fluid in kelvins, and γ_j is an adiabatic constant equal to 3, 2, or $\frac{5}{3}$ for one-, two-, or three-dimensional plasmas, respectively. For constant T_j, γ_j is unity. A plasma can have a different temperature and even a different value of γ for each species. In a fully ionized plasma, j takes on the values i and e, while k takes the opposite value. In a partially ionized plasma with less than about 10% ionization fraction, collisions with the neutral atoms are dominant; then ν_{jk} is ν_{io} or ν_{eo}, the collision rate with the neutral gas. Each species also follows the equation of continuity,

$$\frac{\partial n_j}{\partial t} + \nabla\cdot(n_j\mathbf{v}_j) = 0. \tag{2}$$

A set of Eqs. (1) and (2) can be written for each species of positive or negative ions. The electric and magnetic fields **E** and **B** are governed by the vacuum Maxwell's equations:

$$\epsilon_0\nabla\cdot\mathbf{E} = \sigma, \tag{3}$$

$$\nabla\times\mathbf{E} = \frac{\partial\mathbf{B}}{\partial t}, \tag{4}$$

$$\nabla\cdot\mathbf{B} = 0, \tag{5}$$

$$\nabla\times\mathbf{B} = \mu_0\left(\mathbf{J} + \epsilon_0\frac{\partial\mathbf{E}}{\partial t}\right). \tag{6}$$

Together with the equation of state for p_j given above, the system of equations is closed by defining the plasma charge and current as

$$\sigma = \sum_j n_j q_j, \quad \mathbf{J} = \sum_j n_j q_j \mathbf{v}_j. \tag{7}$$

The charged-particle motions generate the internal electromagnetic fields, and the fields move the particles; thus, Eqs. (1)–(7) must be solved self-consistently. It is also possible to describe the plasma as a dielectric medium with a susceptibility χ and a permittivity $\epsilon = \epsilon_0(1 + \chi)$ that incorporate the effects of the plasma charges and currents, as given by Eqs. (1) and (2). The terms **J** and σ are then omitted from Eqs. (3) and (6), and ϵ_0 replaced by ϵ. Plasmas in a magnetic field are anisotropic, and ϵ is then a rather complicated dielectric tensor. It is a characteristic of plasmas that χ is often negative. The electromagnetic quantities **D** and **H** need not be defined and are generally not used in plasma physics.

An alternative description of a plasma is that of a single conducting fluid. The single-fluid, or MHD (magnetohydrodynamic), equations of motion are linear combinations of Eq. (1) for electrons and Eq. (1) for a single species of ions with charge number $Z = 1$, with a number of terms neglected:

$$\rho\frac{\partial\mathbf{v}}{\partial t} = \mathbf{J}\times\mathbf{B} - \nabla p, \tag{8}$$

$$\mathbf{E} + \mathbf{v}\times\mathbf{B} = \eta\mathbf{J}, \tag{9}$$

where the single-fluid density ρ, velocity $\mathbf{v}$, pressure p, and resistivity η are defined by

$$\rho = \sum_{j=i,e} m_j n_j, \quad \mathbf{v} = \sum_{j=i,e} n_j M_j \mathbf{v}_j/\rho,$$
$$J = \sum_{j=i,e} n_j q_j \mathbf{v}_j, \quad p = p_i + p_e, \quad \eta = m_e\nu_{ei}/n_e e^2. \tag{10}$$

Equation (9) is known as the *generalized Ohm's law.* Equations (2) for ions and electrons are replaced by

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\mathbf{v}) = 0, \quad \frac{\partial\sigma}{\partial t} + \nabla\cdot\mathbf{J} = 0. \tag{11}$$

Note that the quasineutrality condition $n_i = n_e$ used here is almost always a good approximation because only a small difference $\sigma = e(n_i - n_e)$ is enough to create a sizable field **E**. The single-fluid equations are convenient for resistive plasmas, in which the dominant collisions are between ions and electrons, but the equations are less accurate than the two-fluid equations (for instance, the Hall current is neglected in the generalized Ohm's law), and multiple species are not easily handled.

2.1.2 Kinetic Description The fluid description is valid when collisions are frequent enough to maintain a Maxwell–Boltzmann velocity distribution for each species, so that a temperature T can be defined. Fluid theory is also a good approximation for motions perpendicular to a strong magnetic field even when collisions are rare. In the general case, deviations from a Maxwellian distribution are possible, and one has to solve for the distribution function $f_j(\mathbf{r},\mathbf{v},t)$ for each species. A function of seven independent scalar variables, $f_j(\mathbf{r},\mathbf{v},t)$ is governed by the *Boltzmann equation*

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\nabla f + \frac{q}{m}(\mathbf{E} + \mathbf{v} \times \mathbf{B})\cdot\frac{\partial f}{\partial \mathbf{v}} = \left(\frac{\partial f}{\partial t}\right)_c, \tag{12}$$

where $(\partial f/\partial t)_c$ is a collision term. "Collisionless" plasmas are hot enough that this term can be set equal to zero, in which case Eq. (12) is called the *Vlasov equation.* Such "Vlasov plasmas" have been studied intensively by plasma theorists (Nicholson, 1983). Other forms of the collision term are the *Fokker–Planck* term, which describes binary Coulomb collisions, and the *Krook* term, which is used to treat collisions with a neutral species. A simplified form of Eq. (12) in which the Larmor gyrations (cf. Sec. 2.2.3) have been averaged and replaced by the motion of a guiding center is called the *drift-kinetic equation.*

Since the integral of $f(\mathbf{v})$ over all velocities is just the density, the continuity equation [Eq. (2)] can be recovered by integrating the Vlasov equation. The first moment, found by multiplying Eq. (12) by $\mathbf{v}$ and then integrating, yields Eq. (1). The second moment gives the heat-flow equation, and so on; but the process is usually truncated after the first moment. Solutions of Eq. (12) with Maxwell's equations reveal two main features not found in Eqs. (1) and (2). First, electric fields can distort $f(\mathbf{v})$ away from a Maxwellian in the direction parallel to a magnetic field or when there is no magnetic field. Second is the finite–Larmor-radius (FLR) effect, in which the thermal motions of the particles cause them to react to the average field that they experience during a Larmor, or cyclotron, orbit. The fluid equation, Eq. (1), correctly describes the Larmor orbits of *cold* fluids driven by electric fields, but the pressure term ∇p_j does not include all the thermal effects; in particular, the FLR effect is contained in the viscosity tensor, which has been omitted from Eq. (1).

Though plasmas can often be treated as fluids, plasma physics differs from hydrodynamics because non-Maxwellian distributions sometimes occur, which require the kinetic treatment described above; it differs also from electromagnetics because the details of the dielectric tensor ϵ are treated from the particulate point of view. Indeed, the complex motions of charged particles in electric and magnetic fields support a rich variety of wave phenomena that do not occur in ordinary fluids or dielectrics.

2.1.3 Computer Simulation Small-amplitude waves and instabilities can be analyzed by linearizing the plasma equations given above. That is, each fluctuating quantity—for instance, the fluid density n—is divided into an undisturbed, time-independent part and an oscillating part: $n = n_0 + n_1$, where n_1 is assumed to be small relative to n_0. When higher-order terms containing more than one power of fluctuating quantities are discarded, the resulting set of linear equations can be solved to give the possible wave modes. These linear modes can be superimposed without affecting one another. Large-amplitude waves, and instabilities that have grown large, however, are difficult to treat with these equations. In the early years of plasma-physics history, there was a gap between the small-amplitude phenomena accessible by theory and the large-amplitude phenomena observed experimentally. The advent of high-speed computers provided the Rosetta Stone, particle simulation (Dawson and Lin, 1984), needed to relate experiment to theory.

In computer simulation (Hockney and Eastwood, 1988; Birdsall and Langdon, 1991), a large number of particles—typically 10^4 but as large as 10^6—are placed in a "box," and the position and velocity of each ion and electron are recorded in the memory. The **E** and **B** fields caused by these particles are then found from Maxwell's equations by fast Fourier transform. The particles are then allowed to move in response to these fields during a short time step, and the fields are then recalculated with the new positions and velocities. Thus, the response of the plasma to applied forces or unstable initial conditions can be followed step by step from threshold to turbulence regardless of the amplitudes of the perturbations. The boundaries of the "box" can be made to absorb particles, to reflect particles, or to be reentrant or periodic so that particles leaving one side reappear on the opposite side. To facilitate computation, the box is divided into a grid of cells, and a particle that ends up in any particular cell is placed at the center of that cell for the next time step. Such a scheme is called a particle-in-cell, or PIC, code. Since each computer particle represents many real particles, it cannot be given the full electric charge of all those particles, for then the Coulomb collisions between particles would be unduly magnified. These collisional effects have to be properly scaled.

The number of particles, cells, and time steps in the simulation is limited only by the speed and memory of the computer. Programs range from those that can be run on personal computers (PCs) to those that require many hours or days on the most advanced supercomputers. Initially, computer simulation was limited to one-dimensional systems, in which each "particle" was merely a charge sheet. Later, two-dimensional grids could be used, with axes corresponding, for instance, to (x,y) in a Cartesian system or (r,z) in a cylindrical system. A common compromise is a so-called $2\frac{1}{2}$D computation, in which two components of position and all three components of velocity are retained. Fully three-dimensional simulations are now possible. Once a computational run has been finished, it is easy to do diagnostics on the plasma. For instance, one can cull from the data the distribution functions as a function of space or time, the frequency or wavenumber spectrum of the fluctuations, the conservation of energy and momentum, or the direction of the Poynting vector. The results of such computer "experiments" can be used to compare with real measurements, but plasma simulations can be formulated and interpreted only with the insight gained from an intimate knowledge of analytic theory (see SIMULATION AND MODELING BY COMPUTER).

2.2 Characteristics of Plasma Behavior

2.2.1 Quasineutrality and Debye Shielding Plasmas are characterized by an overriding tendency to be neutral. The numbers of positive and negative charges per unit volume cannot be exactly equal, of course; else there would be no electric fields at all. Since the opposing charge densities need differ only by, say, one part per million to create the electric fields normally observed in a plasma, for all intents and purposes these densities can be treated as being equal. This approximation, known as "quasineutrality," is an important concept in plasma physics. The consequences of quasineutrality may not be apparent to physicists from other disciplines. For instance, at frequencies low enough that the heavy and light particles can move together, **E** cannot be calculated from Poisson's equation, Eq. (3), since $n_i - n_e$ is not known accurately enough; rather, Eqs. (1) and (2) determine the value of **E** because the ions and electrons must move in such a way as to make their densities track each other. The density n_i or n_e is simply known as the plasma density n.

A plasma shields itself from external fields by *Debye shielding*. When a positively charged object is placed in a plasma, the mobile electrons are attracted to it and form an electron cloud covering the charge; similarly, a negative object will repel electrons, leaving an ion cloud for shielding. The thickness of these clouds is of the order of the Debye length λ_D, defined by

$$\lambda_D^2 = \epsilon_0 KT_e/ne^2. \tag{13}$$

The shielding is not perfect, however, since electrons near the edge of the cloud can escape because of their thermal energies; consequently, electric potentials of order $\frac{1}{2}KT_e$ can exist in the plasma. [The temperatures of a plasma are specified by the value of KT in electron volts (eV), where 1 eV corresponds to 11 600 K. Thus, the average thermal energy of the electrons in a plasma with $KT_e = 10$ eV is $\frac{3}{2}KT_e$, or 15 eV.] Debye shielding also occurs at the walls confining a plasma, where an ion-rich sheath of about $5\lambda_D$ thickness forms to repel electrons. The Coulomb barrier of the sheath is just high enough to make the escaping electron flux equal to the ion flux, so that no net charge is lost. Unless the plasma is extremely tenuous, these sheaths are much thinner than the dimensions of the plasma, so that the interior is quasineutral.

2.2.2 Characteristic Frequencies and Velocities When the electrons of a plasma are displaced from their equilibrium positions, the ions left behind draw them back with an electric field. The electrons then overshoot and oscillate about their equilibrium positions with a characteristic frequency ω_p, called the *plasma frequency,* which depends on the density of electrons as well as their charge and mass:

$$\omega_p = (ne^2/\epsilon_0 m)^{1/2}\ \text{rad/s}, \quad f_p = \omega_p/2\pi\ \text{Hz}. \tag{14}$$

An *ion plasma frequency* ω_{pi} is similarly defined with the ion charge and mass but is not a natural oscillation frequency because the ions are shielded by Debye shielding.

When a background magnetic field B is present, the ions and electrons gyrate in circular orbits, called Larmor orbits, in a plane perpendicular to the field lines. The frequency of these gyrations is the cyclotron frequency ω_c, given for species j by

$$\omega_{cj} = |q_jB/m_j|, \quad f_{pj} = |q_jB/2\pi m_j|, \tag{15}$$

where q_j is $-e$ for electrons and Ze for ions. The radius of the orbit—the *Larmor radius*—is given by

$$r_L = v_\perp/\omega_c = mv_\perp/|q|B, \tag{16}$$

where $v_\perp$ is the velocity component perpendicular to **B**. For a Maxwellian distribution, the root mean square value of $v_\perp$ is used to evaluate the average r_L, where

$$\langle v^2\rangle = 3KT/m, \quad \langle v_\perp^2\rangle = 2KT/m. \tag{17}$$

Charged particles are constrained from moving freely across **B** and act as if they were tied to the field lines. When these mass-loaded field lines are displaced, the disturbance propagates along the field with a characteristic velocity known as the *Alfvén speed* v_A:

$$v_A = B/\sqrt{\mu_0\rho}. \tag{18}$$

This behavior can occur only if the field B is strong enough to constrain the particles—that is, if the plasma pressure is sufficiently small. The critical quantity is the ratio between plasma pressure and magnetic field pressure, known as "beta":

$$\beta = \frac{p_i + p_e}{B^2/2\mu_0}. \tag{19}$$

Laboratory plasmas have $\beta \ll 1$, but gravitationally confined plasmas in space may have $\beta \geq 1$.

Sound waves in a plasma, called *ion-acoustic waves,* travel at a characteristic velocity v_s given by

$$v_s^2 = (ZKT_e + \gamma_i KT_i)/m_i. \tag{20}$$

Unlike sound waves in air, this velocity does not vanish when $KT_i = 0$. The wave motion is sustained not by pressure fluctuations but by the electric fields, of order KT_e, which extend beyond the Debye clouds shielding the ion-density fluctuations.

2.2.3 Particle and Fluid Drifts In a strong magnetic field **B**, the parallel motions of the particles are unaffected by **B**, while the perpendicular motions can be considered to be circular Larmor gyrations about a moving center, called a *guiding center.* In crossed electric and magnetic fields, the guiding center drifts with a velocity $\mathbf{v}_E$ given by (Kruskal, 1965, p. 67)

$$\mathbf{v}_E = \mathbf{E} \times \mathbf{B}/B^2. \tag{21}$$

This velocity is the same for all species, and this is true to the extent that the FLR effect can be neglected. If we replace the force $q\mathbf{E}$ used in deriving Eq. (21) with a general force **F**, the resulting guiding-center drift $\mathbf{v}_f$ would be in opposite directions for ions and electrons:

$$\mathbf{v}_f = \mathbf{F} \times \mathbf{B}/qB^2. \tag{22}$$

If the magnitude of B is nonuniform, the guiding center suffers a *gradient-B drift* $\mathbf{v}_{\nabla B}$:

$$\mathbf{v}_{\nabla B} = \pm v_\perp r_L\, \mathbf{B} \times \nabla B/2B^2, \tag{23}$$

where ± indicates the sign of the charge. If the direction of **B** is not constant, one can define a local vector radius of curvature $\mathbf{R}_c$ pointing toward the center of curvature; the guiding center then has a *curvature drift* $\mathbf{v}_R$ given by

$$\mathbf{v}_R = \frac{mv_\parallel^2}{q}\frac{\mathbf{R}_c \times \mathbf{B}}{R_c^2 B^2}. \tag{24}$$

When the electric field varies in time, the Larmor gyrations are disrupted, and the guiding center suffers a *polarization drift* $\mathbf{v}_p$ given by

$$\mathbf{v}_p = \pm\frac{1}{\omega_c B}\frac{d\mathbf{E}}{dt}. \tag{25}$$

In fluid theory, the drifts of the fluid elements are similar to the guiding-center drifts, but with some differences. The drifts $\mathbf{v}_E$, $\mathbf{v}_R$, and $\mathbf{v}_p$ are the same; but the gradient-B drift $\mathbf{v}_{\nabla B}$ cancels out when summed over the particles in a fluid element. The summation process gives rise to a fluid drift, called the *diamagnetic drift* $\mathbf{v}_D$, which does not exist for particles (Spitzer, 1967):

$$\mathbf{v}_D = \mathbf{B} \times \nabla p/qnB^2. \tag{26}$$

Since $\mathbf{v}_D$ is in a different direction for ions and electrons, there is a net *diamagnetic current* $\mathbf{j}_D$ whose $\mathbf{j} \times \mathbf{B}$ force is just sufficient to keep the ∇p force from pushing the plasma across $\mathbf{B}$, as seen from Eq. (8).

Because of the electrons' high mobility along $\mathbf{B}$, the net parallel force on the electron fluid must be close to zero except at high frequencies. The dominant terms in Eq. (1) are then

$$0 = en_e\nabla_\parallel\phi - KT_e\nabla_\parallel n_e, \tag{27}$$

where we have taken $E_\parallel = -\nabla\phi$ and $\gamma_e = 1$. For $n_e = n_0 + n_1$, integration of Eq. (27) gives the *Boltzmann relation*

$$n_1 = n_0 \exp(e\phi/KT_e), \tag{28}$$

which has wide applicability and is useful for relating density to potential fluctuations.

2.2.4 Adiabatic Invariants

In addition to energy and momentum, the action of a particle in periodic motion is conserved, permitting a simple way to describe the motion of gyrating particles in slowly varying fields (Northrop, 1963; Kruskal, 1965, p. 91). The first such *adiabatic invariant* is the magnetic moment μ, defined by

$$\mu = mv_\perp^2/2B. \tag{29}$$

This quantity, equal to the magnetic flux enclosed in a Larmor orbit, remains constant if B changes in time or if the guiding center moves to a region of different B. The invariance of μ is broken if the field seen by the particle changes on the time scale $1/\omega_c$ or if B varies spatially over a Larmor radius. The second adiabatic invariant J, defined by

$$J = \int v_\parallel ds, \tag{30}$$

concerns the motion of a gyrating particle between two "magnetic mirrors" (Fig. 1). When such a particle moves into a region of stronger B, conservation of μ causes $v_\perp$ to increase. Since $v_\parallel$ must then decrease to conserve energy, the particle is reflected. If the bounce frequency of a particle trapped between two regions of strong field, such as the polar regions of the Earth's magnetic field, is larger than the rate of change of B, the integral J evaluated between turning points is conserved. Other adiabatic invariants involve slower periodic motions and are rarely used.

2.2.5 Resistivity and Diffusion

2.2.5.1 Weakly Ionized Plasmas. Driven by a pressure gradient or an electric field, electrons and ions in a weakly ionized discharge have their velocities along $\mathbf{B}$ limited by collisions with the constant neutral-gas background. For the isothermal case $\gamma_j = 1$, solution of Eq. (1) with the $\mathbf{v} \times \mathbf{B}$ term and the left-hand side set equal to zero gives the particle flux (Chen, 1983):

$$n_j v_{\parallel j} = \mu_j n_j E_\parallel - D_{\parallel j}\nabla_\parallel n_j, \tag{31}$$

where

$$\mu_{\parallel j} = q_j/m_j\nu_{0j}, \quad D_{\parallel j} = KT_j/m_j\nu_{0j} \quad (j = i,e), \tag{32}$$

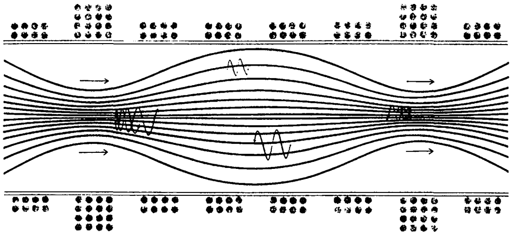

FIG. 1. Charged particles gyrate around magnetic field lines and are trapped between strong-field regions by the magnetic mirror effect, which results from the adiabatic invariant μ. The second adiabatic invariant, J, controls the frequency of the longitudinal bounce motion between mirrors (Fowler and Post, 1966).

μ is the mobility, and D the diffusion coefficient. In the direction perpendicular to **B**, inclusion of the $\mathbf{v} \times \mathbf{B}$ term in Eq. (1) results in

$$n_j\mathbf{v}_{\perp j} = \mu_j n_j \mathbf{E}_\perp - D_{\perp j}\nabla_\perp n_j + \frac{\mathbf{v}_E + \mathbf{v}_{Dj}}{1 + \nu_{0j}^2/\omega_{cj}^2}, \qquad (33)$$

where

$$\mu_{\perp j} = \frac{\mu_{\parallel j}}{1 + \omega_{cj}^2\tau_j^2}, \quad D_{\perp j} = \frac{D_{\parallel j}}{1 + \omega_{cj}^2\tau_j^2}, \quad \tau_j = \frac{1}{\nu_{0j}}, \qquad (34)$$

and $\mathbf{v}_E$ and $\mathbf{v}_D$ are given by Eqs. (21) and (26). We see that $\mathbf{v}_E$ and $\mathbf{v}_D$ are slowed by collisions, whereas cross-field mobility and diffusion exist only by virtue of collisions.

These relations have a simple physical meaning. Ordinary diffusion is a random walk with a step length $L = \lambda_m$, the mean free path, and mean time $\tau = 1/\nu$ between steps. For particles of velocity v, $\lambda_m = 1/n_n\sigma(v) = v\tau$, where n_n is the neutral density. The collision frequency ν_0 averaged over velocities is thus $\nu_0 = n_n\langle\sigma v\rangle$. *The diffusion coefficient is then* $\mathbf{D} = \mathbf{L}^2/\tau = v^2\tau^2/\tau \approx KT/m\nu_0$. Mobility is like diffusion except that the force $qn\mathbf{E}$ takes the place of the pressure force $KT\nabla n$, so that the coefficient of **E** should be q/KT times the coefficient of $\nabla n/n$, as in Eq. (32). For perpendicular diffusion across a magnetic field, a collision displaces the guiding center a distance of order r_L or λ_m, whichever is smaller. Taking $L^{-1} = r_\text{L}^{-1} + \lambda_m^{-1}$ gives the reduction factors in Eq. (34) for perpendicular transport.

Since ions and electrons have different transport coefficients, an *ambipolar electric field* will develop to retard the faster species and accelerate the slower species. In the direction along **B**, electrons will escape rapidly, leaving behind a positive charge the field of which equalizes the electron and ion escape rates to maintain quasineutrality. The net diffusion rate, found from Eqs. (31) and (32), is described by an *ambipolar diffusion coefficient* D_a:

$$D_a = \frac{\mu_i D_e + \mu_e D_i}{\mu_i + \mu_e}. \qquad (35)$$

For diffusion across **B**, the same formula obtains if the definitions in Eq. (34) are used. In this case, the ambipolar field is reversed, since ions generally escape faster than electrons across **B**. In the general case, diffusion in a given density gradient is described by the equation $\nabla\cdot(n\mathbf{v}_i) = \nabla\cdot(n\mathbf{v}_e)$, with the parallel and perpendicular fluxes given by Eqs. (31) and (33), respectively. Though this equation is not separable into perpendicular and parallel components, in principle the solution will yield the ambipolar potential ϕ, which is the only unknown in the problem. Unfortunately, the problem is not well posed because of the *short-circuit effect.* In plasmas whose length along **B** is not extremely large relative to the radius, electrons escaping along field lines can short-circuit the radial ambipolar field through the sheaths at the ends. The ambipolar fields in the axial and radial directions then depend on the details of the end conditions.

2.2.5.2 Fully Ionized Plasmas. Because of detailed balance, Coulomb collisions between like particles—for instance, electrons with electrons—cause neither a drag of the fluid motion along **B** nor a net diffusion of the fluid across **B** unless there is a large gradient on the scale of r_L. Collisions between electrons and ions cause friction between the two fluids, giving rise to a resistivity $\eta_\parallel$ for current flow along **B**. The value of $\eta_\parallel$, called the *Spitzer resistivity* (Spitzer, 1967), to be used in Eq. (9) for $E_\parallel$, is approximately

$$\begin{aligned}\eta_\parallel &= 5.2 \times 10^{-5} Z \ln\Lambda/T_e^{3/2}(\text{eV})\ \Omega\text{m},\\ \ln\Lambda &\approx 31 - \ln(n_e^{1/2}/T_e).\end{aligned} \qquad (36)$$

Here Z is the ion charge number, n_e is in m^{-3}, and T_e is in electron volts. The quantity $\ln\Lambda$, called the *Coulomb logarithm,* is unique to plasma physics (Spitzer, 1967). In averaging the scattering of electrons by ions over all velocities and impact parameters h, one chooses the minimum value of h to be that for a 90° deflection (to avoid the singularity at $h = 0$), and the maximum value of h to be λ_D, to account for Debye shielding. Λ is the ratio $h_\text{max}/h_\text{min}$ and $\ln\Lambda$ varies so slowly that it can be taken as 10 in most cases. The Spitzer resistivity is nearly independent of density and falls rapidly with temperature. At temperatures of 1 keV and above, the value of $\eta_\parallel$ is so small that, according to Eq. (9), $E_\parallel$ must vanish. An ideal, collisionless plasma is a superconductor along **B** and a superinsulator across **B**.

Particles in a fully ionized plasma can move across a magnetic field only by electron–ion collisions. At each collision, the guiding center can be displaced a distance of order $r_L \propto v_\perp/B$. In the random walk, the net displacement is proportional to r_L^2, or $\propto KT/B^2$. Because of momentum conservation at each collision, ions and electrons move across **B** at the same rate; hence, there is a transverse diffusion but no transverse mobility. Similar considerations govern the transport of heat (Braginskii, 1965). The flux of either species is given by

$$nv_\perp = -\mathbf{D}_\perp \nabla \mathbf{n}, \quad \mathbf{D}_\perp = \frac{\eta_\perp n}{B^2} \sum_j KT_j \equiv D_c, \qquad (37)$$

where $\eta_\perp \approx 2\eta_\parallel$, differing from $\eta_\parallel$ only in the way different velocities are weighted. The *classical diffusion coefficient* D_c depends on density, making the diffusion problem nonlinear, and decreases with temperature because of the $T_e^{-3/2}$ dependence of $\eta_\perp$. The value of D_c is so small that it is rarely observed; plasmas normally escape from magnetic traps by *anomalous diffusion* caused by instabilities.

2.2.6 Collisionless Damping Plasmas are the only substances in which dissipation of energy can occur without collisions. This phenomenon, discovered by Landau (1946) in the course of a rigorous solution of the Vlasov equation for the case of linear electron plasma waves, is called *Landau damping*. An apparent damping of these waves is found when Eq. (12) is Fourier analyzed and solved by contour integration, the damping appearing as an imaginary part of the complex frequency ω resulting from the residue around a pole in its complex plane (Jackson, 1960). The physical mechanism was subsequently explained by Dawson (1961). Some electrons in the distribution (the *resonant electrons*) have a thermal velocity close to the phase velocity of the wave, and those that are in the accelerating part of the wave electric field can stay in synchronism long enough to gain energy from the wave. There are also electrons in the decelerating phase of the wave, but for a Maxwellian distribution these are fewer in number; and, hence, there is a net gain of particle energy and a loss of wave energy. In the absence of collisions, the electrons accelerated by this wave–particle interaction maintain their energies. In carefully designed echo experiments, this energy gain can be reversed, and an echo of the wave can be seen after the wave has damped away.

The plasma dispersion function $Z(\zeta)$ is defined by (Fried and Conte, 1961)

$$Z(\zeta) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} \frac{\exp(-s^2)}{s - \zeta}\, ds, \quad \mathrm{Im}(\zeta) > 0, \qquad (38)$$

where the integral is to be taken along the real s axis but passing below all the poles of the integrand. For linear plasma waves of frequency ω and wave number k, solution of the Vlasov equation for $B = 0$ gives the dispersion relation

$$2k^2\lambda_D^2 = Z'(\zeta), \quad \zeta = \omega/kv_{\mathrm{th}}, \qquad (39)$$

where $Z'(\zeta)$ is the derivative of $Z(\zeta)$ with respect to its argument, and the electron thermal velocity v_{th} is $(2KT_e/m)^{1/2}$. Equation (39) gives the Landau damping rate

$$[\mathrm{Re}(\omega)]^2 \approx \omega_p^2 + \tfrac{3}{2}k^2v_{\mathrm{th}}^2,$$
$$\mathrm{Im}(\omega) \approx -\omega_p \sqrt{\frac{\pi}{e^3}} \left(\frac{\omega_p}{kv_{\mathrm{th}}}\right)^3 \exp[-(\omega_p/kv_{\mathrm{th}})^2], \qquad (40)$$

which has been confirmed experimentally.

2.3 Plasma Waves and Instabilities

A rich variety of coherent wave motions is possible in a plasma because of its electromagnetic, anisotropic, and particulate nature. When a source of free energy is available, some of these waves can grow spontaneously and are called *instabilities* (Fig. 2). Most waves can be treated with fluid theory, but *kinetic* waves and instabilities involve distortions of the velocity distribution and must be treated with kinetic equations. The most common waves in a plasma with electrons and a single species of singly charged ions are summarized below. These simple results are modified by multiple species, finite boundaries, and damping (Allis *et al.*, 1963; Swanson, 1989; Stix, 1992). For further details, see PLASMA WAVES AND INSTABILITIES.

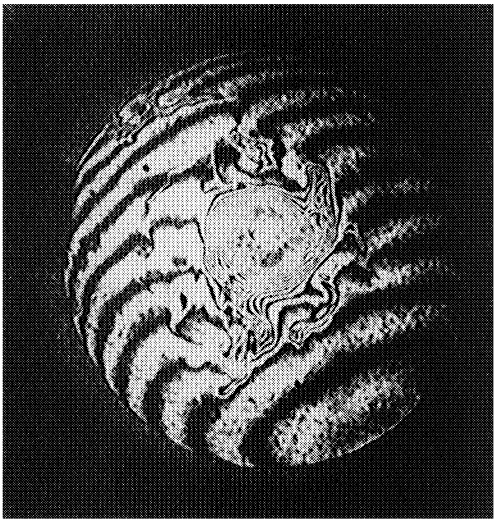

FIG. 2. A plasma instability is revealed by laser interferometry of an initially circular cylinder of dense plasma (Fowler and Post, 1966).

2.3.1 Electrostatic Waves When there is no magnetic field, two electrostatic waves exist:

1. a high-frequency *electron plasma (Bohm-Gross) wave* with a frequency given by Eq. (40), reducing for $T_e \to 0$ to a *Langmuir oscillation,* Eq. (14); and
2. a low-frequency ion-acoustic wave with a constant velocity $\omega/k = v_s$, given by Eq. (20).

These waves can also propagate *along* a background magnetic field $\mathbf{B}_0$; in addition, there are three new waves propagating *across* $\mathbf{B}_0$. At high frequencies, electrons undergo an upper-hybrid oscillation, with $\omega = \omega_{\text{uh}}$; at low frequencies there is an electrostatic ion cyclotron wave at ω_{esic}; and at intermediate frequencies, there is a lower-hybrid oscillation at ω_{lh}:

$$\omega_{\text{uh}}^2 = \omega_p^2 + \omega_c^2, \quad \omega_{\text{esic}}^2 = \omega_{ci}^2 + k^2c_s^2,$$
$$\omega_{\text{lh}}^{-2} = \omega_{pi}^{-2} + (\omega_{ce}\omega_{ci})^{-1}. \tag{41}$$

The hybrid frequencies are commonly occurring combinations of intrinsic frequencies. For propagation in a direction $\mathbf{k}$ at an angle θ relative to $\mathbf{B}_0$, the two high frequencies are given by the solutions of

$$\omega^2(\omega^2 - \omega_{\text{uh}}^2) + \omega_p^2\omega_c^2 \cos^2\theta = 0. \tag{42}$$

When these waves are confined to a conducting cylinder of radius a, the oscillating potentials of the eigenmodes have the form $\varphi_1 = AJ_m(p_{mn}r/a)e^{i(m\theta+\beta z-\omega t)}$, and their frequencies are given by the frequently used *Trivelpiece–Gould* formula:

$$\beta a = \pm p_{mn}\left[\frac{\omega^2(\omega_{\text{uh}}^2 - \omega^2)}{(\omega^2 - \omega_p^2)(\omega^2 - \omega_c^2)}\right]^{1/2}, \tag{43}$$

where p_{mn} is the nth root of the Bessel function J_m. As the axial wave number β is increased, the frequency of one branch increases from 0 to the lower of ω_p and ω_c, while that of the other branch decreases from ω_{uh} to the higher of ω_p and ω_c.

Examples of waves not describable by fluid equations are the electron and ion *Bernstein waves,* whose frequencies are near the harmonics of ω_{ce} and ω_{ci}, respectively. Since these depend on the FLR effect, they are found in solutions of the Vlasov equation.

2.3.2 Electromagnetic Waves Light waves and microwaves propagate in an unmagnetized plasma with a frequency

$$\omega^2 = \omega_p^2 + c^2k^2, \tag{44}$$

corresponding to a dielectric constant

$$\epsilon = c^2k^2/\omega^2 = 1 - \omega_p^2/\omega^2. \tag{45}$$

Transmission is cut off for $\omega < \omega_p$. In the presence of a field $\mathbf{B}_0$, light waves propagating *across* $\mathbf{B}_0$ polarized with $\mathbf{E} \parallel \mathbf{B}_0$ also obey Eq. (44) and are called *ordinary* waves. Those with $\mathbf{E}\perp\mathbf{B}_0$ have the dispersion relation

$$\epsilon = 1 - \frac{\omega_p^2}{\omega^2}\frac{\omega^2 - \omega_p^2}{\omega^2 - \omega_{\text{uh}}^2} \tag{46}$$

and are called *extraordinary* waves. These waves have a "resonance," where $\epsilon \to \infty$, at $\omega = \omega_{\text{uh}}$, and two "cutoffs," where $\epsilon \to 0$, at the *right-* and *left-hand cutoff frequencies* ω_R, ω_L given by

$$\omega_R = \tfrac{1}{2}[(\omega_c^2 + 4\omega_p^2)^{1/2} + \omega_c],$$
$$\omega_L = \tfrac{1}{2}[(\omega_c^2 + 4\omega_p^2)^{1/2} - \omega_c]. \tag{47}$$

Extraordinary waves are reflected at the cutoffs and have forbidden bands for $0 < \omega < \omega_L$ and $\omega_{\text{uh}} < \omega < \omega_R$. The absorption of these waves at the resonance is a method for heating a plasma.

Light waves propagating *along* $\mathbf{B}_0$ have normal modes that are circularly polarized, with dielectric constants

$$\epsilon = 1 - \frac{\omega_p^2/\omega^2}{1 \pm \omega_c/\omega}. \tag{48}$$

Since these two components have different phase velocities, plane-polarized electromagnetic waves along $\mathbf{B}_0$ exhibit *Faraday rotation.* The left-hand circularly polarized mode (upper sign) is cut off below ω_L, and the right-hand mode is cut off between ω_c and ω_R. Below ω_c, the right-hand mode has a low-frequency propagation band in which the waves are called *whistler waves,* named after their gliding tones after passing through the earth's ionosphere.

Low-frequency electromagnetic waves *along* $\mathbf{B}_0$ are called *Alfvén* waves and have the velocity v_A given by Eq. (18). Such hydromagnetic waves propagating *across* $\mathbf{B}_0$ are called magnetosonic waves, or simply "fast" waves and have a velocity

$$v_{ms}^2 = c^2 \frac{v_s^2 + v_A^2}{c^2 + v_A^2} \approx v_s^2 + v_A^2. \tag{49}$$

This wave is useful for heating a plasma. Another wave used for this purpose is the *electromagnetic ion-cyclotron* wave, with a frequency given by

$$\omega_{\text{emic}}^2 = \omega_{ci}^2 \left[1 + \frac{\omega_{pi}^2}{c^2}\left(\frac{1}{k_\parallel^2} + \frac{1}{k^2}\right)\right]^{-1}, \tag{50}$$

where k is the total wave number and $k_\parallel$ is its component along $\mathbf{B}_0$.

2.3.3 Electrostatic Instabilities All the waves of Sec. 2.3.1 can be excited by beams of electrons or ions whose velocity component in the direction of the wave is near the phase velocity (Mikhailovskii, 1974). Beam–plasma interactions can involve any combination of beams and waves. The growth rate of the instability varies typically as the cube root of the beam density. The Buneman instability occurs when the electron and ion fluids of a plasma are both cold and drift through each other.

Current-driven instabilities, on the other hand, involve drifts that are small relative to the thermal velocity. In the *ion-acoustic instability,* an ion wave is excited by the relative motion of a warm electron fluid with a threshold drift velocity that varies from c_s when $T_i \ll T_e$ to v_{the} when $T_i \approx T_e$. In the presence of a magnetic field, the *electrostatic ion-cyclotron instability* [cf. Eq. (41)] has a lower threshold. An intermediate case occurs when a warm beam is added to a thermal-electron population, resulting in a *bump-on-tail* distribution. Resonant electrons can then excite plasma oscillations by *inverse Landau damping.* In addition to this particle effect, there is also the basic hydrodynamic effect, of which the Buneman instability is the zero-temperature limit.

In crossed electric and magnetic fields, electrons and ions can have slightly different $\mathbf{E} \times \mathbf{B}$ drifts due to small effects such as collisions with neutrals [cf. Eq. (33)]. When $\mathbf{E}$ and ∇n_0 are in the same direction, this drift causes an *E × B instability* that is important in the laboratory and in space (Simon, 1963). As in ordinary fluids, velocity shear gives rise to *Kelvin–Helmholtz* instabilities (D'Angelo and von Goeler, 1966; Jassby, 1972); in plasmas, these are modified by the magnetic field. Sources of free energy on which instabilities feed can occur without beams or drifts. In plasmas confined by magnetic mirrors, the velocity distribution can be anisotropic, leading to *velocity-space* or *loss-cone* instabilities (Hasegawa, 1975). Any confined plasma must deviate from complete thermal equilibrium, since it must have a pressure gradient, at least at the edge. This gradient drives drift-wave instabilities with a velocity given by v_{De} [Eq. (26)], and in the collisionless case these are called *universal instabilities* (Kadomtsev, 1965).

2.3.4 Hydromagnetic Instabilities The principal hydromagnetic instabilities (Bateman, 1978; Freidberg, 1987), in which the magnetic field fluctuates, are the *Rayleigh–Taylor instability* and the *kink instability.* These are the primary ones to be considered in designing a fusion confinement device. As in hydrodynamics, a Rayleigh–Taylor instability occurs when a heavy fluid is supported by a light fluid. In plasma physics, the heavy fluid is the plasma, and the light fluid is the massless magnetic field. The role of gravity is played by the centrifugal force on particles following curved magnetic-field lines in their thermal motions. This instability is also called the *gravitational* or *interchange* instability. The ripples that grow have a velocity of the order of v_R [Eq. (24)] and allow the plasma to escape across **B**. At low densities, this instability is electrostatic in nature. The kink instability is driven by currents along $\mathbf{B}_0$. These currents themselves generate a magnetic field $\mathbf{B}_1$ that is perpendicular to $\mathbf{B}_0$, causing the total field to twist into a helix, which then grows. The *sausage instability* is a special case of the kink instability that has azimuthal symmetry; the field lines are pinched into constrictions resembling the links of a sausage.

2.4 Radiation in Plasmas

Most plasmas in the laboratory and in space have densities below 10^{21} m^{-3}, or less than 10^{-4} of atmospheric density. At these densities, the optical depth for most radiation is much larger than the plasma. Consequently, though the particles of a plasma can be in thermal equilibrium, radiation in a plasma is rarely in equilibrium with the plasma and will pass through it freely unless the frequency strikes a particular resonance with a characteristic frequency of the plasma or with an atomic or molecular transition.

2.4.1 Bremsstrahlung The acceleration of electrons when they collide with ions generates *bremsstrahlung* photons, which have energies of the order of thermal-electron energies (Bekefi, 1966). In plasmas with KT_e in the 100–10 000-eV range, bremsstrahlung is in the soft x-ray regime and passes readily through the plasma. X-ray pinhole cameras are often used for imaging the internal features of the plasma. Further information on this appears under FUSION, MAGNETIC CONFINEMENT.

2.4.2 Synchrotron Radiation In a magnetic field, gyrating electrons emit synchrotron radiation at ω_c and its harmonics, in the submillimeter-wave regime. Since the fundamental frequency ω_c is resonant with the gyrofrequency of other electrons of any energy, this radiation is easily reabsorbed before it leaves the plasma. The higher harmonics, however, depend on distortions of the circular orbits due to relativistic mass increase or field inhomogeneities, and they can escape reabsorption. Thus the plasma radiates like a black body at ω_c and its first few harmonics but is transparent to the high harmonics. The transition harmonic number depends on the details (Dawson, 1981).

2.4.3 Scattering of Radiation *Thomson scattering* of laser light occurs when the electric field of the light beam accelerates the electrons of a plasma, and the electrons reradiate in other directions and at different frequencies (Bekefi, 1966). The ratio of scattered power to incident power is proportional to $r_0^2 n_e$, where $r_0 = e^2/mc^2$ is the classical electron radius and n_e is the electron density. The frequency spectrum of the scattered light depends on the parameter $\alpha = 1/k\lambda_D$, k being the magnitude of the wave vector **k** doing the scattering in the plasma. For incident ($\mathbf{k}_0$) and scattered ($\mathbf{k}_s$) waves at a relative angle θ, **k** is given by $\mathbf{k} = \mathbf{k}_0 - \mathbf{k}_s$, so that $k^2 = k_0^2 + k_s^2 - 2k_0k_s \cos\theta$. Incoherent scattering from individual electrons occurs when $\alpha \ll 1$, since the scattering wavelength is smaller than the Debye length λ_D and does not average over a Debye cloud. Coherent scattering occurs at small angles θ when $\alpha \geq 1$; then the scattering wavelength extends over plasma structures, and the spectrum yields the frequencies of these macroscopic motions

2.4.4 Diagnostics with Radiation In spite of the small Thomson cross section of 6.65×10^{-29} m^2, the large intensities available with Nd-glass or CO$_2$ lasers make Thomson scattering a commonly used, nonperturbative diagnostic for temperatures and densities inside a plasma (Lochte-Holtgreven, 1968; Griem and Lovberg, 1970; Sheffield, 1975). In this technique, the laser wavelength is much shorter than the wavelengths being probed, so that $|\mathbf{k}_0| \approx |\mathbf{k}_s| \gg |\mathbf{k}|$. The scattering parameter defined above is then approximated by $\alpha \approx 1/2k_0\lambda_D \sin(\theta/2)$. For $\alpha \ll 1$, the Doppler-shifted light yields the temperature or, more generally, the velocity distribution of the electrons. For $\alpha \gg 1$, the light probes the cooperative motions of the plasma, including electron plasma waves, whose frequency yields the density, and ion-acoustic waves, whose frequency and damping yield the electron and ion temperatures.

Microwave interferometry (Huddlestone

and Leonard, 1965) provides a reliable way to measure plasma density; it is based on the change of the index of refraction given by Eq. (45). Since the waves cannot propagate for $\omega_p > \omega$, densities above 10^{19} m^{-3} cannot be measured by centimeter waves; and, in fact, millimeter waves must be used for such densities because of refraction. To measure higher densities, far-infrared lasers are used for interferometry with submillimeter waves (Fig. 2). The reflection of far-infrared radiation at the cutoff frequency ω_p or ω_R [Eq. (47)] can be used in reflectometers for density profiles and fluctuations. Emission of electron-cyclotron harmonic radiation gives information on electron temperature. Detection of optical emission gives information based on the intensity ratios of spectral lines and on Stark and Doppler broadening (Lochte-Holtgreven, 1968; Griem and Lovberg, 1970; Selwyn, 1993). For the intense plasmas of laser fusion, x-ray spectrometry is used. Finally, the sophisticated method of laser-induced fluorescence permits measurements of ion velocities and of plasma motions by following tagged metastable ions.

2.5 Nonlinear Phenomena

Plasma methods devised for studying nonlinear phenomena been found useful in other fields of applied physics also. A few examples of interesting results are given below.

2.5.1 Nonlinear Waves and Wave–Particle Interactions When ion-acoustic waves reach large amplitude, their sinusoidal wave forms steepen into sawteeth, as predicted by the *Korteweg–de Vries* equation (Davidson, 1972). Ion-acoustic shock waves have a steep front followed by a wave train and have velocities larger than v_s (Fig. 3). Single pulses called *solitons* are also possible and have been studied experimentally. Plasmas can support collisionless shock waves of both ion-acoustic and Alfvén-wave nature. Nonlinear electron plasma waves tend to form *envelope solitons,* or wave packets, described by the nonlinear Schrödinger equation (Hasegawa, 1975). The envelopes can shrink in length and grow in amplitude as a result of a *modulational instability.* Waves and particles can affect each other through nonlinear interactions (Sagdeev and Galeev, 1969), resulting in, for instance, the generation of harmonics.

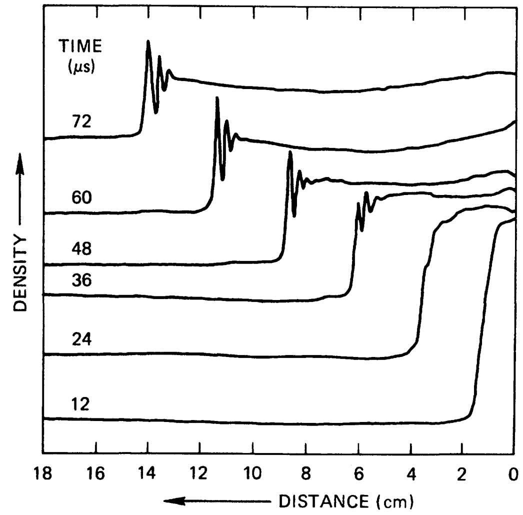

FIG. 3. Ion-acoustic shock waves, as produced and detected in the laboratory. Many such nonlinear plasma phenomena are well described by theory (Chen, 1983).

2.5.2 Sheaths and Double Layers The ion-rich sheath at the wall of a discharge has an electron density that falls exponentially, so that the description of such *Debye sheaths* is intrinsically a nonlinear problem. A negatively biased electrode has, in addition, a *Child–Langmuir sheath,* which is well known to be nonlinear. In space plasma physics, it was found that free-standing sheaths, called *double layers,* can be formed away from all boundaries if at least one of the species has a streaming velocity. Such double layers have been reproduced in the laboratory.

The oldest and simplest plasma diagnostic is the electrostatic probe, whose current–voltage characteric gives information on density and temperature, and sometimes even the nonthermal electron components. Based on sheath theory, the theory of probes was first worked out by I. Langmuir. Though Langmuir probes cannot be used in plasmas so hot and dense that they would destroy anything inserted into them, probes are especially valuable for localized, rather than integrated, measurements (Griem and Lovberg, 1970).

2.5.3 Solitons, Cavitons, and Collapse The study of ion-acoustic solitons has led to light-wave solitons in optical fibers, useful for long-range communications. A *caviton* is a density cavity filled with radiation that is trapped because the plasma around it is overdense; that is, $\omega_p > \omega$. The radiation pressure, which is called *ponderomotive force* when modified by a plasma, creates the density cavity. A caviton can also be filled with electron plasma waves, which also exert a ponderomotive force. Turbulent Langmuir waves are predicted to precipitate into a number of such cavitons by a process called *collapse* (Zakharov, 1984; Hasegawa, 1975).

2.5.4 Turbulence and Chaos The growth of unstable waves into nonlinear waves and finally into turbulence was studied first analytically (e.g., Galeev and Sagdeev, 1983), and more recently by plasma simulation on high-speed computers (e.g., White, 1983). Plasma turbulence is quite different from turbulence in fluid dynamics, in which the "inertial range" spectrum postulated by Kolmogoroff to vary as $k^{-5/3}$ has been observed, k being the reciprocal of the eddy size. Plasma turbulence in strong magnetic fields tends to be two-dimensional, in which case small eddies tend to coalesce into larger ones, instead of vice versa. If an inertial range exists for magnetized plasmas, the energy spectrum can be shown to vary as k^{-5} (Chen, 1965), but many other spectra have also been predicted depending on the assumed origin of the turbulence (e.g., Zakharov, 1984; Sagdeev *et al.*, 1991). For treating drift-wave turbulence, many theoretical techniques have been devised because of its perceived importance in magnetic fusion.

The approach to a state of disorder is not always gradual. Mechanisms such as period doubling or mode coupling can cause oscillations to jump suddenly into or out of a chaotic state with a small change in parameters. Such discontinuous changes are mathematically predicted in the field of *chaos* (Ott, 1993) (see CHAOTIC PHENOMENA), but it is not clear whether or not these processes are the same as those observed in real plasmas. Abrupt changes from order to disorder were first found in computational studies of the behavior of particle orbits and magnetic-field lines in fusion devices (Lichtenberg and Lieberman, 1983) (Fig. 4). This modern field of nonlinear dynamics was initiated in large part by plasma physicists.

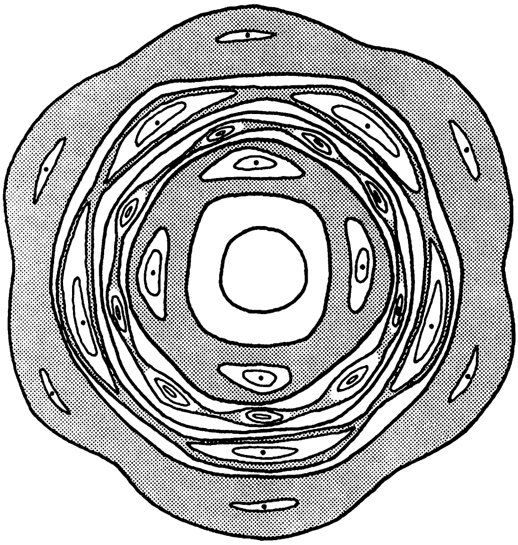

FIG. 4. Numerical mapping of a perturbed Hamiltonian reproduces the magnetic island structure of the field lines in a toroidal tokamak fusion machine. In this cross section, the magnetic surfaces break up into "islands" at those radii where the field lines return to the same position after a rational number of turns around the torus. Between these islands, the field lines lie in KAM (Kolmogoroff–Arnol'd–Moser) surfaces and cover the space ergodically (Lichtenberg and Lieberman, 1983.)

2.6 Nonneutral and Strongly Coupled Plasmas

2.6.1 Single-Species Plasmas Pure electron plasmas can be trapped for days in a uniform magnetic field with electrostatic confinement at the ends (a *Penning trap*), there being no unlike-particle collisions to cause diffusion. Since the electron charge is not neutralized by ions, the resulting electric field causes the plasma to rotate, but a stable equilibrium is possible (Davidson, 1974). Many of the features of normal plasmas, such as Debye shielding, are retained in *single-species*, or *one-component*, plasmas. Because of their simplicity, they have been successfully used to study basic phenomena such as conservation laws and the details of Coulomb collisions. Single-species plasmas can also be made with ions or positrons. Ions can be confined also by rf in *Paul traps*. Of particular interest are plasmas of extremely low temperature. Electrons can be cooled by synchrotron radiation, but ions can be cooled much more efficiently with lasers. In laser cooling, a laser is tuned to the Doppler-shifted wavelength of ions that are moving rapidly toward the laser. The radiation pressure of the beam is then preferentially applied to slowing down these fast ions.

2.6.2 Liquid and Solid Plasmas When a plasma is cooled sufficiently, the number of particles in a Debye sphere, $N = n\lambda_D^3$, falls to the order of unity or below, and Debye shielding can no longer occur. This is the regime of *strongly coupled plasmas* (Ichimaru, 1994). The controlling parameter Γ, proportional to the ratio of Coulomb energy to thermal energy, is defined by

$$\Gamma = q^2/a_s KT, \quad \tfrac{4}{3}\pi a_s^3 n = 1, \tag{51}$$

where a_s is the average interparticle distance. When $\Gamma \geq 2$, the thermal energy of the particles is too weak to overcome interparticle Coulomb forces, and the plasma exhibits the short-range order of a liquid. When Γ exceeds 100 or so, the ions fall into a solid lattice. This has been seen in a pure ion plasma. An easier method to form a solid plasma is to use negatively charged particulates or powders, with a typical grain size of 1 μm. Since these particles can have as many as 10^4 electron charges each, the condition $n\lambda_D^3 \leq 1$ can easily be achieved. Such plasma lattices have been produced in the laboratory. Since $n\lambda_D^3$ varies as $n^{-1/2}$, strongly coupled plasmas also occur at very high densities, such as in white dwarf and neutron stars and in compressed inertial-fusion targets (see FUSION, INERTIAL CONFINEMENT). The equation of state of matter under such conditions is an active field of study.

3. PHYSICS OF MAGNETIC CONFINEMENT

3.1 Effects of Magnetic Fields on Plasmas

Magnetic confinement of plasmas in space and in small laboratory experiments is usually only partially effective: Diffusion across field lines is reduced to the rates given by Eq. (34) for partially ionized plasmas and Eq. (37) for fully ionized plasmas. The physics involved with reduced motion across straight magnetic fields is relatively straightforward and contains few surprises. To trap a plasma so that it cannot escape *along* the field lines, however, is considerably more difficult. This requires specially shaped magnetic fields and elegant methods to suppress the instabilities that such fields engender. Total confinement in complex geometries entails a large number of new concepts. For this reason, the extensive body of knowledge on magnetic confinement is connected primarily with controlled fusion, for which plasma containment in all directions is required.

Two types of magnetic containment geometries are possible: *open* and *closed.* Open systems consist of two or more regions of strong magnetic field separated by a weak-field region. Charged particles in the weak-field region are reflected from the strong-field regions by the magnetic mirror effect (Fig. 3). Particles with small magnetic moment [Eq. (29)], however, can escape through the mirrors at too fast a rate for efficient fusion, and methods for stoppering the ends had to be devised. Closed, or toroidal, geometries have magnetic field lines that do not reach the walls, so that plasma cannot escape along field lines. However, the curvature of the field induces a number of instabilities that destroy the confinement. The problem in closed systems is to devise methods for suppressing these instabilities. (Many books on fusion have been written; several are listed under Further Reading.)

3.2 Magnetic-Confinement Fusion

Controlled fusion energy is generated when deuterium and tritium ions in a plasma combine to form a helium nucleus and a neutron. Because of Coulomb repulsion, directed beams of ions will scatter elastically, and undergo a fusion reaction only in rare head-on collisions. In a plasma with a Maxwellian distribution of ion energies, however, the mean energy will not be changed by elastic collisions, and fusion events will eventually occur. These are called *thermonuclear* reactions. An ion temperature of about 10 000 eV is usually required. The electron fluid may be cooler; but since the temperatures will equilibrate in about the same time as needed for the fusion reactions, the electrons will also be hot enough to maintain the high conductivity of the plasma.

The helium "ash" of the D-T fusion reaction consists of 3.5-MeV α particles, which are confined by the magnetic field. *Ignition* is achieved when the transfer of energy from the α's sustains the plasma temperature against losses via radiation and particle escape. Electrical energy is derived from the other reaction product, the 14-MeV neutrons, which are captured in a *blanket* and thermalized to produce heat for a conventional power plant. For net energy gain, the *Lawson criterion* $n\tau_E \geq 10^{20}$ s/m^3 must be satisfied, where n is the plasma density and τ_E is the energy confinement time given by the plasma energy content divided by the power input. For toroidal systems, n is typically 10^{20} m^{-3} and τ_E is typically 1 s at this *breakeven* condition. Since high ion temperature is also required, the triple product $T_i n\tau_E$ should exceed 10^{21} keV-s/m^3. References and details on this subject can be found under FUSION, MAGNETIC CONFINEMENT and FUSION TECHNOLOGIES.

3.3 Particle and Energy Transport

In principle, plasma can escape from a closed system only at the classical diffusion rate given by Eq. (37). Under fusion conditions the *particle confinement time* τ_p would then be of the order of hours. In practice, confinement times as long as 1 s are difficult to achieve because of *anomalous diffusion* caused by instabilities and field errors. Kinetic energy is also transported across **B** in Coulomb collisions. Classically, the heat flow q_e of electrons, for instance, should be proportional to $n_e\nabla T_e$:

$$q_e = \chi_e n_e \nabla T_e, \tag{52}$$

where the heat diffusivity χ_e has the same $n_i T_e^{-1/2} B^{-2}$ dependence as does $D_\perp$ [Eq. (37)]. In tokamaks, the measured value of χ_i agrees approximately with this prediction when it is modified by the neoclassical effects described below, but χ_e is highly anomalous. Not only is it large, but it can depend on ∇T_e itself, and its dependences on T_e and B can be inverted. In view of this rapid transport, the loss of energy by radiation can be neglected. The energy confinement time τ_E, which should then be proportional to $1/\chi_e \propto T_e^{1/2}B^2/n_i$, is actually found to increase with n and decrease with B. Much of magnetic fusion physics concerns the explanation of such anomalies through the study of instability and turbulence.

3.4 The Energy Principle

To enumerate the possible instabilities in the complicated magnetic geometries required for confinement would be an impossible task. Fortunately, the discovery of an energy principle for hydromagnetic stability (Bernstein *et al.*, 1958) reduces the distinction between stability and instability to evaluating the sign of a quantity δW, which represents the change of the potential energy of the magnetic-field–plasma system when the fluid is given a displacement $\xi(\mathbf{r})$. If the field **B** and pressure p are known everywhere in the volume V, δW in its simplest form is given by the integral

$$\delta W = \tfrac{1}{2}\int [\mathbf{Q}^2 + (\nabla \times \mathbf{B})\cdot(\xi \times \mathbf{Q}) + (\nabla\cdot\xi)(\xi\cdot\nabla p) + \gamma p(\nabla\cdot\xi)^2]d^3V, \tag{53}$$

where $\mathbf{Q} = \nabla \times (\xi \times \mathbf{B})$. Stability requires $\delta W > 0$ for all trial functions $\xi(\mathbf{r})$.

3.5 Toroidal Confinement

Bending straight magnetic-field lines into circles, thus forming a torus (pictured here as a horizontal doughnut), would prevent plasma from escaping along **B**. Unfortunately, the field would then be nonuniform, and the gradient-B drifts [Eq. (23)] would separate the ions and electrons, causing a vertical electric field that drifts the plasma outward by the drift v_E [Eq. (21)]. Toroidal devices must be designed to have twisted, or helical, **B** lines so that the particles, in their thermal motion along **B**, experience an oscillating gradient-B drift with zero average. There are three general types of toroidal devices. Tokamaks employ a plasma current to add a *poloidal B* field (around the minor axis) to the basic *toroidal* field generated by external coils. Helical devices employ currents in windings outside the plasma to generate the poloidal component. *Stellarators, torsatrons, heliacs,* and *spherators* are examples of helical devices. If a closed configuration has no hole in the center and all the fields are generated by currents in the plasma, it is a *compact torus.*

3.5.1 Rotational Transform Let θ be the azimuthal angle at which a given helical field line crosses a given cross section of the torus. After going once around the torus, this field line will have an azimuth angle $\theta + \Delta\theta$. The rotational transform ι, defined as the average value of $\Delta\theta$ over many traverses, is a measure of the amount of twisting. For tokamaks, the reciprocal quantity $q = 2\pi/\iota$ is known as the *quality factor.* Kink instabilities will occur if the plasma current is large enough to give $\iota > 2\pi$, or $q < 1$, a condition known as the *Kruskal–Shafranov limit.* The value of q generally varies with minor radius r. At most radii, q is an irrational number, and the field lines cover an inner torus, called a *magnetic surface,* without ending. In steady state, a perfectly conducting plasma will have $\nabla_{\parallel} p = E_{\parallel} = 0$, according to Eqs. (8) and (9), so that such magnetic surfaces are surfaces of constant pressure and potential. Particle drifts [Eqs. (21) and (23)] cannot cross these nested surfaces. However, at radii such that $q(r)$ is a rational number, the field lines close upon themselves and form *magnetic islands* (Fig. 6). Overall hydromagnetic stability of toroidal configurations depends on the existence and positions of these *rational surfaces,* and hence on the profile of $q(r)$.

3.5.2 Instabilities In a perfectly conducting plasma, in which $E_{\parallel} = 0$, the gravitational and kink instabilities discussed in Sec. 2.3.4 can be controlled by shaping the magnetic field. Unfortunately, a small resistivity η suffices to invalidate the assumption $E_{\parallel} = 0$ and to allow growth of waves localized within a magnetic surface. The primary resistive instability is the *tearing mode.* Modes localized to the outside regions of a torus where the effective "gravity" is strong are called *ballooning* modes. The drift-wave instability discussed in Sec. 2.3.3 is believed to be the cause of electrostatic turbulence, leading to anomalous diffusion. Drift waves can be made unstable not only by finite resistivity but also by the trapping of particles in banana orbits (Sec. 3.5.4); these are called *trapped particle* instabilities. The η_i instability is a drift wave driven by ion temperature gradients. The α-particle product of fusion reactions is predicted to drive Alfvén waves unstable. The number of known instabilities is large (Wesson, 1978), but fortunately only a few in practice are deleterious to plasma confinement.

3.5.3 Stabilization Methods The two primary methods for suppression of instabilities are *shear* and *minimum-B.* Magnetic shear occurs when $q(r)$ varies with radius, so that the **B** lines have different pitch angles on each magnetic surface. This has the effect of scrambling unstable displacements and suppressing them. A minimum-B configuration is one in which the magnitude $|\mathbf{B}|$ is larger on the outside of the plasma than on the inside, forming a potential hill that unstable motions must overcome. These field lines bulge inward toward the plasma rather than outward. A similar benefit accrues if only the average of $|\mathbf{B}|$ along a field line has an interior minimum; such configurations have minimum-average-B, or minimum-$\bar{B}$.

3.5.4 Banana Orbits Let a magnetic surface intersect a cross section of the torus in a circle. As a particle's guiding center moves along a field line on this magnetic surface, the points at which it passes a given cross section should eventually cover the entire circle. However, particles with large magnetic moments will be reflected from regions of strong field by the magnetic mirror effect (cf. Sec. 2.2.4) and will not be able to reach the inside part of the cross section, near the major axis, where the field is strong. The guiding center will then trace out not a circle but a banana-shaped path localized to the outside of the cross section. The particle is then a *trapped particle.* We define the aspect ratio of a torus as $A = R/a$, where R is the major radius and a the minor radius, and the inverse aspect ratio as $\epsilon = a/R$. The fraction of trapped particles is proportional to $\epsilon^{1/2}$. The width of the banana orbits is $(B_t/B_p)r_L$, where B_t and B_p are respectively the toroidal and poloidal field components, or approximately the Larmor radius evaluated with the poloidal field. The step length for diffusion is therefore increased by the factor $\epsilon^{1/2}(B_t/B_p)$ (Kadomtsev and Pogutse, 1971).

3.5.5 Neoclassical Diffusion Because of the toroidal effects described above, transport by classical Coulomb collisions is increased even without instabilities. The resulting "neoclassical" diffusion coefficient has three ranges as the collision frequency ν is increased (Hinton and Hazeltine, 1976). In the banana diffusion regime (small ν), $D_\perp$ is given by

$$D_\perp = D_c q^2/\epsilon^{3/2} = q^2 r_L^2 \nu/\epsilon^{3/2} \tag{54}$$

In the large-ν limit, diffusion is governed by the Pfirsch–Schlüter coefficient

$$D_{PS} = (1 + 2q^2)D_c \cong q^2 r_L^2 \nu. \tag{55}$$

Here the enhancement over D_c [Eq. (37)] is caused by the added electron–ion friction as electrons flow along **B** to cancel their gradient-B drifts, as described above. At intermediate collisionalities, $D_\perp$ is independent of ν; in this *plateau* regime, $D_\perp$ is given by

$$D_\perp = q r_L^2 v_{th}/R. \tag{56}$$

3.5.6 Bohm and Gyro-Bohm Diffusion Observed losses are much faster than neoclassical. In the presence of electrostatic turbulence, the guiding centers of ions and electrons suffer random $\mathbf{E} \times \mathbf{B}$ drifts, and the resulting diffusion can be shown to scale as KT_e/B. The infamous Bohm diffusion coefficient contains an empirical factor of $\frac{1}{16}$:

$$D_B = \tfrac{1}{16} KT_e/eB\ . \tag{57}$$

This scaling holds for both random *diffusion* and steady *convection* as long as the eddy sizes are scaled to the plasma radius. Improvements in stabilization have reduced $D_\perp$ to below this value, at least for electrons. If the correlation lengths are scaled instead to the ion Larmor radius, as is predicted for certain instabilities such as the *ion temperature gradient instability*, the diffusion coefficient would have a smaller value, called the *gyro-Bohm* coefficient:

$$D_{GB} = \frac{r_{Li}}{a}\frac{KT_e}{eB} \tag{58}$$

Electron transport has been observed to follow this scaling law, which recovers the $1/B^2$ dependence of classical diffusion but is still much larger in magnitude.

3.6 Tokamak Physics

3.6.1 Fields and Currents A tokamak (Furth, 1981) has at least three sets of coils: TF (toroidal field) coils, which encircle the doughnut and produce the primary toroidal field; VF (vertical field) coils, which provide a $\mathbf{j} \times \mathbf{B}$ force to prevent expansion of the torus; and OH (Ohmic heating) coils (or a transformer) for inducing the toroidal current. In addition, there are often field-shaping coils. The all-important q profile is determined by the radial distribution of the toroidal current $j(r)$. The Ohmic dissipation of this current heats the plasma in the absence of auxiliary heating. Since the resistivity is sensitive to electron temperature [Eq. (36)], $q(r)$, $j(r)$, and $T_e(r)$ are related to one another. The value of q typically varies from below 1 on the minor axis to above 3 at the periphery. The current tends to be concentrated on reentrant field lines, for instance on the $q = 2$ or 3 surfaces, generating localized poloidal fields. These form magnetic islands that degrade the confinement.

3.6.2 Sawteeth and Disruptions Sawtooth-shaped fluctuations in n and T_e are invariably seen near the $q = 1$ surface. Inside this surface, the plasma is unstable and turbulent because the Kruskal–Shafranov limit is not satisfied. Heat and density are redistributed by the sawtooth oscillations; this is a mechanism for the plasma to readjust $j(r)$ to regain stability. This self-regulation mechanism is not available to stellarators, where $\iota(r)$ is primarily fixed by external currents. In contrast to sawteeth, disruptive instabilities occur unpredictably and are believed to be caused by the growth and overlapping of magnetic island chains. A major disruption stops the plasma current completely and brings the plasma to the wall.

3.6.3 Auxiliary Heating Ohmic heating can be supplemented in four main ways. In ECRF (electron-cyclotron range of frequencies) heating, microwaves from powerful gyrotrons are used to generate the extraordinary wave [Eq. (46)], which is absorbed at the upper hybrid resonance. In ICRF (ion-cyclotron range of frequencies), radio frequency is applied from antennas to generate the fast wave [Eq. (49)]. In lower hybrid heating (LHH), an intermediate frequency is applied by phased grid arrays to excite the lower hybrid resonance [Eq. (41)]. The most successful method has been neutral-beam injection (NBI) heating, in which 100–200-keV beams of neutral deuterium atoms are injected across the magnetic field. The atoms are then ionized by the plasma and trapped. The resulting fast ions transfer their energy first to electrons, and then to the ions. In fusion reactors, these fast ions enhance the fusion rate, since they pass through the region of maximum fusion cross section as they slow down. The current of these fast ions significantly modifies the plasma equilibrium, depending on *coinjection* (in the OH current direction) or *counterinjection* (opposite), and can cause new instabilities.

3.6.4 H-Mode Confinement With neutral-beam injection, it was found that the plasma sometimes makes a spontaneous transition to a new mode of confinement in which the density and potential gradients at the edge of the discharge become extremely steep. When this happens, the oscillation level drops near the edge, presumably because instabilities are suppressed by the large, sheared electric field there. There is then a transport barrier at the edge, which increases the overall confinement time by about a factor of 2. The details of the edge physics are still under study.

3.6.5 Current Drive Since the toroidal current in a tokamak must be induced by a transformer, with or without an iron core, the length of a current pulse is limited by the number of volt-seconds available. Helical systems do not require an internal current and can be operated cw. Currents can be driven without transformers by using the principle of Landau damping (Sec. 2.2.6), by which electrons are accelerated by radio-frequency waves excited in the plasma. In toruses in which plasma is escaping with a radial velocity v_r, there is an automatic current drive due to the $-ev_r \times B_p$ force on the electrons. Since this is always in the direction of the current creating B_p, it is called the *bootstrap current.* Steady-state operation of tokamaks may be possible using the combination of bootstrap current and rf current drive.

3.7 Magnetic Mirrors

3.7.1 Loss Cone A simple magnetic mirror field can be produced by two separated circular coils with currents in the same direction. The field B along the common axis is strongest at the coils ($B = B_{\max}$) and weak at the midplane between them ($B = B_{\min}$). The mirror ratio R_m and the loss-cone angle θ_m are defined by

$$R_m = B_{\max}/B_{\min}, \quad \sin\theta_m = 1/R_m. \tag{59}$$

Particles with $v_\perp/v_\parallel < \tan\theta_m$ at the midplane cannot be reflected at the mirror throats and are lost. Particles diffuse in velocity space into the loss cone by collisions. Since electrons have a large collision frequency, they are lost rapidly, creating an ambipolar potential that accelerates ions through the mirror. Thus, the ions are driven out with a finite drift velocity. In the limit of large R_m, the confinement time is proportional to $\ln R_m$. The loss rate from a simple mirror is too rapid to satisfy the Lawson criterion (Sec. 3.1).

3.7.2 Instabilities Since the field lines of a simple mirror curve outward instead of inward, the configuration is subject to the Rayleigh–Taylor gravitational instability (Sec. 2.3.4). Early experiments were stabilized by *line tying,* the short-circuiting of electrostatic potentials by conducting plates on which the field lines end. Mirrors can easily be stabilized by the addition of a quadrupole field applied by *Ioffe bars,* which are four equally spaced current-carrying conductors parallel to the axis, placed outside the plasma. Above a critical current, these bars convert the mirror into a minimum-B configuration, with a dramatic increase in stability (Post, 1981). It is common to combine the Ioffe bars with the mirror coils into a single conductor, called a *baseball coil,* which has the shape of the seam on a baseball. For ease of assembly, the baseball coil can be split into two halves, which together are called a *yin-yang* coil. In addition to hydromagnetic instabilities, magnetic mirrors are subject to velocity-space instabilities due to the absence of particles in the loss cone. The most dangerous of these is the drift cyclotron loss cone (DCLC) instability, which can be stabilized by adding a cool but isotropic plasma to the hot plasma (Baldwin, 1977).

3.7.3 Tandem Mirrors Even after instabilities have been brought under control, magnetic mirrors still suffer from large end losses. To minimize these losses, it is necessary to build a *tandem mirror* (Fowler, 1981). This has a large central cell with a weak, uniform B field connected to a mirror with strong B field at each end. These "plugs" have yin-yang coils to provide MHD stability and must be filled with hot, dense plasma. Their volumes, however, are relatively small. In addition, the injection of ion beams and ECRF power into the plugs produces a specially tailored potential distribution that, in one section, electrostatically confines the ions and, in another section, forms a thermal barrier for the electrons. These devices for plugging the end losses have been successfully demonstrated, but they detract from the basic simplicity of the mirror concept.

4. PHYSICS OF INERTIAL CONFINEMENT

4.1 Laser Fusion

In laser fusion, a small pellet of frozen deuterium–tritium fuel is suddenly heated by laser or particle beams impinging symmetrically on the surface, turning it into a hot plasma. As the plasma expands, its momentum is transferred to the solid part of the pellet, compressing it in a violent implosion to a density between 10^3 and 10^4 times solid density (Duderstadt and Moses, 1982). The fusion rate at these densities is high enough to give a net energy gain in the short time, of the order of picoseconds, during which this compressed state is maintained by inertia. The Lawson criterion of Sec. 3.1 can be expressed here as $\rho R > 3$ g/cm^2, where ρ is the density and R the radius in the compressed state. Here, the range of the α particles produced is so small that their energy is efficiently used in keeping the plasma at fusion temperature. In practice, the pellets are hollow shells covered with various layers of absorbers; a small piece of fuel at the center is ignited first, and the α particles from this are used to ignite the rest of the fuel in a propagating burn. In laser fusion, there are two approaches. The laser energy can be directed at the fuel pellet (*direct drive*), or it can be directed through the ends into a tiny high-Z canister, in the center of which the fuel pellet is mounted (*indirect drive*) (Yamanaka, 1991). The laser light is converted into x rays, and the latter are used for heating the pellet symmetrically. *Inertial confinement* is a generalization of the compression–ignition process to include drivers other than lasers (see Sec. 4.4). A more detailed treatment of this subject can be found under FUSION, INERTIAL CONFINEMENT.

4.2 Parametric Instabilities

The hope that inertial fusion would be free from the problems of plasma instabilities that plagued magnetic confinement was not realized: Laser fusion had instabilities of its own, called *parametric instabilities* (Nishikawa *et al.*, 1976). Ideally, laser light of frequency ω_0 should penetrate the plasma cloud up to the critical density $n_c = \epsilon_0 m \omega_p^2 / e^2$ where $\omega_0 = \omega_p$ [Eq. (14)]. At that point, the laser energy would be absorbed by collisional damping (*inverse bremsstrahlung*) and by the generation of plasma waves that are subsequently Landau damped (*resonance absorption*). Unfortunately, reflective instabilities occur in the underdense ($n < n_c$) region, preventing the absorption of the light. Furthermore, these instabilities generate fast electrons that can move forward into the solid fuel and preheat it, making it harder to compress. In *stimulated Brillouin scattering* (SBS), the laser light excites an ion-acoustic wave, which then acts as a grating to reflect the laser beam at a red-shifted frequency. *Stimulated Raman scattering* (SRS) is similar except that an electron plasma wave is generated, and the redshift is of order ω_p. If the plasma wave has $k\lambda_D \leq 1$ so that it is strongly Landau damped, the induced scattering from individual electrons is called *stimulated Compton scattering.* The laser light can also decay into two plasma waves in a *two-plasmon decay* instability occurring at the *quarter-critical layer,* where $n = n_c/4$. The *filamentation* instability can divide the laser beam into smaller beamlets, thus reducing the uniformity of power deposition. Fast electrons accelerated out from the pellet have such large current densities that they can generate multimegagauss magnetic fields, which degrade the smoothing effect of heat conduction. These parametric effects can be minimized by increasing ω_0, since the critical layer is then moved to higher densities, where classical collisions are more dominant. Nd-glass lasers are used for the 100-TW power levels required, the 1.06-μm (red) fundamental being frequency doubled to 0.53 μm (green) for diagnostics and tripled to 0.35 μm (blue) for compression. Though the conversion efficiency in crystals can be of order 75%, frequency-quadrupled light at 0.25 μm (UV) would require unusual optical materials. In indirect drive, the x rays have such high frequency that parametric instabilities are not a problem, but the light still has to pass through a low-density plasma before reaching the metal canister.

4.3 Rayleigh–Taylor Instability

After parametric instabilities, the most important remaining instability is the Rayleigh–Taylor instability (Bodner, 1991). As the pressure of the ablating plasma pushes on the solid wall of the pellet, small irregularities in the surface or the driving force create growing ripples, which prevent symmetric compression. Large-aspect pellets that have an outer shell that is thin compared with its radius are more easily imploded, but they are also more susceptible to the R-T instability. A beneficial effect not available in magnetic fusion is *vorticity shedding,* in which the escaping plasma carries away some of the instability energy. In direct drive, the laser energy must be divided into many beams to spread out the driving force uniformly over a sphere. In indirect drive, the x-ray *hohlraum* is supposed to provide a uniform pressure, but the laser illumination of the canister and the blockage of x rays escaping from the ends of the cylinder have to be adjusted carefully.

4.4 Driver Technology

Glass lasers are exceptionally inefficient and cannot be pulsed rapidly because of heat dissipation in the glass. For fusion power production, therefore, other drivers are necessary. The KrF laser, with 0.3-μm wavelength, is a possible alternative, being a gas laser that can run cw, but its development is in a relatively early stage. Beams of light ions, such as Li, can be produced by pulsed power (cf. Sec. 6.2 below) and directed toward a larger target than in laser fusion, heating the surface in the same way. The main problem is the focusing and transport of the ion beam from the diode structure in which it is produced to the target through an evacuated space that must also accommodate the neutron blanket. In *light-ion fusion,* the pulse length, energy per pulse, target size, and fusion energy per shot are all scaled upward from the laser case. The difficulties with transport are overcome in heavy-ion drivers. In *heavy-ion fusion,* beams of ions such as uranium are accelerated to MeV energies by particle-accelerator techniques. As in high-energy physics, the beams can be transported and focused to small radii. The energy deposition in the target is sharply concentrated at the end of the ions' range. New types of linear accelerators are being developed for these drivers.

5. PLASMAS IN SPACE

5.1 Plasmas in the Solar System

That plasmas exist naturally in outer space has long been apparent from displays of the Aurora Borealis and from disruptions of short-wave radio communications, including the mysterious glide tones now called *whistler waves* (Helliwell, 1965). The exploration of the environments of the Earth and other planets with spacecraft has brought not only an understanding of these phenomena (see IONOSPHERE) but also the realization that the sun and planets form an electromagnetic system controlled by the laws of plasma physics. The dipole magnetic field of the Earth traps ions and electrons coming from the sun by the magnetic mirror effect (Sec. 3.1.5), forming the *van Allen radiation belts.* The plasma density in this ionosphere rises from zero in the atmosphere, where the neutral gas cools the plasma so that it recombines readily, to a peak of the order of 10^5 cm^{-3}, and then falls to the order of 1–10 cm^{-3} in interplanetary space. Occasionally, electromagnetic disturbances drive energetic electrons into the atmosphere, exciting the oxygen atoms to emit the light of the aurora. A thunderstorm in the southern hemisphere can generate electromagnetic plasma waves that are channeled along the Earth's magnetic field to give whistling sounds detected by radio near the north pole, since the higher frequencies travel faster. A stream of charged particles from the sun, called the *solar wind* (Brandt, 1970), populates the ionosphere and controls its behavior. A solar storm can cause the ionosphere to fluctuate and disrupt its normal reflection of communications signals. The ionospheric plasma can even be manipulated by man, using powerful radio-frequency generators at the plasma frequency.

Outside the ionosphere, the plasma is nearly collisionless and is therefore frozen to the magnetic field. Since this is a high-beta plasma [beta is defined in Eq. (19)], the magnetic field cannot hold the plasma; rather, the field lines are shaped by the plasma motion. In particular, the plasma of the solar wind pushes the dipole field of the Earth into a long tail on the night side, called the *magnetotail.* The field lines of the Earth's field are joined to those of the interplanetary magnetic field discontinuously at a boundary called the *magnetopause,* which encloses the *magnetosphere* (*q.v.*). The discontinuity is possible because of sheet currents in the plasma. As the Earth orbits the sun, it can be viewed as plowing through the interplanetary magnetic field, dragging its own plasma and magnetic field with it, the field lines adjusting themselves at every instant by the process of *reconnection.* Since the earth's velocity is supersonic in the interplanetary plasma, a collisionless shock front, called the bow shock, forms ahead of the Earth. For further information and references, see IONOSPHERE and MAGNETOSPHERE.

Each planet has a different plasma environment depending on its magnetic field and ionosphere. The magnetosphere of Jupiter has been explored extensively and is particularly interesting because of its major satellites, which have their own magnetic fields and can even inject particles into Jupiter's magnetosphere through volcanic action. The rings around Saturn have features that may depend on plasma effects. For instance, it has been proposed that the radial spokes in these rings may be caused by charged dust that orbits over the poles of the planet. Comets can often be seen to have two tails, one blown by the sun's photons and the other by the solar wind. The dust cloud that is ejected from a comet as it nears the sun can be ionized if it collides with an existing plasma at greater than the *critical ionization velocity.* Dusty plasmas are of importance not only in comets and planetary rings, but also in plasma processing (see Sec. 7.2).

5.2 Plasmas in the Sun

The sun is a fusion reactor with gravitational plasma confinement. The heat that is generated at the core is convected out to the surface by turbulent motions. In a manner not yet understood, these motions generate complicated magnetic fields, which control the appearance of the sun and its interaction with the Earth via the solar wind. Some magnetic lines leave the sun's surface and loop back, forming the north and south poles of a sunspot pair. Solar prominences reveal the presence of magnetic loops further out. Some field lines do not loop back but reach out into space through holes in the corona, carrying the solar wind with them. The corona itself is extremely hot (Fig. 5). The mechanism of coronal heating and the dynamo that creates the magnetic fields are unsolved problems. For further information and references, see SOLAR RADIATION.

5.3 Magnetic-Field Reconnection

Since the particles in a collisionless plasma gyrate around magnetic-field lines and are effectively "frozen" to them, it is not possible to change the magnetic configuration without a mechanism for particles to jump from one field line to another. This problem of *magnetic reconnection* or *field annihilation* arises both in space plasma physics (Fig. 6) and in magnetic-confinement fusion (Sec. 3.1.4.2). If two oppositely directed

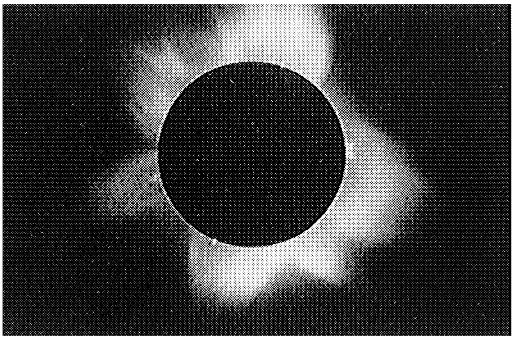

FIG. 5. The sun's corona, prominences, and sunspots are examples of magnetized plasmas. The solar wind carries some of this plasma to the Earth and controls its plasma environment. Fusion reactions in the interior of the sun generate its energy, as in all stars.

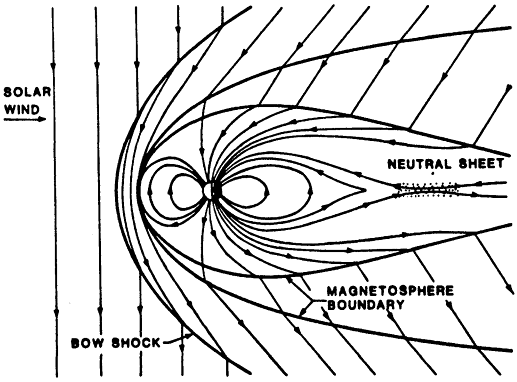

FIG. 6. The magnetic environment of the Earth, showing the neutral sheet in which field lines of opposite polarity coalesce and magnetic reconnection occurs. The transition between the interplanetary magnetic field and the Earth's field is controlled by the presence of plasma from the solar wind that is entrained by the magnetic fields.

field lines come together to cross each other at an X point, entraining plasma with them, eventually the plasma is squeezed into a thin layer in which the density is high enough for collisions to occur. Collisions permit particles to cross field lines, and so the field lines can lose their identity momentarily and reconnect. In this process, some of the magnetic energy is converted into kinetic energy, and acceleration of particles can occur. Reconnection is independent of collisionality, because the thickness of the interface layer can adjust itself to guarantee a sufficiently high density. A peculiarity of plasmas is that reconnection can occur even if the collision rate is identically zero, because collisionless processes such as Landau damping or instabilities can provide an effective resistivity.

5.4 Plasma Astrophysics

Hydrogen atoms are photoionized in interstellar space by starlight, and the plasma does not readily recombine when the density is of order 1/cm^3. The Debye length is nonetheless much shorter than the dimensions of the system, so that interstellar and intergalactic space is filled with true plasmas. The motions of magnetic-field lines are subject to the same constraints as in the solar system. The presence of magnetic fields can be seen in the Crab Nebula, in which the organization of gas into filaments can only be due to magnetic fields (Fig. 7). The directions of these fields can be measured from the polarization of the synchrotron radiation emitted by the magnetized electrons.

Quasistellar objects such as neutron stars, quasars, pulsars, and black holes involve plasmas of extremely high density with magnetic fields as high as 10^{12} G. Radioastronomy has revealed the presence of extended radio sources and astrophysical jets, which also emit plasma radiation. When an object with a large magnetic field spins, possibly with plasma streaming from the poles, there will be a radius at which the field lines will be rotating at the speed of light. Relativistic astrophysics is the name of the science of such phenomena, but the concepts of plasma physics are deeply imbedded in this science. The acceleration of cosmic rays can be attributed to these objects, but also to other phenomena such as field annihilation and magnetic mirroring.

On a larger scale, the formation of galaxies (Plate 3) has been treated as a plasma problem, with the particles of a plasma replaced by stars and the electromagnetic force replaced by gravity. Spiral arms can thus be considered to grow as a result of an instability. The formation of stars from gas and dust is a problem in plasma hydrodynamics involving dusty plasmas, which also occur in the solar system and in industrial plasmas (Secs. 5.1 and 7.2). For further information and references, see ASTROPHYSICS.

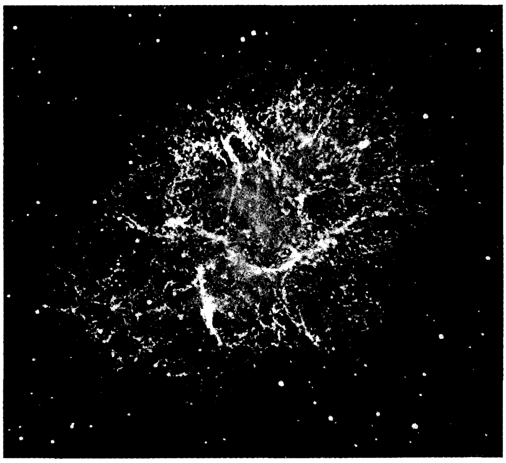

FIG. 7. The filamentary structure of the Crab Nebula reveals the presence of plasma constrained by magnetic fields.

6. LIGHT AND PARTICLE BEAMS

6.1 Coherent Radiation Generators

6.1.1 Microwave Sources Originally developed for radar, microwave generators are now used by everyone in personal communications, television, and microwave ovens. For the scientist, microwave sources are useful in particle accelerators, controlled fusion, and spectroscopy of organic substances. Coherent radiation is generated by electron beams, which are basically single-species plasmas; and their motions, space-charge effects, and instabilities are described by plasma-theoretical techniques. In a *klystron,* an electron beam is shot through two resonant cavities. The electric field in the first cavity modulates the electrons' velocities so that they become bunched. The bunched beam then passes through the second cavity and excites the microwaves in it. A portion of this energy is fed back to drive the first cavity, and the rest is the output energy. In a traveling-wave amplifier (TWT), a slow-wave structure such as a coil surrounds the beam and propagates electromagnetic waves with approximately the electrons' velocity. A beam–plasma instability occurs, with the plasma replaced by the slow-wave structure, and the wave on it is amplified. In both cases, radiation is generated at the expense of electron energy. In a magnetron, a magnetic field causes the electrons to drift at the $E \times B$ velocity. Magnetrons at 2.45 GHz are mass produced economically and are used in microwave ovens. In a gyrotron, the electron beam travels both perpendicular and parallel to a magnetic field, and the electron are bunched in their gyro-motions. The radiation is near the cyclotron frequency. To produce higher frequencies at a reasonable magnetic field, harmonic gyrotrons operate at high multiples of ω_c. Gyrotrons can produce prodigious power in the megawatt range for use in heating fusion plasmas. The technology of gyrotrons has also been used in isotope separation and materials processing. A recent variant is the cyclotron autoresonant maser (CARM), in which the electrons' parallel velocity is larger than their perpendicular velocity, providing an energy source for maintaining the proper relativistic mass to stay in cyclotron resonance.

6.1.2 Free-Electron Lasers The microwave sources mentioned above are generally not tunable over a large range of frequencies. Tunability is the distinguishing feature of the free-electron laser (FEL) (*q.v.*) (Roberson and Sprangle, 1989). In a FEL, a relativistic electron beam and a beam of electromagnetic radiation are injected together into a channel in which there is a spatially alternating magnetic field (a *wiggler* or *undulator*). The combined fields cause the electron beam to oscillate and generate radiation at higher frequency and higher power. Tunability is achieved by varying the wiggler wavelength or the electron energy, since the frequency upshift is proportional to γ^2, where γ is the relativistic Lorentz factor. Thus, FELs are useful not only for applications where tunability is essential, such as spectroscopy, but also for generating short-wavelength radiation. Powerful FELs have been proposed for defense purposes. When the density of electrons is so large that $k\lambda_D \leq 1$ in their rest frame, microwave devices are said to operate in the *Raman regime,* but no such devices have yet been made practical.

6.2 Pulsed Power

6.2.1 Relativistic Electron Beams Extremely intense beams of electrons can be produced by charging a room-sized array of capacitors immersed in oil (a *Marx bank*) and switching the voltage to a pulse-forming transmission line (a *Blumlein*) that ends in a diode (Miller, 1982). By charging the capacitors in parallel and connecting them in series via spark gaps before discharging, voltages of 0.1–10 MV can be achieved. The Blumlein is usually insulated by pure water, which can maintain a high dielectric constant (≈89) for short pulses, and can deliver ≈80-ns pulses of order 1–20 MA, depending on whether the device is designed for high or low impedance. The relativistic electron beams (REBs) emitted by the diode can carry powers up to the order of 10^{13} W. The beam density is large enough to prevent propagation in a vacuum; a gas fill is normally used to provide the ions needed for space-charge neutralization. The beam current also has to be neutralized, since it is beyond the *Alfvén limit,* at which the Larmor radius of the electrons in their self-generated magnetic field is smaller than the beam radius. A return current of dense but slow electrons flows backward in the beam to cancel the magnetic field. REBs can be used to study the behavior of matter under extreme energy conditions, such as in nuclear weapons tests, and to generate multi-megagauss magnetic fields (Turchi, 1980).

6.2.2 Light-Ion Beams By reversing the polarity of the diode in a pulsed-power machine and introducing a source of light ions such as plastic fibers, it is possible to produce intense ion beams up to the order of 1 MA. Magnetic insulation can be used to prevent the electrons from short-circuiting the diode. Light-ion beams are studied as alternate drivers for inertial-confinement fusion. For this purpose, circular arrays of tens of pulsed-power generators have been built to concentrate the power onto a fusion target (cf. FUSION, INERTIAL CONFINEMENT).

6.2.3 Pinches, Switches, and Exploding Wires The advent of pulsed power opened up research on different types of single-shot devices. A *Z* pinch is a linear, high-current discharge whose self magnetic field is sufficient to confine, or even pinch, the plasma radially. Such a plasma is known to be unstable to kink or sausage instabilities, but useful radiation, for instance for x-ray lithography, can be created before breakup. A Marx bank discharged through a solid deuterium fiber or an imploding metal cylinder has been used to study the possibility of a simple fusion device that requires no external coils. Pulsed discharges through solid wires or wire arrays are used to generate short pulses of light or pressure. Fast-opening switches that can transfer large currents have a number of uses including the charging of an inductor for inductive energy storage (Früngel, 1976). A dense plasma generated by pulsed power can be used for this purpose. (See also SPARKS, ARCS, AND OTHER ELECTRIC DISCHARGES.)

6.3 Plasma Accelerators

New ideas from plasma physics have been applied to the technology of high-energy accelerators used for fundamental particle-physics research and for synchrotron light sources. For instance, the *modified betatron* adds a toroidal magnetic field to the betatron accelerator, and the *inverse free-electron laser* (IFEL) accelerates a beam of electrons using a laser beam and an undulator. Conventional accelerators driven by microwave sources are limited to acceleration rates of the order of 100 MeV/m by voltage breakdown. Since a plasma is already ionized, plasma-based schemes do not suffer from this limit and in principle can achieve gradients of order 100 GeV/m (Chen, 1991a).

6.3.1 Beat-Wave Accelerator In this concept, two infrared laser beams of different frequencies are sent into a plasma whose plasma frequency matches the lasers' difference frequency. The beat between the laser beams then resonantly excites an electrostatic plasma wave with a velocity equal to the group velocity of the light (Fig. 8). Electrons injected into this wave at the right phase will be continuously accelerated by the electrostatic field. The maximum electron energy in eV is roughly equal to $n^{1/2}$, where n is the density per cm^{-3}, so that $n = 10^{18}$ cm^{-3} would give 1 GeV/cm. Such linear accelerators would be a factor of 1000 shorter than conventional ones and make the *in situ* production of medical isotopes much easier. Preliminary tests have shown acceleration to 30 MeV, in agreement with theory.

6.3.2 Wake-Field Accelerator Another method to generate a fast plasma wave is to inject a short pulse of electrons into a plasma. A "wake" oscillating at ω_p then follows the pulse like the wake of a boat. If another pulse of electrons is injected into this wake, it can be accelerated in the same way as in the beat-wave accelerator. The wake-field accelerator is effectively a transformer, turning a large bunch of electrons of low energy—say, 100 MeV—into a smaller bunch of electrons at a higher energy—say, 1 GeV. A related concept employs a short laser pulse to generate the wake. In any case, these methods all require a dense, uniform plasma source and either a large laser or a large accelerator.

6.3.3 Plasma Lenses To maximize the rate of high-energy reactions, particle beams must be focused to submicron diameters. Plasmas can provide a focusing force orders of magnitude larger than conventional magnets. A charged relativistic beam can propa-

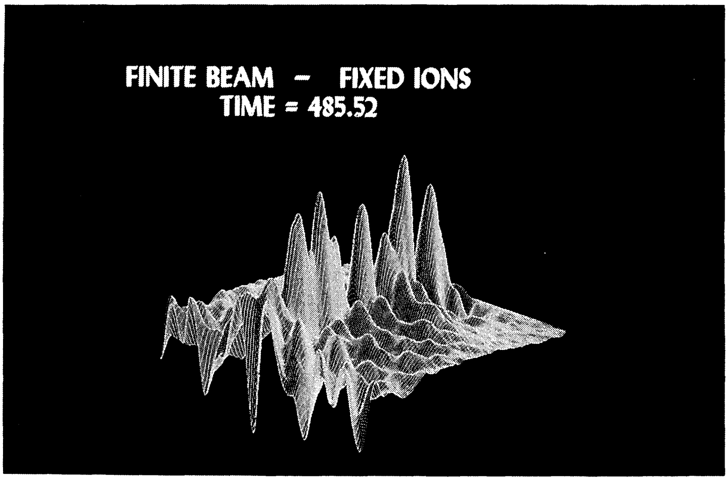

FIG. 8. A two-dimensional (r,z) particle simulation of the beat-wave accelerator mechanism. The laser beams enter from the right (along z), and the ponderomotive force at their beat frequency bunches the electrons into the density fluctuations of a plasma wave. The electric potential of the wave is plotted vs. z and radius r. The pattern travels along z at the laser beams' group velocity. Beam electrons injected into the wave can be trapped in the potential wells and accelerated to the wave's phase velocity (Mori, 1990).

gate without spreading because its electrostatic repulsion is balanced by the inward force of the self magnetic field. When sent through a plasma, the beam electrons replace the thermal electrons, and the ions cancel the electrostatic field. The pinch force is then able to focus the beam.

6.4 X-ray and Short-Pulsed Lasers

6.4.1 X-ray Lasers The dream of generating coherent light in the x-ray regime has been realized by the use of the powerful pulsed lasers developed at the Lawrence Livermore Laboratory for laser fusion. Inner-shell transitions in multiply ionized atoms can be induced by irradiating a plasma several centimeters in length with intense laser pulses (Kauffman, 1991). The medium for x-ray lasers is necessarily in the plasma state. X rays have also been produced by laser heating of carbon fibers and with Z pinches. In each case, special methods are used to depopulate the lower level of the transition. So far, no efficient x-ray reflectors have been developed, and all x-ray lasers are superradiant.

6.4.2 Femtosecond Lasers Pulse-compression techniques on glass lasers have been developed to the extent that tens of terawatts can be delivered in 100 fs (1 fs = 10^{-15} s), with peak intensities exceeding 10^{18} W/cm^2. At these intensities, the electric field of the light wave exceeds that which holds the orbital electrons in an atom, and the ponderomotive force is measured in megabars. Under such conditions of high energy density, almost any material would be turned into a plasma. The behavior of matter in this plasma state would be highly nonlinear; for instance, the electrons moving in the light wave would change their mass relativistically in each half cycle. Production of even shorter pulses will permit the observation of ultrafast biological and chemical phenomena, such as the generation of nerve impulses or the formation of a molecule.

7. INDUSTRIAL APPLICATIONS

Plasmas are extensively used in manufacturing and in the production and improvement of materials. These applications call for low-temperature, partially ionized plasmas, which have properties different from the hot, collisionless plasmas used in fusion and present in space. Industrial plasmas are likely to have many species of atoms and molecules, including negative ions, and are usually collisional, involving simultaneously many different scattering, excitation, and ionization processes (Lieberman and Lichtenberg, 1994).

7.1 Plasma Sources

In some manufacturing procedures, the type of plasma is not crucial; only the existence of electrons is needed. In the "barrel etcher," for instance, a simple discharge between two electrodes is used to create a low degree of ionization. For the fabrication of large-scale integrated semiconductor circuits, however, the plasma performs several functions and must be carefully controlled. By far the most common and the best developed plasma generator for this purpose is the parallel-plate capacitor discharge, called the RIE (reactive ion etching) source (Fig. 9). The RIE plasma is made by applying a rf voltage at 13.56 MHz between two parallel electrodes about 5–10 cm apart. The gas is a mixture containing Cl or F compounds, which are dissociated by the plasma electrons; it is the neutral Cl or F atoms that chemically attack the target in etching. A sheath forms on both electrodes to confine the electrons, that on the negative electrode being thicker. During the rf cycle, these sheaths oscillate, and the plasma "sloshes" back and forth between electrodes. On average, the ions experience a sheath potential that accelerates them toward the substrate, or object to be treated, which is mounted on one electrode. That electrode can be grounded through a separate rf power supply to adjust the rectified sheath voltage. Since the sheath drop, rf oscillation, and plasma density all depend on rf power, the degree of control over the plasma is restricted.

New plasma sources have been proposed to be more flexible than the RIE source and to produce higher plasma densities (Lieberman and Gottscho, 1994). (See also PLASMA ETCHING.) The leading contenders are the electron-cyclotron resonance (ECR) source, inductively coupled plasmas (ICP), the radiofrequency inductive (RFI) or transformer-coupled plasma (TCP) source, and the helicon source. The ECR source, driven by 2.45-GHz microwaves, is a spinoff from ECRF technology used for plasma heating (cf. Sec. 3.1.4.3). This source can produce high densities at low pressures but requires a magnetic field of 875 G at the resonance layer. The other sources operate at the industrial frequency of 13.56 MHz or its harmonics. ICPs utilize a helical winding around a cylindrical tube for applying the rf power, usually with an electrostatic shield to eliminate direct electrostatic coupling. RFI and TCP sources are similar, each with a pancake-shaped rf antenna lying on a quartz plate, which separates it from the plasma chamber. These rf sources do not require a magnetic field and do not resonate with a natural frequency of the plasma. In the helicon source, an external antenna launches a low-frequency whistler wave, called a helicon wave, which ionizes the plasma as it is damped. A magnetic field of 0.1–1 kG is required. When the helicon resonance is struck, ionization is particularly efficient. In all these sources, the plasma is often drifted into a chamber with magnetic confinement at the walls provided by arrays of permanent magnets, called a *magnetic bucket*, to smooth out density variations before the plasma arrives at the substrate.

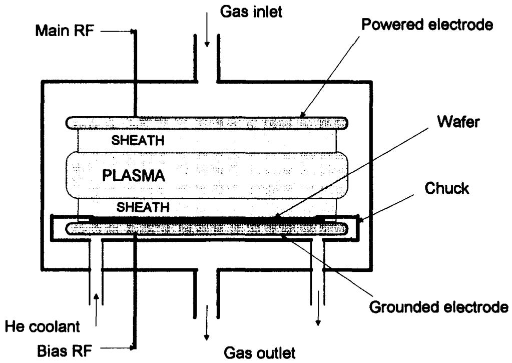

FIG. 9. Diagram of a RIE (reactive ion etching) plasma source commonly used for etching and deposition of silicon wafers in semiconductor fabrication. A 13.56-MHz radio-frequency source applied between the parallel-plate electrodes creates the plasma, which impinges on the wafer mounted on the bottom plate.

7.2 Plasma Etching and Deposition

Plasma processing is essential in the production of semiconductor integrated circuits, in which the individual features can be smaller than 0.5 μm. The manufacture of flat-panel displays, such as the active-matrix liquid-crystal displays (AMLCDs) used in portable computers, also benefits from plasma processing, though it is not essential, since the elements here are on a larger scale. Integrated circuits are made, hundreds at a time, on a polycrystalline silicon wafer, typically eight inches or larger in diameter. The various components of a chip—transistors, capacitors, conductors, etc.—are made in a series of steps involving deposition, masking, stripping, and etching (Manos and Flamm, 1989). Different processes are used for handling semiconductor material, oxide or nitride insulators, conductors, and photoresist. The patterns are of such fine scale that photolithography with short-wavelength x rays must be used; the x-ray sources are often plasma devices. Since the gases, pressures, and even plasma sources are generally different for each step, the wafers are shuttled under vacuum from one "reactor" to the next in a transfer mechanism known as a *cluster tool.*

The role of plasma in the etching process is twofold. First, the electrons produce the active species, and ion bombardment prepares the surface so that chemical etching occurs more readily. The combined effect is to increase the etch rate by over an order of magnitude over chemical etching without plasma or plasma sputtering without chemicals. Second, the sheath electric field accelerates ions so that they strike the substrate at right angles, thus guiding the etching process to proceed in a straight line, so that sharply defined features can be chiseled. Low-pressure operation is desirable for reducing ion scattering in the sheath. The plasmas used for etching are designed for the following attributes:

1. *uniformity* of density over an entire wafer;
2. directionality, or *anisotropy* of ion orbits;
3. high density, and hence high *etch rate;*
4. high *selectivity* in etching the desired material; and
5. compactness, simplicity, and low cost.

Examples of problems that occur in plasma etching and deposition are contamination by particulates and damage to oxide insulators. Micron-size dust particles are formed from the ambient gases, and, being charged negatively by electron bombardment, they are trapped in local maxima of electric potential. When the plasma is turned off, the particles are driven into the wafer and cause defects in some of the chips. Device damage occurs when energetic electrons or ions imbed themselves into an insulating layer and cannot be removed. To prevent damage to delicate circuits, one can use a *downstream reactor,* in which the plasma produces the active species but is swept away before any charged particles can reach the wafer. More detailed information on this subject may be found in PLASMA ETCHING.

7.3 Gaseous Electronics

Traditionally, gaseous electronics is the study of plasmas in gas-filled electronic tubes and switches and of atomic processes such as collisions, ionization, and radiation. Subjects such as positive columns, glow discharges, arcs, coronas, field emission, breakdown, and cathode spots have now been replaced by the microwave and radio-frequency discharges used for plasma processing. The most common efficient light source, the fluorescent light, retains its eminent position in gaseous electronics; but new light sources with higher brightness and efficiency and with no internal electrodes are being developed using microwave and rf technology. For more information on this subject, see SPARKS, ARCS, AND OTHER ELECTRIC DISCHARGES.

7.4 Implantation and Polymerization

Ion implantation with energetic ion beams is used to improve the surface hardness, for instance, of metals or to create special semiconductor materials (Conrad and Sridharan, 1994). In this process, a three-dimensional object has to be rotated to expose its surfaces to the ion beam. In plasma-source ion implantation (PSII), the object is immersed in a plasma and is given a negative pulse of tens of kilovolts. If the Debye length is sufficiently small, a sheath is formed on all surfaces, and the sheath voltage drives ions at near-normal incidence into all surfaces regardless of their irregular shapes. This method is used for implanting nitrogen into cutting tools and other metallic objects to increase hardness and reduce corrosion. Medical prostheses can be hardened and smoothed by PSII. Eventually, PSII might be applied to the manufacture of magnetic and optical disks.

Strong plastic coatings can be created with plasma discharges in organic compounds such as methyl methacrylate (d'Agostino, 1990). When polymerized in the presence of electrons, a plastic material becomes highly cross linked, resulting in a strong and resistant layer. Organic plasmas can be used for a number of practical purposes: for barrier coatings in gasoline tanks, soft drink bottles, and medical capsules; for making textile fibers more absorbent to dyes; for increasing the water resistance of papers and wood; for cleaning and sterilization of biomedical containers; for producing optical fibers with graded indices of refraction; and eventually for producing integrated optics chips for optical computing.

7.5 Thermal Plasmas

Thermal plasmas are plasmas at near-atmospheric pressure that are so collisional that they are in kinetic, though not radiative, equilibrium (Boulos *et al.*, 1994). Plasma spray treatment of aircraft and automobile parts such as turbine blades is a widespread industrial application of plasma physics. Thermal plasma jets are capable of growing diamond coatings at a much faster rate than with low-pressure plasmas. Development of this process can lead to diamond coatings on all cutting tools, and even to diamond substrates for semiconductors. Thermal plasmas can also be used to develop new types of ultrahard materials. Further information can be found in THERMAL PLASMA DEVICES.

7.6 Isotope Separation

The production of U^{235} by gas-diffusion methods is notoriously slow, and many ideas for faster processes have been proposed. The use of plasmas for isotope separation started during World War II with the ill-fated Calutron project, named after the University of California, in which instabilities were so strong that the plasma was lost at what is now called the Bohm diffusion rate. Though new types of plasma centrifuges are still being researched, the major avenues for advanced isotope separation use lasers or radio-frequency generators.

7.6.1 Laser Isotope Separation With narrow linewidth, lasers can selectively excite an isotopic species either as an atom or in a molecule. In atomic-vapor laser isotope separation (AVLIS), the naturally occurring isotopic mixture of an element is vaporized and introduced into a long chamber. A laser beam tuned to a particular line is directed into the gas and selectively ionizes the desired isotope. A high voltage applied to the walls of the chamber then causes the ions to be collected at the cathode (Vitello *et al.*, 1992). This method is limited by the rate at which the ions can drift across the chamber, and to those isotopes for which a suitable laser line can be found.

7.6.2 Ion-Cyclotron Isotope Separation In this scheme, the raw material is vaporized, then ionized by microwaves from a gyrotron, and is confined radially by a uniform magnetic field (Chen, 1991b). A radio-frequency signal near the cyclotron frequency of the desired isotope is then applied to the plasma with a helical antenna. Those atoms that are in cyclotron resonance are selectively accelerated to large perpendicular energies and, because of their large Larmor radii, can be "scraped off" onto suitable collectors. Since both the frequency and the magnetic field can be tuned, this method will obviously work for any isotope; for this reason, it is particularly useful for producing medical isotopes.

GLOSSARY

Adiabatic Invariant: A physical quantity that stays constant under slowly changing conditions.

Alfvén Speed: The propagation speed of displacements of magnetic-field lines imbedded in a plasma.

Alfvén Wave: A low-frequency wave in a magnetized plasma traveling at the Alfvén speed.

Ambipolar Diffusion: Collisional diffusion of ions and electrons to the wall at rates that are made equal by an electrostatic field.

Ballooning Mode: A plasma instability localized to a region in which the magnetic field has unfavorable curvature (see **Magnetic Curvature).**

Banana Orbit: The curve, in a cross-sectional plane of a toroidal confinement device such as a tokamak, traced by an ion or electron as it moves along the magnetic-field lines. These orbits are caused by the magnetic mirror effect, which reflects some particles before they can reach the strong-field region on the inside of the torus.

Bernstein Wave: Electrostatic waves near the ion- and electron-cyclotron frequencies and their harmonics.

Beta: Ratio of plasma pressure to magnetic-field pressure.

Blanket: A meter-thick region surrounding the plasma in a fusion reactor, containing compounds of lithium and used to absorb the product neutrons and convert their energy into heat.

Blumlein: A high-voltage transmission line, filled with water or oil, used for pulse shaping in a pulsed-power device.

Bohm Diffusion: Instability- or convection-driven transport of plasma across a magnetic field, which not only is much faster than collisional diffusion but also scales more weakly with field strength.

Bohm–Gross Wave: An **Electron Plasma Wave.**

Boltzmann Distribution: The Gaussian velocity distribution of a gas in thermal equilibrium.

Boltzmann Relation: Relation between the local electric potential and the density of a charged species with a Boltzmann velocity distribution.

Bootstrap Current: In a closed fusion device, a self-induced toroidal current driven by the momentum loss of radially escaping plasma.

Breakeven: In fusion reactors, the condition for the nuclear energy release to exceed the energy used to produce the plasma.

Bremsstrahlung: X radiation emitted by the electrons of a plasma by the accelerated charge effect when they collide with ions.

Bremsstrahlung, Inverse: Classical collisional absorption of laser light.

CARM: Cyclotron AutoResonant Maser: one of several types of microwave generator based on the cyclotron motion of electrons in a magnetic field.

Caviton: A density cavity in a plasma caused by the radiation pressure of electromagnetic radiation trapped in it.

Chaos: The mathematically random behavior of a variable subject to a small perturbation from a well-organized, periodic state.

Child–Langmuir Sheath: The layer surrounding a charged electrode, which contains only one charge species and in which the potential varies according to the theory of space-charge-limited diodes.

Collapse: The ultimate fate of Langmuir turbulence, according to theory: Langmuir waves become trapped in density cavities that they themselves create, and these cavities become smaller and deeper until the wave energy is dissipated by the acceleration of fast electrons.

Confinement Time: Particle confinement time is the average time an ion–electron pair resides in a plasma before it is lost to the walls; energy confinement time is the ratio of the heat content of a plasma to the power input in steady state.

Coulomb Collision: Deflection of an ion or electron by the electric field of another charged particle.

Coulomb Logarithm ($\ln\Lambda$): A numerical factor of order 10 that accounts for the cumulative effect of many small-angle deflections; here Λ is the ratio of the maximum to minimum impact parameters used in the calculation.

Current Drive: The induction of a steady toroidal current in a closed fusion device by the entrainment of electrons in a toroidally propagating wave.

Cutoff Frequency: A characteristic frequency of a wave at which its phase velocity becomes infinite and beyond which it cannot propagate.

Cyclotron Frequency: The frequency at which an ion or electron executes circular orbits in a magnetic field.

Cyclotron Radiation: Radiation at the cyclotron frequency and its harmonics emitted by electrons gyrating in a magnetic field; also called **Synchrotron Radiation.** The origin of signals received from space, as well as a cause of energy loss from fusion plasmas.

Debye Length: A characteristic length below which a plasma behaves like individual particles without long-range cooperative motions.

Debye Sheath: A thin layer, of the order of several Debye lengths, separating a plasma from walls and electrodes. The sheath forms a self-adjusting potential barrier to equalize the escape rates of the positive and negative charge carriers.

Debye Shielding: The formation of sheaths around externally imposed electrodes to prevent strong electric fields from appearing in a highly conductive plasma.

Debye Sphere: A sphere with radius equal to a Debye length.

Diamagnetism: The tendency for a material to generate magnetic fields opposite to those imposed on it; plasmas are diamagnetic because of the field generated by gyrating particles.

Diffusion, Anomalous: Transport across magnetic fields at a rate exceeding that expected from classical Coulomb collisions, and caused by such effects as instabilities, convection in dc electric fields, and magnetic errors.

Diffusion, Bohm: See **Bohm diffusion.**

Diffusion, Classical: Transport of particles or heat via ordinary Coulomb collisions.

Diffusion, Gyro-Bohm: An anomalous diffusion rate smaller than the Bohm rate by the ratio of Larmor radius to plasma size.

Diffusion, Neoclassical: Classical diffusion in a torus, embodying no anomalous processes other than predictable toroidal effects such as the trapping of particles in **Banana Orbits.**

Direct Drive: In laser fusion, the use of laser light to compress the fuel pellet without first converting the radiation to x rays.

Disruption: A sudden termination, unpredictable and sometimes violent, of the discharge in a tokamak, resulting in deposition of the stored energy into the walls.

Double Layer: A region inside a plasma that contains alternating layers of excess positive and negative charge and that is sustained by the presence of non-Maxwellian velocity distributions.

Drift Instability: Unstable growth of drift waves driven by a pressure gradient; also called a **Universal Instability** in the collisionless limit.

Drift Wave: A low-frequency wave, with a phase velocity near the diamagnetic drift velocity, which exists only in nonuniform plasmas.

ECRH: Electron-cyclotron resonance heating, a method for heating plasmas with microwave power at the electron-cyclotron frequency. Also called ECRF: electron-cyclotron range of frequencies.

Electron Plasma Wave: A Langmuir oscillation that propagates by virtue of finite electron temperature; also called **Langmuir Wave** or **Bohm–Gross Wave.**

Energy Principle: A formulation, based on the calculus of variations, of the criterion for stability or instability of a plasma in a magnetic field of arbitrary shape.

Extraordinary Wave: An electromagnetic wave propagating in a plasma in a direction normal to the background magnetic field.

Faraday Rotation: Rotation of the plane of polarization of a light wave traveling through an anisotropic medium, such as a magnetized plasma.

Favorable Curvature: Concavity of magnetic-field lines that bulge toward the center of the plasma rather than in the normal, convex direction; this sign of the curvature stabilizes the **Gravitational Instability.**

FEL: Free-electron laser: a generator of coherent radiation based on the excitation of waves of upshifted frequency when an electromagnetic wave is passed through a periodically varying magnetic field in the presence of an electron beam.

Field Annihilation: See **Reconnection.**

Filamentation: In laser–plasma interactions, the tendency for an intense laser beam to break up into smaller beamlets when passing through a plasma; in magnetic fusion, the tendency for a toroidal current to do likewise, thus creating **Magnetic Islands.**

Fusion: Release of nuclear energy by the transmutation of light elements into heavier ones; the conversion of heavy hydrogen into helium requires a hot plasma in near-thermal equilibrium and is then called **Thermonuclear Fusion** or **Controlled Fusion.**

Gravitational Instability: A hydrodynamic instability of a plasma confined by a magnetic field; the centrifugal force of particles following curved field lines acts like a gravitational force in pushing small ripples in the plasma surface into large bulges.

Gyrotron: One of several types of microwave generator based on the cyclotron motion of electrons in a magnetic field.

H-Mode: A regime of operation of tokamaks characterized by High confinement, small internal gradients, and an edge layer with highly sheared electric fields that forms a transport barrier.

ICRH: Ion-cyclotron resonance heating: a method for heating plasmas with radio-frequency power at the ion-cyclotron frequency. Also called ICRF: ion-cyclotron range of frequencies.

Ignition: Maintenance of fusion conditions in a thermonuclear plasma by the retained heat of the charged-particle products of the reactions.

Indirect Drive: In laser fusion, compression of the fuel pellet by a uniform bath of x rays, which are generated when laser beams strike the interior of a metal canister surrounding the pellet.

Inertial Confinement: Attainment of fusion conditions by using radiation or particle beams to compress the fuel to more than 1000 times solid density; at such densities, the fusion reactions take place during the instant when the fuel is held together by its own inertia.

Interchange Instability: Same as **Gravitational Instability.** The plasma and magnetic-field regions are imagined to be interchanged, with a decrease in potential energy.

Inverse Bremsstrahlung: Classical collisional absorption of laser light.

Ion Wave: Plasma analog of an acoustic, or sound, wave in air. Only one of the species in the plasma needs to have a finite temperature for the wave to exist.

Ionosphere: The region surrounding the Earth or other planet that contains a plasma.

Kink Instability: The bending or coiling of a current channel in a magnetized plasma.

Landau Damping: Reversible damping of a wave in a collisionless plasma, caused by the loss of wave energy to particles that surf on the wave.

Langmuir Oscillation: The high-frequency oscillation of electrons in a plasma when displaced from their normal positions relative to the relatively immobile ion background. These oscillations do not propagate in an infinite, cold plasma, but they become propagating **Electron Plasma Waves** in a warm plasma and propagating **Trivelpiece–Gould Modes** in a bounded plasma.

Langmuir Probe: A small electrode that, when inserted in a plasma, gives information on local temperatures, densities, and potentials via its current–voltage characteristic.

Langmuir Turbulence: The disorganized state of a plasma subject to large-amplitude Langmuir waves.

Langmuir Waves: Same as **Electron Plasma Waves.**

Larmor Orbit: The circular path of a charged particle in a magnetic field.

Lawson Criterion: The value of the product of plasma density and confinement time above which energy breakeven is achieved in a fusion reactor.

Line-Tying: In an open confinement device, the stabilizing effect of currents in conductors on which magnetic-field lines terminate.

Loss Cone: The range of pitch angles for which particles are not reflected by a magnetic mirror.

Magnetic Bottle: Popular term for fusion confinement device.

Magnetic Curvature: Technical term for the convex (unfavorable) or concave (favorable) curvature of magnetic-field lines, with reference to the stability properties of the plasma in a fusion confinement device; see **Favorable Curvature.**

Magnetic Island: One of a chain of azimuthally distributed regions in the cross section of a torus that contain an isolated group of magnetic-field lines that do not reach other parts of the cross section.

Magnetic Mirror: A region of increasing magnetic field that reflects a fraction of the impinging plasma particles; also refers to a fusion confinement system consisting of a set of two magnetic mirrors.

Magnetic Trap: Same as **Magnetic Well.**

Magnetic Well: A magnetic configuration containing a point from which the field strength increases in all directions.

Magnetosphere: The region surrounding a planet in which the planet's magnetic field is dominant over the interplanetary magnetic field.

Marx Bank: A capacitor bank that is charged in parallel but discharged in series, in order to obtain high voltages.

MHD: MagnetoHydroDynamics: a discipline in which the plasma is treated as a conducting fluid without regard for individual particle motions or deviations from thermal equilibrium.

Minimum-B: Characterizing an absolute **Magnetic Well**; a minimum-$\bar{B}$ configuration is an average magnetic well, in which the average **Magnetic Curvature** experienced by a particle is in the favorable direction.

Mirror Ratio: The ratio between maximum and minimum field strengths in a magnetic mirror.

Modulational Instability: In nonlinear plasma theory, an instability in which the unstable waves develop a growing ripple in the envelope of their amplitudes.

NBI: Neutral Beam Injection: the leading method for heating the plasma in controlled fusion experiments.

Nonlinear: Beyond the scope of validity of small-amplitude, linear theory, in which the behavior of a system can be described by a simple sum over Fourier components.

Non-neutral Plasma: A plasma containing only positive or only negative charges.

Parametric Instability: A phenomenon occurring in laser–plasma interactions in which one wave is excited by another (usually the laser beam), but only in the presence of a third wave. The name comes from *parametric amplifiers* in electronics.

Particulate (adj.): Possessing the characteristics of individual particles, rather than of a continuous fluid.

Particulate (n.): A charged "dust" grain, of the order of 1 μm to 1 mm in size, usually negative in industrial plasmas and positive in space plasmas.

PECVD: Plasma-Enhanced Chemical Vapor Deposition.

Pinch: An electrical discharge in which the plasma is squeezed by the magnetic-field pressure generated by currents within the plasma.

Plasma Dispersion Function: A complex function of a complex argument, found by contour integration, arising in the theory of collisionless plasmas.

Plasma Etch: A step in the manufacture of semiconductors in which material is removed chemically with the aid of a plasma.

Plasma Frequency: The characteristic electron oscillation frequency in a plasma; see **Langmuir Oscillation.**

Plasma Instability: A growing perturbation or wave in a plasma.

Plasma Processing: The use of plasmas in manufacturing.

Plasma Torch: An atmospheric-pressure discharge used for treatment of materials or wastes.

Plasma Wave: Any wave in a plasma, but usually referring to an **Electron Plasma Wave.**

Ponderomotive Force: The force exerted on a plasma by a wave with a gradient in its amplitude; radiation pressure modified by the presence of plasma.

PSII: Plasma-Source Ion Implantation.

Pulsed Power: A discipline involving the generation of terawatt bursts of energy by means of **Marx Banks** and **Blumleins,** usually resulting in an intense electron or ion beam.

q: A quality factor of tokamaks, inversely proportional to the degree of twist of the magnetic-field lines.

Quarter-Critical Layer: In laser–plasma interactions, the density region in which the plasma frequency is $\frac{1}{4}$ of the laser frequency.

Quasineutrality: A characteristic trait of plasmas in which the positive and negative charges move so as to maintain almost equal numbers everywhere, but with small deviations to permit the existence of electric fields.

Rayleigh–Taylor Instability: The hydrodynamic instability of a heavy fluid supported by a light fluid, which, in plasma physics, is the magnetic field or laser beam; see **Gravitational Instability.**

REB: Relativistic Electron Beam generated by **Pulsed Power.**

Reconnection: The joining of one group of magnetic-field lines to another in the presence of plasma. Since plasma particles are entrained by magnetic fields, reconnection can occur only if the particles can cross field lines, and reconnection can occur only in a region, no matter how thin, in which dissipation, including Landau damping, is important.

Resonance Absorption: Absorption of laser radiation by the generation and subsequent damping of plasma waves.

RIE: Reactive Ion Etching, a common process in the fabrication of semiconductors; also a type of plasma discharge used for this.

Resistive Instability: a hydromagnetic instability that occurs only if the plasma resistivity is nonzero.

Rotational Transform: In a torus, the number of turns a magnetic-field line encircles the minor axis for each time around the major axis; the reciprocal of ***q***.

Sawtooth: A temperature or density fluctuation with triangular wave form observed in tokamaks; thought to be caused by small **Kink Instabilities** and to be the mechanism by which a tokamak plasma adjusts its internal current distribution.

SBS: Stimulated Brillouin Scattering: a **Parametric Instability** in which a laser beam excites an ion-acoustic wave and a reflected light wave.

Shear: The change of pitch angle of magnetic-field lines on different surfaces; the radial variation of **Rotational Transform** or ***q***.

Simulation, Computer: Numerical calculations, stepwise in time, following the development of plasma motions.

Simulation, Particle: A computer simulation in which the particle motions, rather than fluid elements or distribution functions, are followed.

Solar Wind: A stream of ions and electrons ejected from the sun.

Soliton: A wave with only one maximum; a solitary wave.

Spitzer Resistivity: Resistivity of a fully ionized plasma accounting only for binary Coulomb collisions of electrons with ions.

SRS: Stimulated Raman Scattering: A **Parametric Instability** in which a laser beam excites an electron plasma wave and a reflected light wave.

Strongly Coupled Plasma: A plasma of such high density and low temperature that the number of particles in a Debye sphere is of order unity or below.

Synchrotron Radiation: Same as **Cyclotron Radiation.**

Tandem Mirror: A magnetic mirror fusion device plugged at both ends with short mirror sections containing a hot, dense plasma.

Tearing Mode: A type of **Resistive Instability** driven by current and involving **Reconnection.**

Thermonuclear: Pertaining to nuclear reactions in a Maxwellian plasma.

Theta Pinch: A **Pinch** in which the current is in the azimuthal direction.

Thomson Scattering: A plasma diagnostic technique in which laser light is scattered by plasma particles or density fluctuations.

Tokamak: A toroidal fusion device in which the magnetic configuration is determined by the distribution of toroidal current within the plasma.

Toroidal Confinement: Trapping of plasma in a closed magnetic-field configuration.

Trapped Particle: In tokamaks, ions or electrons that are prevented from circulating around the minor axis by the magnetic mirror effect of the strong fields near the major axis.

Turbulence: A statistically steady state of random fluctuations outside the realm of linear theory.

Universal Instability: A **Drift Wave Instability** occurring in collisionless plasmas.

Van Allen Belts: Plasma trapped in the Earth's magnetic field by the magnetic mirror effect.

Vlasov Equation: An equation describing the evolution of velocity distribution functions in the absence of collisions.

Whistler Wave: An electromagnetic wave in a plasma propagating along magnetic-field lines; first detected in radio reception as whistling sounds from the ionosphere.

Z Pinch: A **Pinch** in which the current is in the axial direction.
